Local anesthetic is used, typically lidocaine without epinephrine with or without bicarbonate buffering, at the general site of insertion of the foramen finder needle on the left and right sides. A wheal is raised and subcutaneous infiltration is performed. Care is taken not to anesthetize the foramen. Foramen finder needles come in 3.5- or 5-inch lengths and are chosen based on body habitus. The finder needle is introduced. The finder needle is held like a dart between the index and thumb fingers during placement through the skin and subepithelial tissues. If the needle hits bone, it is walked down the sacrum until it drops into the foramen. A fluoroscopic image is taken and then stimulation is applied to test for sensory and motor responses. Sample settings are displayed for the screener box (Table 47.1). If motor responses suggest too high or low of a foramen placement, the finder needle is simply brought back to the subdermal level and walked to the appropriate S3 foramen in the same line. Difficult cannulation of the foramen can be aided by stepping back from the patient's side and assessing the needle entry from the feet looking toward the head. From this vantage point, proper medial to lateral orientation can be ensured. Localization of the S3 foramen can also be aided with a cross table lateral image to identify the relation of the needle to the hillock.

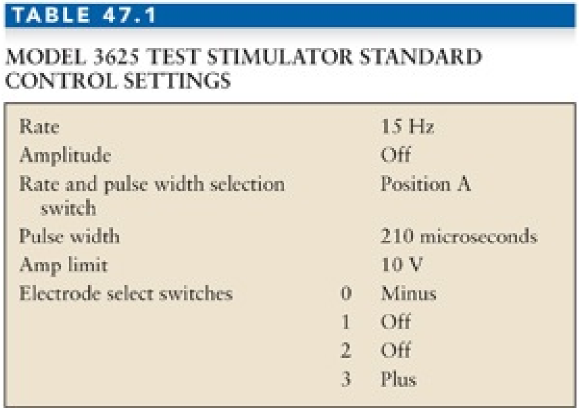

TABLE 47.1

MODEL 3625 TEST STIMULATOR STANDARD CONTROL SETTINGS

Rate		15 Hz
Amplitude		Off
Rate and pulse width selection switch		Position A
Pulse width		210 microseconds
Amp limit		10 V
Electrode select switches	0	Minus
	1	Off
	2	Off
	3	Plus

A response is tested by applying the J hook of the patient testing cable to the noninsulated portion of the finder needle. The amplitude on the screener box is gradually increased until stimulation is localized and a motor response is visualized. The proper motor response for S3 nerve root stimulation is ipsilateral plantar flexion of the big toe and levator contraction resulting in anal bellows (Table 47.2). Sensory localization should be described as a fluttering or tugging sensation in the rectum, vagina or labia (female), or penis or scrotum (male). The procedure is repeated for the contralateral S3 foramen. Once proper S3 placement is confirmed, the lead is placed. This is performed by removing the stylet in the finder needle while holding the position constant at the skin. The temporary lead and stylet are passed through the finder needle. Proper depth is achieved by delivering the temporary lead down to the first marker (Fig. 47.6). The lead is tested again to assess for proper response. The finder needle and lead stylet are then removed while keeping the lead in place. The same is done for the contralateral foramen. The leads are then secured to the patient with a clear adhesive dressing. The exposed ends of the leads are tamped into the grounding pads, which are affixed to the patient's back. The test stimulator cords are then connected to the grounding pads (Fig. 47.7).

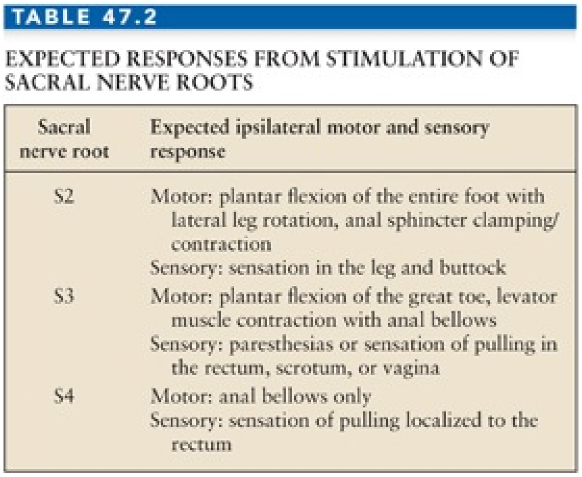

TABLE 47.2

EXPECTED RESPONSES FROM STIMULATION OF SACRAL NERVE ROOTS

Sacral nerve root	Expected ipsilateral motor and sensory response
S2	Motor: plantar flexion of the entire foot with lateral leg rotation, anal sphincter clamping/contraction Sensory: sensation in the leg and buttock
S3	Motor: plantar flexion of the great toe, levator muscle contraction with anal bellows Sensory: paresthesias or sensation of pulling in the rectum, scrotum, or vagina
S4	Motor: anal bellows only Sensory: sensation of pulling localized to the rectum

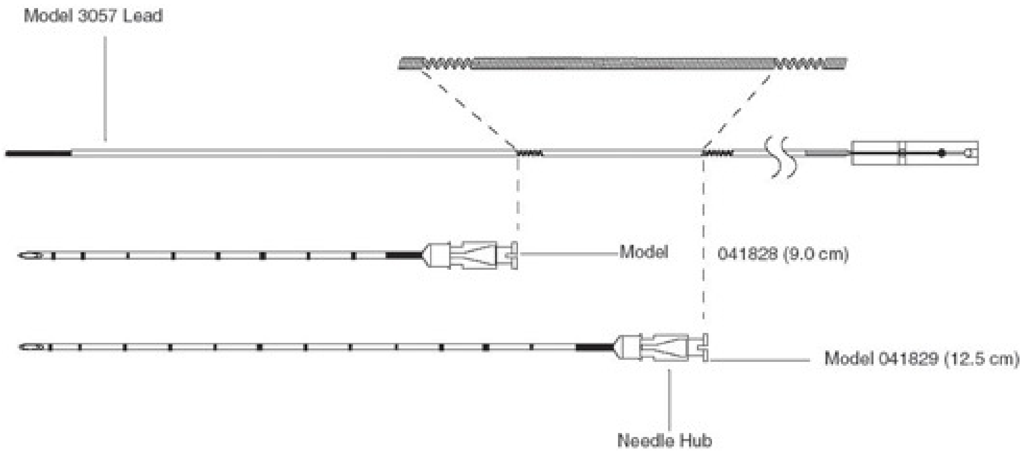

FIGURE 47.6 The PNE test lead is shown here next to the 9 and 12.5 cm finder needles. Note the indicators on the PNE lead which demonstrate proper depth placement of the temporary test lead. These also correspond to the length of finder needle being used.

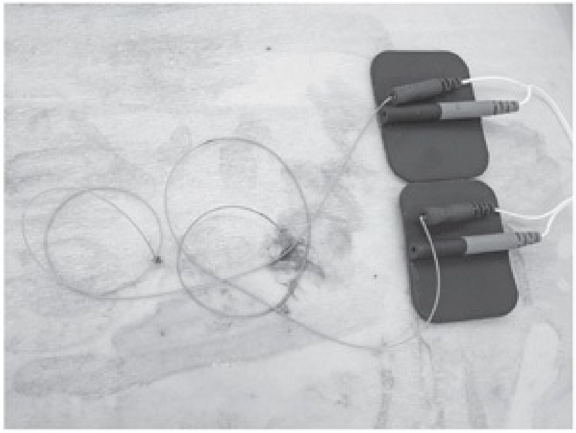

FIGURE 47.7 Once the PNE test lead is in place, dressing is applied over the excess test cable. The test cord simulator is attached to the external ground pad and the test stimulator/screener box is turned on and placed on the patient's clothing during the test period. Stage I Tined Lead Placement

During a stage I tined lead placement, the patient is brought into the room and positioned like a PNE. They are placed in the prone position with a pillow or roll under the hips and/or chest for comfort and optimal positioning. An intravenous antibiotic is given prior to the start of the procedure such as a cephalosporin, macrolide, and/or aminoglycoside. Anesthesia consists of either a general anesthetic or monitored anesthesia care with local anesthetic. If a general anesthetic is used, long-term paralytics should not be administered because motor responses need to be assessed for proper foramen placement. The patient is then prepped and draped. The bottom portion of the drape can be cut or placed below the level of the anus to allow for viewing of a bellows reflex. A plastic drape is then placed over the anus to keep it separated from the rest of the clean procedure while allowing visualization of the bellows when necessary. The patient's foot should be exposed to monitor for great toe response.

After administration of local anesthetic, a finder needle is used to enter the S3 foramen and obtain a confirmatory bellows and toe response. Errant needle placement through S2 or S4 can catch the S3 nerve roots and give a false-positive bellows and toe response.

Once the proper motor and sensory response is obtained and radiographic imaging demonstrates proper placement, the inner stylet of the finder needle is removed and a directional guide is placed. Advancement of the directional guide stops when resistance is met. A fluoroscopic image is obtained to ascertain proper depth. The finder needle sheath is removed over the guide while keeping the directional guide in place. An incision is made completely through the dermis and an introducer sheath is placed over the directional guide. Fluoroscopic imaging is obtained to ensure that the introducer sheath radiopaque marker is midway through the bone. The tip of the sheath should be just past the ventrum of the sacral spine. The package with the tined lead should then be opened and ready on the field for prompt placement. The obturator and directional guide are then removed while holding the sheath in place. Any delay in placing the lead could increase bleeding, which could cause decreased motor or sensory response during testing. Tined leads currently are packaged with a straight stylet, although a curved one is included in the kit. The theoretical benefit of a curved stylet is the ability to follow the natural trajectory of the sacral nerve root as it exits the sacrum and increase lead and nerve root contact for maximal efficacy. A randomized prospective crossover study with 40 patients from Irvine, California, demonstrated consistently lower amplitude stimulation with placement of the lead with a curved stylet versus a straight stylet (14).

Electrodes on the tined lead are conventionally referred to as 0 (the most distal electrode) through 3 (the most proximal). The tined lead is optimally placed to position the 2 and 3 electrodes straddling over the ventral surface of the sacrum (Fig. 47.8). The sheath is brought back to the second white line on the tined lead to expose the electrodes but to leave the tines protected (Fig. 47.9). Testing is performed at each electrode. Both motor and sensory responses are recorded. The goal during optimal placement of the lead is to obtain responses at all four electrodes at low amplitudes. Once the surgeon is satisfied with lead placement, the sheath and stylet are discontinued while the lead is held in place. When the sheath passes over the second white line, the tines are engaged and the lead cannot be easily repositioned. Fluoroscopic equipment can then be taken away after a final image is taken in the cross table lateral and AP orientations (Figs. 47.10 and 47.11).

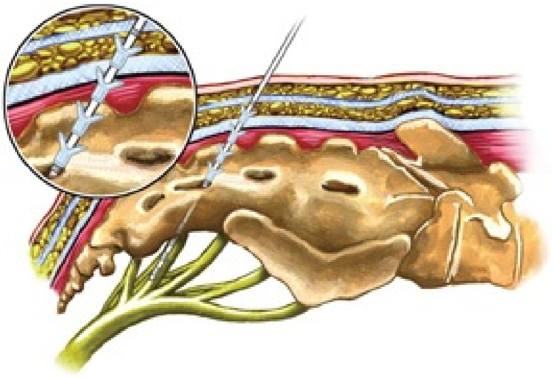

FIGURE 47.8 Lateral anatomic view of a tined lead during stage I testing. The electrodes of the lead follow the nerve as it exits the S3 foramen. The second and third electrodes straddle the anterior bony plate and the tined leads anchor into the thoracolumbar fascia, the multifidus muscle layer and the sacral periosteum. Note that given the proximity of the nerve roots, errant entry into either the S2 or S4 foramen can cause a false-positive motor response by stimulating the S3 nerve root. (Reprinted with the permission of Medtronic, Inc. Copyright © 2015.)

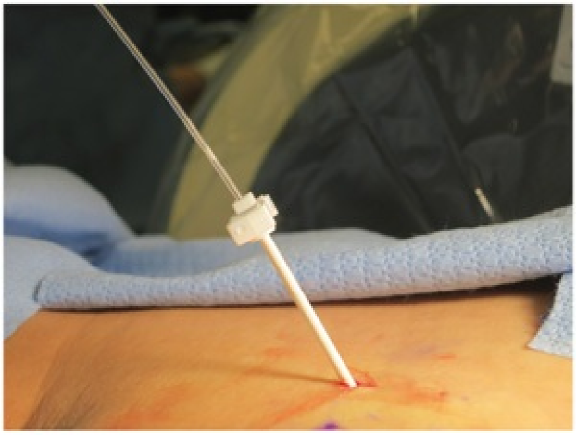

FIGURE 47.9 Placement of tined lead during stage I testing. Two markers indicate the depth of the lead. When testing the electrodes of the lead, the sheath needs to be move back to the second marker to expose the electrodes. (Reprinted with the permission of Medtronic, Inc. Copyright © 2015.)

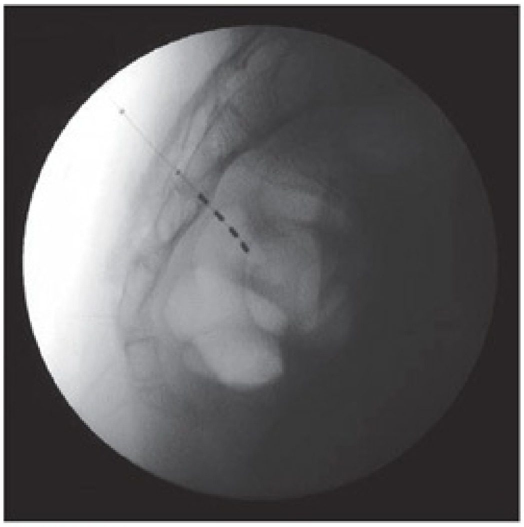

FIGURE 47.10 Lateral fluoroscopic view of a tined lead. Proper lead placement can be fluoroscopically confirmed by evaluating the iliac shadow and the S3 hillock in addition to motor and sensory responses. Note the straddling of the anterior plate with electrode 2 and 3 and also the orientation of the lead suggesting lateral deviation along the path of the nerve root. (Reprinted with the permission of Medtronic, Inc. Copyright © 2015.)

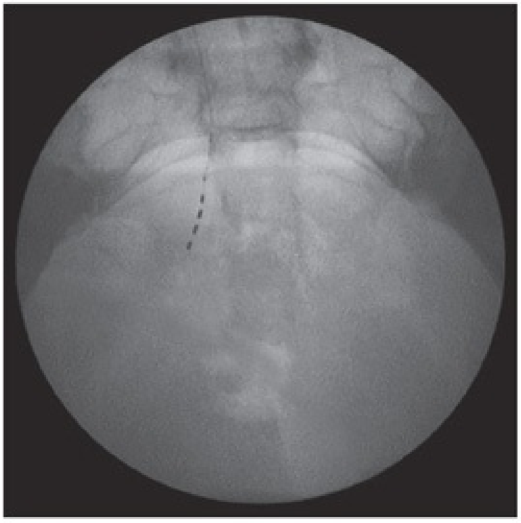

FIGURE 47.11 AP fluoroscopic view of a tined lead. Proper lead placement can be confirmed fluoroscopically in the AP position by evaluating the lead position in relation to the sciatic notches, the inferior border of the sacroiliac joints, and the medial to lateral placement of the lead. Sensory and motor responses confirm proper placement of the lead. (Reprinted with the permission of Medtronic, Inc. Copyright © 2015.)

A transverse incision is made in the patient’s left or right upper buttock below the belt line, approximately 3 to 5 cm below the superior iliac crest. This incision is extended into the subcutaneous tissues and a space is developed to accommodate the connection between the permanent tined lead and the percutaneous extension wire. This incision will also be the final pocket site for the IPG if the testing phase is successful. The external portion of the tined lead is then tunneled to the medial portion of this site through the subcutaneous tissue using the tunneling device. The lead is cleaned off with sterile water and attached to the percutaneous extension wire with the set screws. A plastic boot is placed over the set screws and secured using nonabsorbable nonbraided suture. The percutaneous extension wire is then tunneled to an area on the contralateral buttock and brought through the skin. The tunneling of the percutaneous lead across the back to the contralateral side minimizes bacterial seeding of this pocket. Care is taken while tunneling the lead so as not to injure the lead at its original insertion point. Also, an exit site should not be so distal from the pocket that the tunneling device sheath does not reach. The directional guide can be used as a pusher to move the percutaneous lead wire through the sheath to reach the contralateral side.

At this point, the upper buttock pocket is irrigated with sterile water, bacitracin, or Betadine solution (saline should not be used) and then closed in a two-layer fashion with an interrupted 2-0 absorbable layer in the subcutaneous tissues and a running 4-0 absorbable suture layer for the skin. The wound should be closed meticulously with awareness of the lead at all times. The skin is dressed with either cyanoacrylate glue or adhesive strips. The percutaneous extension wire is connected to the external test simulator cable. Patient instructions include no full-body showers that would include the area where the percutaneous extension wire exits the skin and no strenuous activities that could dislodge the lead. Patients are typically discharged home on a short antibiotic regimen to cover skin flora.

Medtronic has introduced a new external neurostimulator that can wireless communicate with the patient controller for stage I testing. While the prior "brown box" test stimulator can still be used for the testing phase, the new Verify system has the theoretical advantage of not tethering the patient to the test stimulator box, a decreased chance of accidental lead discontinuation and ease to change program stimulation with a graphical user interface. (Fig 47.12)

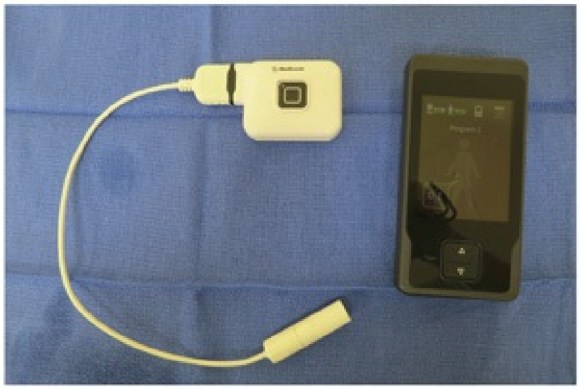

FIGURE 47.12 The Verify system can be used during stage I testing. The external neurostimulator (ENS) communicates wirelessly with the patient controller. Theoretically patients are not tethered to their control box which can decrease the incidence of accidental lead displacement and patient discomfort.

The test stimulator is programmed in postanesthesia recovery, and patients record their improvement in symptoms by maintaining a voiding diary during the trial period. The patient proceeds to a stage II procedure if they have a 50% improvement in symptoms from baseline as evidenced by their records.

Stage II

After a successful first stage test stimulation, the patient is brought to the operating room for a stage II IPG implantation. The stage II procedure is shorter than a stage I procedure because the tined lead is already in place. Although no sensory/motor responses are tested during stage II implantation, the patient is positioned and draped similar to a stage I procedure in case the lead is inadvertently dislodged. Perioperative antibiotics appropriate for device implantation are given and anesthesia is administered. Adhesive remover is used to clean the skin of prior residual tape. The presacral and buttock region are prepped and draped. The prior incision in the upper buttock area is opened in a medial to lateral fashion with extension of this incision laterally if needed to accommodate the IPG. Prior suture material encountered during the dissection is removed. Care is taken during subcutaneous dissection to avoid severing the lead. The percutaneous extension wire, boot, and lead are found and the suture securing the boot is cut. The plastic boot is removed and the set screws are loosened. The miniscule set screws can dislodge out of the percutaneous extension wire if loosened too much. The percutaneous extension wire is cut, the lead connector is removed from the incision, and the external tail can be removed after the drapes have been pulled off and the incision has already been closed.

The subcutaneous pocket is made deep and wide enough to fit the IPG so it will lie flat but not rotate freely. The pocket depth should be adequate to prevent erosion and provide acceptable cosmesis. The skin should close easily without tension. The area is irrigated with sterile water, bacitracin, or Betadine solution, and careful cautery is used to ensure hemostasis. An IPG such as the InterStim II is opened and connected to the lead wire with a set screw. The IPG is placed in the pocket with the etched writing facing up and the lead protected behind the IPG. After ensuring proper IPG placement, the IPG is turned on with an external test device and impedances are tested to ensure proper functioning of the system. Once completed, closure of the wound is performed with two layers using 2-0 and 4-0 absorbable suture. The wound is then dressed. Patients are discharged with instructions to avoid heavy or strenuous activity and directions for using the iCon patient controller. A short course of antibiotics and pain medication are prescribed upon discharge.

Single-Stage Implantation

After a successful PNE trial, patients are brought back for a single-stage implantation. PNE wires are usually discontinued in the office prior to single-stage implantation. Single-stage implantation then follows the procedure of stage I and stage II implantation but instead of connecting the tined lead to a percutaneous extension wire, it is directly connected to the IPG.

OUTCOMES

Complications

Historically, rates for safety of SNM included patients who had undergone prior lead implantation with now obsolete techniques such as anchoring the lead to the thoracolumbar fascia or implantation of the IPG in the lower abdomen. In 2000, long-term results were published on a prospective nonrandomized cohort who underwent implantation of the InterStim system (lead and generator). Adverse events were then pooled across a total of 581 patients who underwent SNM testing. Adverse events were seen in 18.2% of the total 941 test stimulations performed with the most common being related to lead migration (11.8%). Of the 219 patients who underwent implantation, pain at the neurostimulator site was the most commonly observed adverse effect at 12 months (15.3%). Infection rate was 6.1%. Surgical revisions of the implanted neurostimulator or lead system were performed in 33.3% of cases (73 of 219 patients) to resolve an adverse event. These included relocation of the neurostimulator because of pain at the subcutaneous pocket site and revision of the lead for suspected migration. Explantation of the system was performed in 10.5% for lack of efficacy (15).

Al-zahrani et al. (16) also evaluated their 14-year experience with SNM from 1994 to 2008. The patient population predominantly involved patients with bladder pain syndrome (47.9%). A total of 96 SNM devices were implanted. There were no infections noted which they attributed to a predominantly PNE to a single-stage procedure for most patients. For the entire cohort, the revision rate was 39%. When evaluating UUI and retention patients separately, the revision rate was 32% and 56%, respectively. Symptom deterioration was the main reason for revision in both UUI (64%) and retention (55%) cases. Of those patients with UUI and UR, they noted a 14.7% and 12.5% explantation rate, respectively. The most common reason for explant in patients with UUI was for painful stimulation three-fifths (60%) of cases. The reason for explant in UR patients was loss of efficacy. Given that the technique changed during the study period, there was a significant decrease in lead revision after use of the tined lead from 50% down to 31% (16).

Marcelissen et al. (17) reported on safety and adverse events in patients undergoing SNM with a tined lead. A total of 64 patients underwent SNM implantation. Three patients had hematomas that were treated with postoperative antibiotics and observation. One patient developed a wound infection requiring explantation. The total explantation rate was 10.9%. Twenty-one patients needed revisions (33% reoperation rate). Seventeen patients (27%) reported pain with the predominant form being pain at the site followed by bothersome stimulation. Nine patients (53%) had reprogramming, which alleviated their pain.

Hijaz and Vasavada (18) reported on a single institution's results on 161 patients in a larger contemporary series dealing with only tined lead implantations. By following their previously reported troubleshooting algorithm, they retrospectively analyzed their patients from 2002 to 2004. After second-stage implantation, the revision rate was noted to be 26/161 patients (16.1%) with the majority of revision performed due to decreased response (17/26 patients). The explantation rate was 17/161 patients (10.5%) with reasons being infection (8/17 patients) or failure to maintain function (9/17) (19).

Results

Although the original outcomes regarding SNM were derived from two randomized studies dealing with patients who had idiopathic urgency-frequency and UUI, since 2007, multiple studies have been published regarding efficacy of SNM (20,21). Most of these have been prospective nonrandomized studies.

Van Kerrebroeck et al. (22) published their results of a 5-year prospective post-approval multicenter study in 2007. There were 163 total patients included in their study. The majority were female and had an indication of UUI. There were 128 of the enrolled patients who were part of an earlier randomized controlled study regarding the efficacy of InterStim (MDT-103). At 5 years follow-up, 105 patients completed follow-up visits and 87 patients completed voiding diaries. Clinical success rate was defined as a 50% or greater improvement from baseline. At 5 years, this remained statistically significant for multiple variables including UUI episodes per day (58% of patients), number of voids per day (40% of patients), and number of catheterizations per day in UR patients (58% of patients) (22).

Marcelissen et al. (17) evaluated the long-term results of tined lead placement for SNM. A total of 92 patients were included in this single-center observational study and 70% were implanted. The majority were female with an indication of OAB wet. Mean follow-up was 51 months with a success rate of 64%. For OAB wet patients, mean leakage per day and pads per day was observed to significantly decrease (7.7 ± 5 to 4.0 ± 3.8 leakage per day, 4.6 ± 3 to 2.3 ± 2.8 pads per day) (17).

Cameron et al. (23) evaluated successful sacral nerve test stimulation by evaluating medical claim data from a 5% sample of Medicare beneficiaries and compared this to a sample of private insurance patients working for large Fortune 500 companies. A total of 358 patient records were evaluated in the Medicare group versus 266 with private insurance. The majority of patients were white, female, and had a diagnosis of OAB. Success was defined by implantation of IPG. In the Medicare population, 45.8% of the PNE patients went on to IPG placement compared to 24.1% in the privately insured group. For staged procedures, 35.4% of Medicare patients received an IPG compared to 50.9% in the private insurance group. Overall success was 39.9% and 49.1% in the Medicare and privately insured populations, respectively. The only variable that was consistently associated with higher rate of success in both groups was female gender. Age did not consistently predict success. Given this was a large health care claim–based review, their study was limited by not knowing whether patients did not undergo IPG placement based on lack of efficacy with stage I trial versus not wanting to proceed with implantation. Also, they mention that their data spans a 10-year period when the technology and efficacy may have changed. Multiple providers with different experiences were also included which could have confounded results (23).

The most recent multicenter randomized trial comparing SNM to standard medical therapy enrolled a total of 147 patients. Thirty-eight sites were included in the study. The InSite trial evaluated the 6-month success rate for these two groups. Ninety-three percent of the patients were female and were diagnosed with either UUI or urgency-frequency and had failed at least one anticholinergic medication. Of the 70 patients who were randomized to SNM, 51 (72.9%) patients went on to implantation. By intention to treat analysis, 61.4% had a 50% or greater improvement in symptoms from baseline in the SNM group versus 41.6% in the standard medical therapy group. Of the 51 patients who were implanted, 76.5% had a clinical success rate of 50% or greater improvement in symptoms at 6 months. The significant improvement in symptoms was also mirrored in International Consultation on Incontinence Questionnaires (ICIQ) domain improvements in concern, coping, sleep, and social domains (24). Twelve-month data evaluating the prospective multicenter portion of this arm revealed a responder rate of 85%, 79%, and 59% for OAB, UUI, and urinary frequency, respectively (25).

CHAPTER 48 SURGICAL TREATMENT OF PELVIC ORGAN PROLAPSE

ARIANA L. SMITH, POLINA REYBLAT, AND JA-HONG KIM

Pelvic organ prolapse (POP) is a prevalent women's health issue affecting nearly 40% of postmenopausal women (1). The etiology of POP is multifactorial, with most cases being attributable to genetics (2), followed by aging, white race, obesity, parity, hormonal status, birth and surgical trauma, smoking, chronic constipation, chronic cough, and family history of prolapse (3,4). It is estimated that surgical demand related to POP will increase by 46% over the next four decades (5).

For any pelvic reconstructive surgeon attempting correction of vaginal prolapse, it is paramount to understand the relationship between pelvic floor anatomy and function in order to optimize both objective and subjective outcomes. For this reason, we will begin this chapter with detailed review of female pelvic anatomy and musculofascial support, with emphasis on the integral structures that allow normal voiding and defecatory function. We will then focus on the various surgical techniques used to correct the defect categorized by anterior, apical, and posterior compartments.

ANATOMY OF PELVIC SUPPORT

Conceptually, the vaginal canal can be divided into three compartments that have distinct anatomic structures: (a) the anterior compartment, which includes the urethra, bladder neck, and bladder; (b) the apical compartment, which includes the uterus and cul-de-sac after hysterectomy; and (c) the posterior compartment, which includes the rectum, anal canal, and perineum. These compartments are functionally and anatomically dependent as they share the same pelvic floor foundation. Structurally, the vaginal and pelvic support starts with a framework of bones and ligaments that are lined with fascia and muscles. These components are intimately related and in some cases are continuations of each other, especially in the case of ligaments and fascia.

The Pelvic Diaphragm

Bones

The framework of the pelvic floor is provided by the bony structures, including the pubis, ilium, ischium, sacrum, and coccyx. The pelvic bones create a diamond shape, with the pubic symphysis and coccyx at the apices and the ischial tuberosities dividing the diamond into anterior and posterior compartments. The anterior or urogenital triangle contains the clitoris, urethra, and vaginal vestibule. The posterior or anal triangle contains the anal canal and anal sphincter. The pubic rami, ischial spines, and sacrum are important anchoring points of muscular and fascial structures in the pelvis (6).

Ligaments and Fascia

The name *ligament* has been given to what are truly dense condensations of connective tissue in the pelvis. The structures commonly called fascia are sheets of connective tissue separating the vagina from the urethra, bladder, cervix, and rectum (7). The fascia overlying the pelvic floor musculature plays a critical role in pelvic support. Both sides of the muscle, the abdominal side and the vaginal side, are covered with fascia and have distinct nomenclature. On the *abdominal* side, it is called endopelvic fascia and represents a continuation of the transversalis fascia. On the *vaginal* side, it is named according to the structure it supports (periurethral fascia, perivesical fascia, and pararectal/prerectal fascia). These two components of fascia join together to form the ligaments that give support to the various pelvic organs.

Pubourethral Ligaments. The pubourethral ligaments anchor the urethra anteriorly to the inferior ramus of the pubic symphysis (Fig. 48.1). They also divide the urethra into proximal and distal halves, with the proximal, intra-abdominal portion responsible for passive, involuntary continence. The midportion, or the striated external sphincter, is responsible for active, voluntary continence.

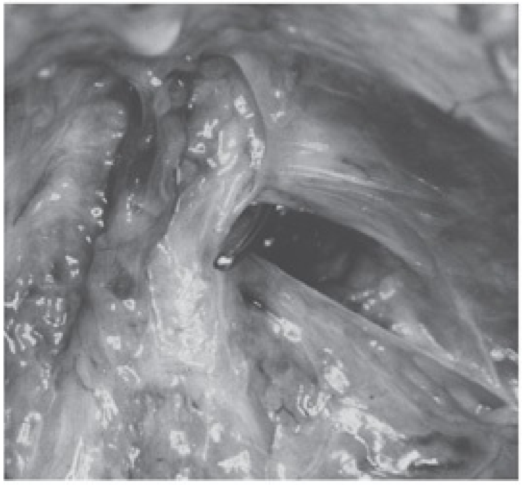

FIGURE 48.1 Abdominal view of the pelvis in a cadaver. The retropubic space has been entered from the vaginal side, detaching the urethropelvic ligaments from the lateral pelvic wall and exposing the pubourethral ligament.

Urethropelvic Ligaments. The urethropelvic ligaments are condensations of periurethral fascia and endopelvic fascia that provides anatomic support of the bladder neck and proximal urethra to the pelvic sidewall (Fig. 48.2). They do so by anchoring the urethra laterally to the arcus tendineus fasciae pelvis (ATFP; see the following section). The urethropelvic ligaments provide elastic, musculofascial support to the bladder outlet, thereby maintaining passive continence. Voluntary or reflex contractions of the pelvic floor increase the tensile force across these ligaments, enhancing outlet resistance and preventing incontinence. Restoration of support is important in the surgical correction of stress incontinence.

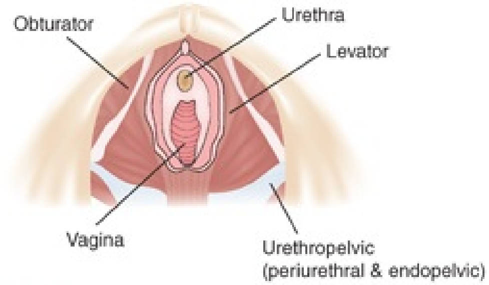

FIGURE 48.2 Urethropelvic ligaments supporting the urethra to the levator musculature of the lateral pelvic sidewall. In patients with multiple deliveries, the levator musculature is weakened and the ligament is thin, elongated, or detached from the lateral pelvic wall.

Vesicopelvic Ligaments. The vesicopelvic ligaments consist of perivesical fascia and endopelvic fascia which anchor the bladder to the pelvic sidewall. During voluntary or reactive pelvic floor contraction (i.e., contraction of the levator muscles), the ligamentous structures tighten and elevate the bladder, preventing mobility and descent into the vagina. Restoration of lateral bladder support is an important component in the correction of anterior wall prolapse, or cystocele.

Cardinal–Uterosacral Ligament Complex. The cardinal liga ments, or ligaments of Mackenrodt, are thick, triangular condensations of pelvic fascia that originate from the greater sciatic foramen and insert into the cervix and vaginal wall. They also extend to the perivesical fascia, providing support to the bladder base (Fig. 48.3). These ligaments contain numerous blood vessels branching from the hypogastrics that supply the uterus and upper vagina (6). The cardinal ligaments fuse posteriorly with the uterosacral ligaments, which stabilize the uterus, cervix, and upper vagina posteriorly toward the sacrum (Fig. 48.4). The uterosacral ligaments originate from the second, third, and fourth sacral vertebrae and insert posterolaterally into the cervix and vaginal fornices (8). The trauma of vaginal delivery can cause relaxation of the cardinal–uterosacral complex and allow descent of the cervix and uterus. It is very important to reapproximate the cardinal ligaments to the midline during hysterectomy and prolapse repair to close the gap and prevent bladder herniation.

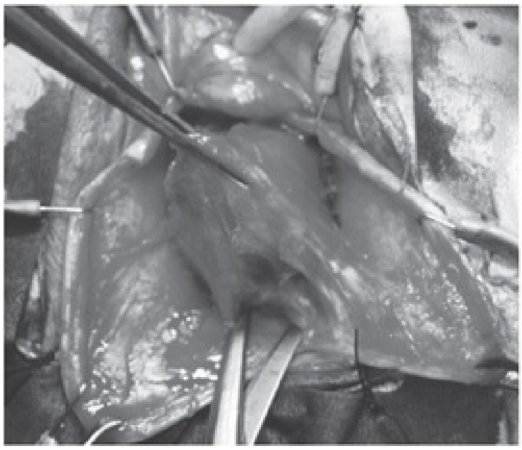

FIGURE 48.3 Dissection of the bladder wall during repair of grade IV cystocele exposes the cardinal ligaments as they attach to the bladder base.

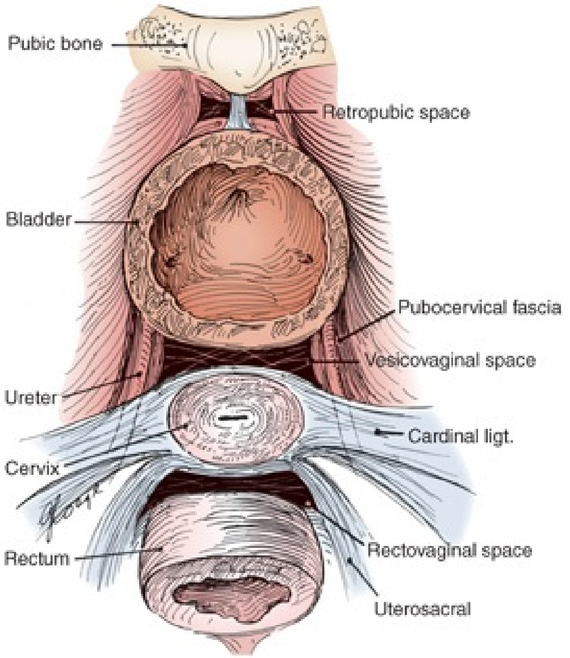

FIGURE 48.4 Uterine support and its relations to the bladder and rectum. The cardinal ligaments provide support of the cervix to the lateral pelvic wall.

Broad Ligaments. The broad ligaments attach the lateral walls of the uterine body to the pelvic sidewall and contain the fallopian tubes, the round and ovarian ligaments, and the uterine and ovarian vessels. The broad ligaments are covered by an anterior and posterior sheet of peritoneum.

Sacrospinous Ligaments. The sacrospinous ligaments span the posterior portion of the pelvic floor, from the ischial spines to the sacrum and coccyx (Fig. 48.5). The coccygeus muscle lies over the top of the sacrospinous ligament and is a very important landmark in vaginal surgery. Cephalad to the coccygeus muscle, the lumbosacral plexus spreads its fibers, which if injured can cause chronic debilitating pain. Lateral to the coccygeus muscle the pudendal nerves and vessels traverse in Alcock canal. Also in this area is the ureter, which can be injured with a suture placed too laterally during prolapse repair (9).

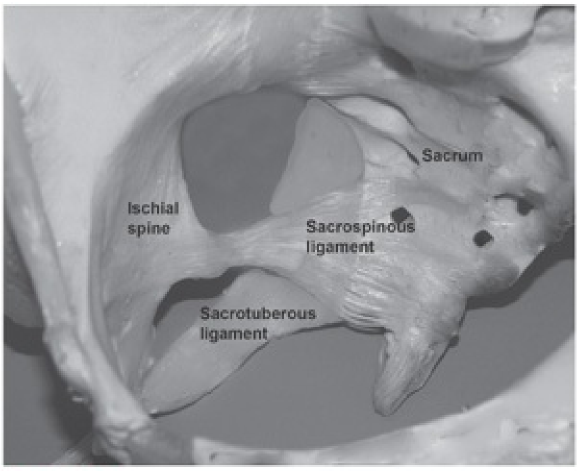

FIGURE 48.5 The sacrospinous ligament is an important area of anchoring for vaginal vault suspension.

Perineal Body. The perineal body is a tendinous structure located in the midline of the perineum between the anus and vaginal introitus. It provides a central point of fixation for the transverse perineal muscles, which extend from the ischial tuberosities laterally (10) (Fig. 48.6). The perineal body provides an additional level of support to the posterior vaginal wall and rectum, incorporating the levator ani, bulbocavernosus muscle, and transverse perineal musculature as well as the external anal sphincter. This level of support is elastic in nature, allowing distortion and recoil during childbirth and intercourse.

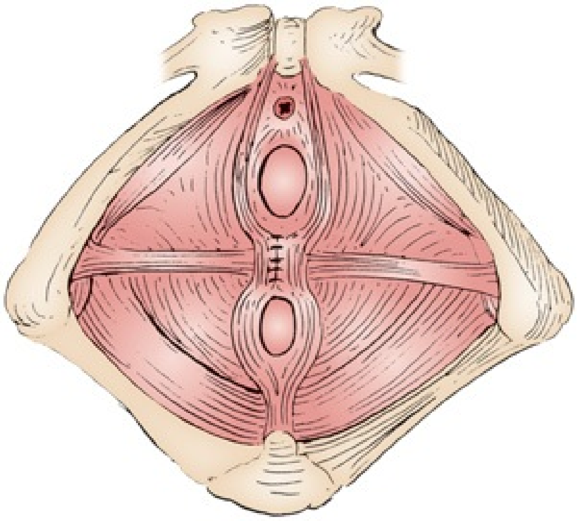

FIGURE 48.6 Repair of the perineal body. The bulbocavernosus muscle, the transverse perineal muscles, and the anal sphincter fibers are approximated to recreate the central tendon of the perineum.

Pubocervical Fascia. On the vaginal side, it is often referred to as the pubocervical fascia but can be divided into discrete areas of specialization depending on the associated organ it supports (periurethral and perivesical fascia). As a whole, the pubocervical fascia is a trapezoid-shaped continuous sheet of connective tissue support that extends from the pubic symphysis to the cervix and laterally to the ATFP (11). The fascia is fused to the bony scaffold by the cardinal ligaments laterally and the uterosacral ligaments posteriorly.

Arcus Tendineus Fasciae Pelvis. ATFP is a curvilinear condensation of pelvic fascia that arises from the obturator internus muscle and runs from the pubic symphysis to the ischial spines (Fig. 48.7). This tendinous arc of the obturator is the line of insertion of the levator muscles on the obturator fascia. This crucial structure provides musculofascial attachment for the anterior and posterior pelvic organs and anchoring point during pelvic floor reconstructive surgery.

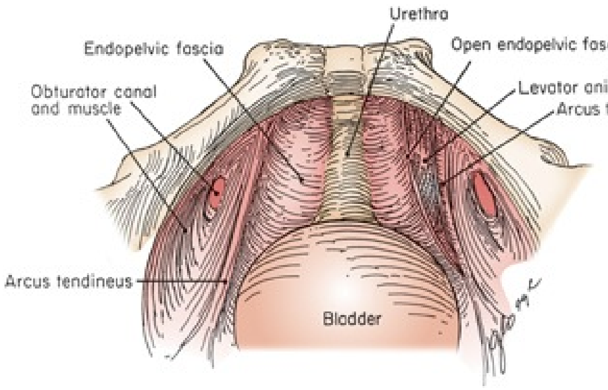

FIGURE 48.7 View of the anterior pelvis. The endopelvic fascia covers the bladder and urethra. The levator musculature is attached to the ATFP.

Prerectal/Pararectal Fascia. Prerectal and pararectal fascia extends from the cardinal–uterosacral complex to the perineal body and is sometimes referred to as the rectovaginal septum.

Musculature

The striated musculature supporting the pelvic floor is composed of the levator ani muscles and the coccygeus muscles. Together they cradle the visceral contents of the pelvis, providing dynamic support.

Levator Ani. The levator ani is composed of pubococcygeus, puborectalis, and the iliococcygeus and extends from the pubic symphysis to the ischial spines and coccyx, taking origin from the ATFP laterally. These muscle groups have overlying endopelvic fascia that allows direct attachment to the bladder, urethra, vagina, uterus, and rectum to give support during increases in intra-abdominal pressure, preventing organ descent and release of urine and stool (6).

Coccygeus. The posterior portions of the levator ani, together with the coccygeus muscle, provide a horizontal plate from the rectal hiatus to the coccyx. Resting tone of the levator ani and coccygeus, as well as reflex and voluntary contraction, acts to pull the vagina and rectum forward, closing the lumens of these structures. Re-establishing this axis is critical in maintaining sexual function as well as long-term success in prolapse surgery.

Levator Hiatus. The levator hiatus is a U-shaped midline aperture in the levator ani that allows passage of the urethra, vagina, and rectum (Fig. 48.8). These structures are supported by a fascial hammock, the urogenital diaphragm, as they exit the pelvis (12). Fibers from the pubococcygeus enter into the hiatus and surround the urethra and anus, forming the sphincter musculatures.

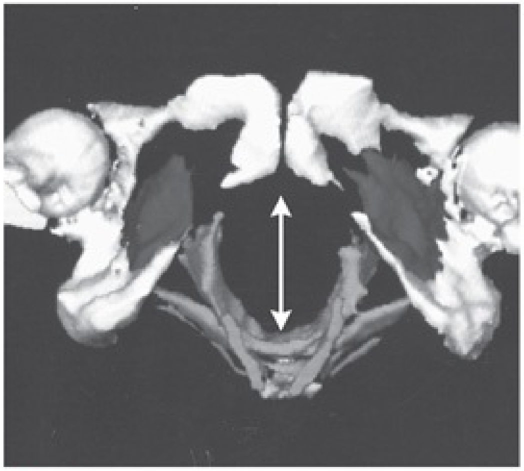

FIGURE 48.8 Three-dimensional MRI reconstruction of the levator musculature, bony pelvis, and obturator musculature in a patient with multiple deliveries. The levator hiatus is widened (*arrow*); this represents the distance between the rectal canal and the pubic bone, called the puborectal line.

Areas of Special Interest: Obturator Anatomy

Prior to the introduction of the transobturator tape, the obturator anatomy was rarely studied in the context of POP. With the dramatic increase in the number of procedures, both for continence and prolapse, performed in this area and the arising complications, it is important for all urologists to understand the anatomic landmarks. The adductor longus tendon is a major landmark for trocar passage and protects the patient from injury to the neurovascular bundle. Safe entry and exit zones exist when the patient is properly positioned and landmarks are obeyed. When a sling is placed using this technique, it is important to understand that the mesh sling is placed through the obturator internus muscle via passage of the trocar. Complications are possible as a result of this placement; these include difficulty ambulating and pain with contraction of the obturator internus muscle.

PATHOPHYSIOLOGY OF PELVIC ORGAN PROLAPSE

Although the exact etiology of pelvic prolapse has yet to be clearly defined, many risk factors have been proposed in the development of prolapse. These risk factors can be placed into four categories:

(a) *predisposing* factors: genetics, race, and gender; (b) *inciting* factors: pregnancy and delivery, surgery, myopathy, and neuropathy; (c) *promoting* factors: obesity, smoking, pulmonary disease, constipation, and recreational or occupational activities that cause chronic increases in intra-abdominal pressure; and (d) *decompensating* factors: aging, menopause, debilitation, and medications (13). Any of the risk factors can result in attenuation of the uterosacral–cardinal ligament complex or breaks along the endopelvic fascia. Furthermore, muscle atrophy of the levator ani and coccygeus can lead to a widened levator hiatus and a compromise in the excretory function of the bladder and rectum. The loss of uterine support causes the cervix to move anteriorly, and the uterus then begins to shift posteriorly such that the intra-abdominal pressure is then directed on the anterior surface of the uterus. The uterus becomes progressively more retroverted until the axis of the uterus is essentially vertical. This position allows uterine prolapse to occur (14).

DIAGNOSIS

Standard evaluation of the patient with uterine prolapse includes a comprehensive history and physical examination, focusing on urinary and defecatory symptoms, sexual function, reproductive status, and other pelvic pathology. Postvoid residual urine volume and urinalysis are obtained for all patients. Urodynamic evaluation is not routinely performed unless there is a history of stress or urgency incontinence, incomplete emptying, obstructive voiding complaints, or bothersome overactive bladder symptoms. It is important to recognize that stress incontinence may be masked by the prolapse, which can cause kinking of the urethra.

The pelvic examination begins with external genitalia inspection for atrophy, tissue quality, and integrity of the perineum. The uterus and cervix is assessed for size, mobility, and any abnormal gross pathology. The anterior, posterior, and apical vaginal walls are examined separately with the aid of a half speculum to assess the presence of cystocele or rectocele. In both the lithotomy position and standing, the patient needs to bear down or cough to fully elicit the degree of prolapse. The Pelvic Organ Prolapse Quantification System (POP-Q) is a commonly used staging system for describing vaginal prolapse (15). The screening neurologic examination should evaluate gross sensory and motor function of both lower extremities, and lumbosacral function. This can be quickly achieved by assessing pelvic floor muscle strength, anal sphincter resting tone, voluntary anal contraction, and perineal sensation.

Often, the viscera behind the prolapsed vaginal wall cannot be accurately diagnosed. This is especially true for posterior vaginal wall protrusion, which may represent an enterocele, a rectocele, or a sigmoidocele. A careful bimanual examination with two separate fingers simultaneously in the rectum and vagina can help distinguish rectocele from enterocele or sigmoidocele. When the patient strains, an enterocele or sigmoidocele will often fill the space between the two viscus, whereas a rectocele will result in no change in the plane.

Dynamic magnetic resonance imaging (MRI) is unrivaled in its ability to characterize pelvic soft tissue. No contrast is used as the bladder is distinct on T2-weighted images. Sagittal images are taken of the pelvis with the patient at rest and then bearing down (Fig. 48.9). Additional radiologic imaging such as defecogram may be indicated for evaluation of bowel dysfunction associated with posterior prolapse. MR defecography involves dynamic evaluation of the pelvic floor, providing both structural and functional information. Standardization of the testing and interpretation of defecography is not established, however, and therefore, it is not recommended for routine clinical use, although it can be helpful in “high” rectoceles when an enterocele is suspected (16).

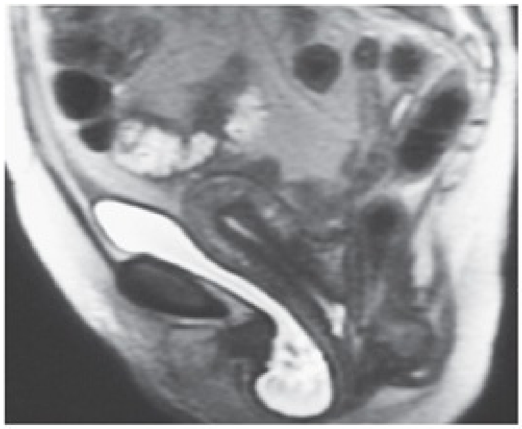

FIGURE 48.9 MRI of the pelvis. Dynamic MRI of the pelvis demonstrating uterine and bladder prolapse.

INDICATIONS FOR SURGERY

An individualized approach to patients with advanced POP should be undertaken after consideration of multiple factors. The surgeon must consider all site-specific defects present as well as the patient's urinary, bowel, and sexual function. Surgical intervention for POP is indicated in patients with urinary retention, obstructive voiding, hydronephrosis, difficult defection, chronic vaginal discharge, and/or ulceration as well as persistent pelvic pressure, dyspareunia, and sensation of the bulge. It is of paramount importance to determine the most bothersome symptoms for the patient and to highlight the patient's goals and expectations of treatment. Following this, the patient's general medical condition and other factors are considered when deciding on a management plan.

Isolated rectoceles usually do not need surgical repair due to the possibility of postoperative dyspareunia unless the patient is bothered by symptoms. Obstructive defecation, lower pelvic pressure, and symptomatic prolapse of the posterior wall are some of the indications for rectocele repair. Some suggest conservative management with pelvic floor rehabilitation or referral to colorectal surgery or occupational therapy for defecation disorders prior to surgical intervention.

ALTERNATIVE THERAPY

Asymptomatic or minimally bothered patients may opt for observation or pelvic floor muscle rehabilitation. For those symptomatic patients who are poor surgical candidates or prefer a nonsurgical approach, mechanical support with a pessary made of silicon or soft plastic can be used to reduce the POP. These patients undergo a pessary fitting in one or two office visits, followed by a teaching session with a nurse or physician. Women with symptomatic improvement are taught to place and remove the pessary at least twice weekly and prior to intercourse and should return every 6 to 12 months for an office evaluation and examination. Women who are unable to remove the pessary may leave it in continuously and return every 3 months for pessary care. Such patients may benefit from vaginal estrogen cream, unless contraindicated, to reduce the risk of erosion. If vaginal erosion develops, the pessary should be removed and vaginal estrogen cream applied until the erosion is healed. The pessary can then be replaced, although a reduction in pessary size or type is advisable. Pessaries generally are less effective in supporting the posterior vaginal wall than in apical and anterior vaginal wall prolapse.

SURGICAL TECHNIQUES

There are several options for surgical management of POP. Prolapse can be approached vaginally or abdominally depending on its degree, patient characteristics, affected compartments, and desired outcomes. Colpocleisis can be offered to older frail women or to patients who no longer desire preservation of coital function. Although anterior vaginal prolapse is the most common, most women who present with POP have a combination of pelvic floor support defects affecting multiple compartments (anterior, apical, and posterior). Therefore, the importance of a thorough evaluation and complete repair of the whole pelvic floor cannot be overemphasized. Subtotal segmental repairs which do not address concomitant compartment defects may allow subsequent postoperative exaggeration of preexisting defects due to functional and anatomic changes.

The need to augment support of the pelvic floor with grafts such as synthetic mesh or biologic fascia is debated. Many would argue that supporting the patient’s weakened intrinsic fascia using a graft can achieve a better anatomic result and a more durable response. However, patient reported outcomes measures have not consistently favored augmented repairs. As a result, individualized approaches and thorough counseling on the risks and benefits of graft augmentation is advocated.

Regardless of technique, three basic tenets must be obeyed in pelvic reconstruction: (a) restoration of normal vaginal depth, caliber, and axis; (b) prevention of further POP; and (c) restoration and maintenance of normal bladder, bowel, and sexual function (7). We will now describe the various techniques of POP repair categorized by apical, anterior, and posterior compartments.

SURGICAL TECHNIQUES FOR APICAL COMPARTMENT

There is growing recognition that adequate support for the vaginal apex is an essential component of a durable surgical repair for women with advanced prolapse (17,18). Restoration of apical support has several good options with relatively high success rates and can be performed transvaginally or abdominally. Several studies suggest that the transvaginal approach is used in 80% to 90% of cases (19–22); it is believed that abdominal approach is a better choice for younger and sexually active women because it maximizes functional vaginal length and axis.

Vaginal Hysterectomy with Vault Suspension

Hysterectomy is commonly performed in the treatment of POP and can be approached abdominally, vaginally, laparoscopically, or robotically. Vaginal hysterectomy is preferred over abdominal surgery in the setting of benign disease such as uterine prolapse due to shorter operative time, fewer postoperative complications, and a shorter hospital stay (23,24). Relative contraindications for vaginal hysterectomy include a large uterus in proportion to a narrow introitus, uterine or cervical cancer, ovarian pathology, significant endometriosis, and a history of pelvic inflammatory disease, which may result in extensive scarring in the pelvis, making dissection difficult. As a genitourinary surgeon, one should be familiar with the surgical principles and technique of vaginal hysterectomy, as it is a critical component of female pelvic reconstruction.

The pear-shaped uterus consists of the corpus and the cervix and lies in the medial axial position, anteverted with the vertical axis of the uterus perpendicular to the axis of the vagina. The corpus or body of the uterus is enclosed between the double-layered broad ligaments. The main uterine support is provided by the uterosacral and cardinal (Mackenrodt) ligaments. During hysterectomy, these ligaments must be carefully identified and controlled, as they will be incorporated into the vaginal cuff to successfully re-establish proper vault support. Complete correction of uterovaginal prolapse at the time of hysterectomy should include not only fixation of the vaginal apex to the uterosacral or cardinal ligaments but also reapproximation of the bladder and rectum to close the cul-de-sac.

Broad-spectrum prophylactic antibiotics are administered preoperatively. Compression stockings are placed prior to incision to prevent venous thromboembolic events and subcutaneous heparin administered based on patient risk stratification. Following successful induction of anesthesia, the patient is placed in the high lithotomy Trendelenburg position. Care should be taken to avoid hyperflexion of the hips, which can result in femoral neuropathy. An iodine-based solution is used to cleanse the skin from the suprapubic area to the posterior perineum. A ring retractor with skin hooks is used to maintain exposure. The bladder is drained with a urethral catheter. The cervix is grasped at the 12 and 6 o'clock positions using Lahey clamps. A circumferential incision is made at the cervicovaginal junction using electrocautery (Fig. 48.10). The vagina and bladder base is dissected off the cervix for several centimeters. The anterior cul-de-sac is carefully entered using sharp dissection (Fig. 48.11A). Gentle downward traction, visualization of the glistening surface of the uterus, and limiting the dissection to the midline of the uterus are used to help to minimize risk of cystotomy. Once the anterior cul-de-sac is entered, electrocautery is used to extend the incision laterally to allow placement of a Heaney retractor (Fig. 48.11B).

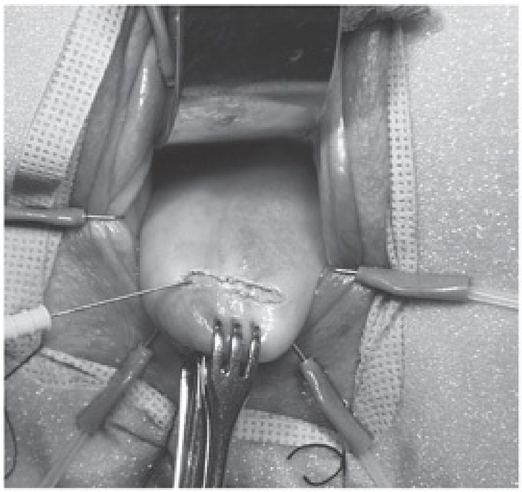

FIGURE 48.10 Incision. A circumferential incision is made approximately 1 cm from the cervical os with electrocautery.

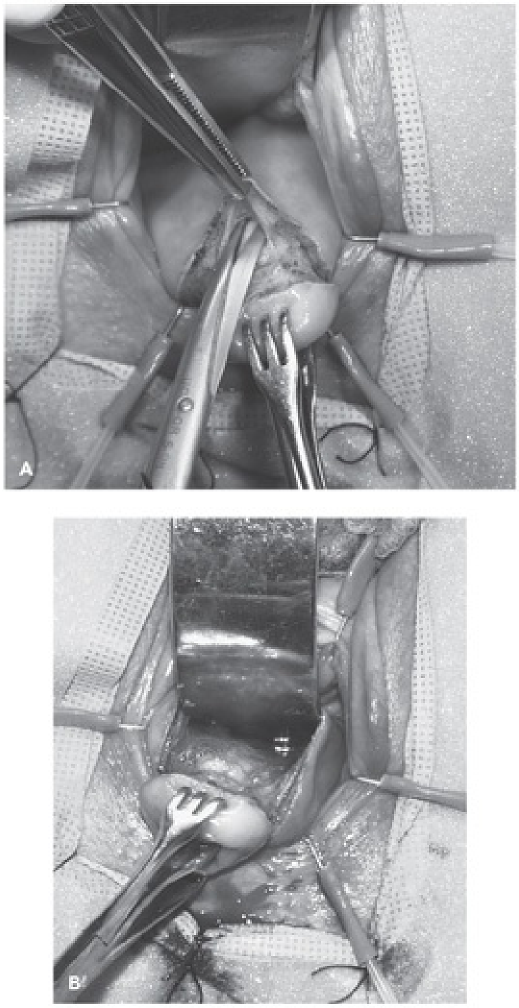

FIGURE 48.11 Exposure of the anterior uterus. Sharp dissection is used to (A) expose the anterior cul-de-sac and (B) place a Heaney retractor.

The posterior cul-de-sac is entered similarly, and the peritoneum is opened sharply using curved Mayo scissors (Fig. 48.12). Any adhesions encountered should be lysed with limited sharp dissection to allow placement of another Heaney retractor. If difficulty is encountered when attempting to enter the peritoneum, the hysterectomy can be initiated in an extraperitoneal fashion by severing the uterosacral ligament and caudal portions of the cardinal ligament close to the cervix. This maneuver mobilizes the uterus to provide better visualization.

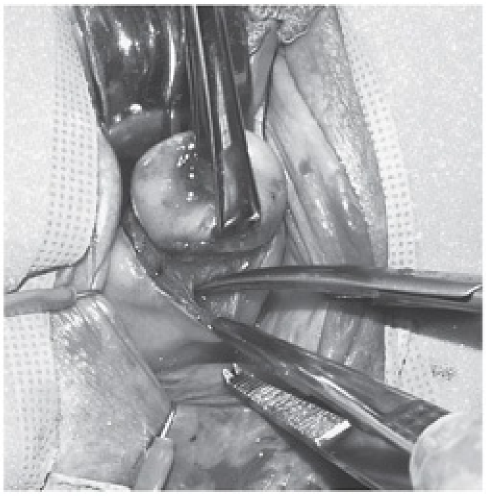

FIGURE 48.12 Exposure of posterior cul-de-sac and sharp entry into the peritoneum.

Next, the uterosacral and cardinal ligament complex is divided by placing the cervix on careful traction and passing a large right-angle clamp from the posterior cul-de-sac parallel to the cervix.

The right-angle clamp is used to expose the ligament, which is then grasped with a Phaneuf clamp and ligated with electrocautery (Fig. 48.13). The stumps are oversewn with figure-of-eight 0 Vicryl sutures. The ends of the sutures are clamped and secured on the ring retractor. Then the uterine pedicles are carefully identified, isolated, and divided in similar fashion (Fig. 48.14). After the contralateral ligament and pedicles are likewise controlled, the uterus can then be manually everted and brought outside the introitus (Fig. 48.15). Safe entry into the anterior peritoneum can be made by placing a finger anteriorly over the uterine fundus to elevate the peritoneum. Electrocautery can then be used to incise the peritoneum overlying the surgeon's finger. The broad ligaments are now ligated as previously discussed (Fig. 48.16). If an oophorectomy is not planned, the ovarian attachments are also now divided and the uterus is removed.

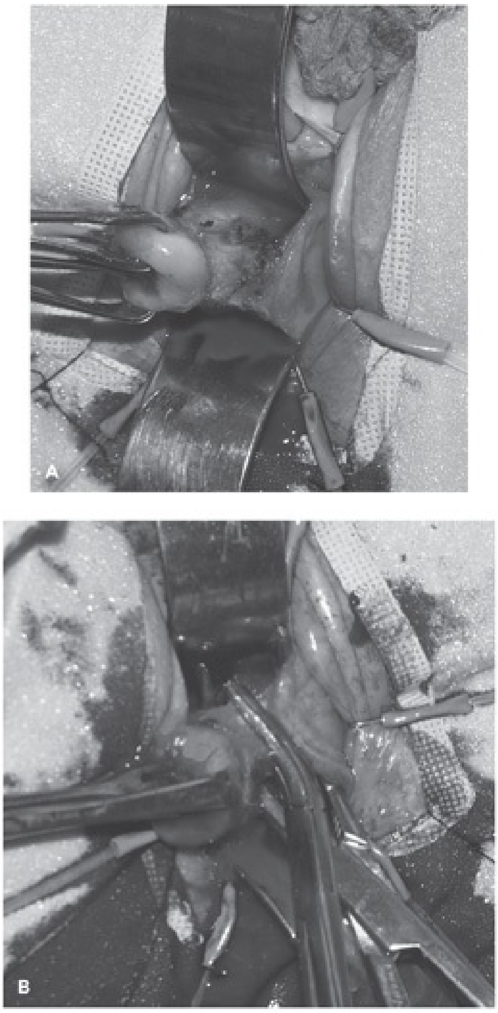

FIGURE 48.13 Isolation of cardinal–uterosacral ligaments. Right-angle and Phaneuf clamps are used in succession to (A) better delineate the cardinal–uterosacral complex before (B) transection.

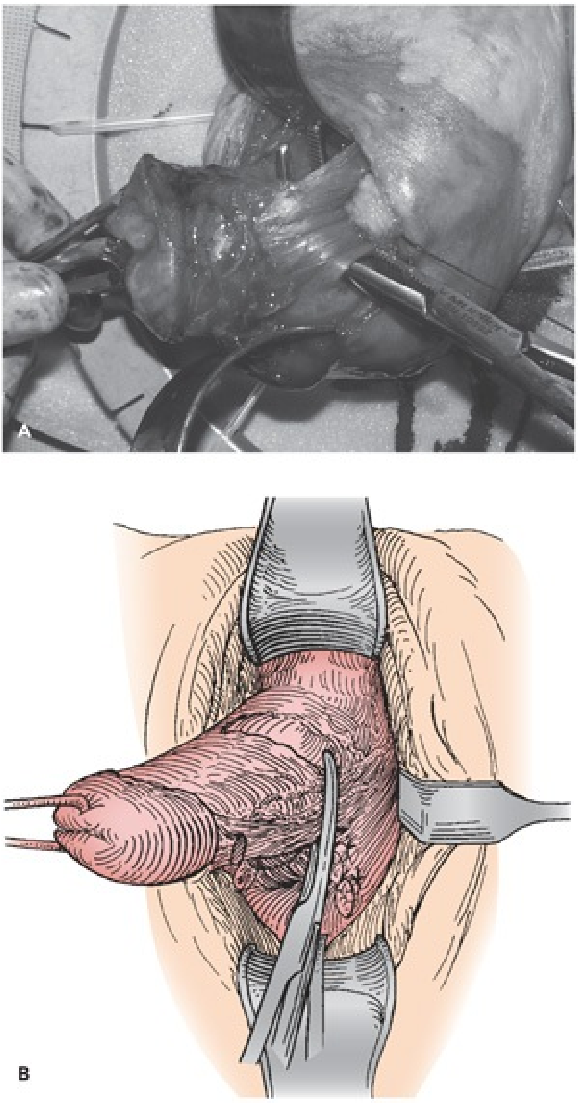

FIGURE 48.14 The uterine pedicles are carefully identified (**A**), isolated, and divided (**B**).

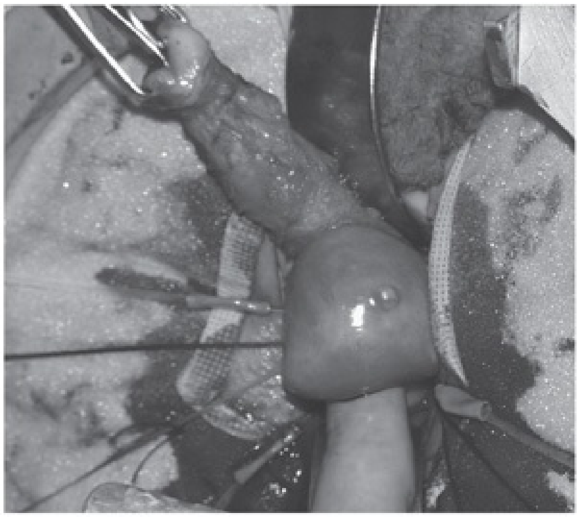

FIGURE 48.15 Eversion of the uterus. After the bilateral cardinal–uterosacral ligaments have been ligated, the uterus is manually everted.

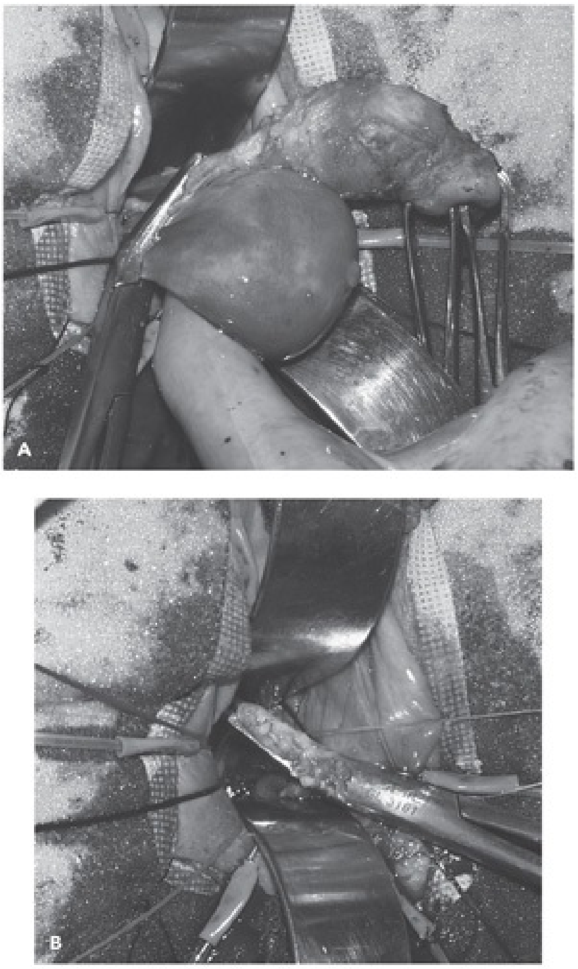

FIGURE 48.16 Division of the broad ligament. The surgeon's index finger is (**A**) inserted into the peritoneal cavity and hooked around the broad ligament, which is (**B**) then ligated in the same fashion as the cardinal–uterosacral ligaments.

After hysterectomy, the vault support and vaginal depth must be restored. This is accomplished by obliterating the cul-de-sac to prevent enterocele recurrence and by sacrospinous or uterosacral ligament fixation of the vaginal apex.

Two Betadine-soaked laparotomy pads are placed intraperitoneally to pack away the peritoneal contents. Next, the coccygeus–sacrospinous ligament complex is identified by palpating the ischial spine and tracing the taut triangular band of fascia medially and posteriorly as it attaches to the edges of the sacrum. Next, we use two Allis clamps to grasp the area of the future vaginal cuff and apply downward traction toward the coccygeus–sacrospinous ligament complex to determine the extent of the apical prolapse and associated pelvic support defects. If concomitant cystocele still exists after reducing the apical prolapse, we will perform a formal cystocele repair. The technique of bilateral sacrospinous ligament fixation is challenging due to the difficulty in maintaining good visualization in the deep pelvis through the vagina and the risk of injuring the pudendal vessels, the lumbosacral plexus, and the ureters, which are in close proximity. To optimize this exposure, three retractors are employed: (a) A long-handled Breisky is placed anteriorly to retract the peritoneal contents from descending; (b) another Breisky or Heaney is used to displace the rectum laterally; and (c) a Heaney retractor is then carefully placed posteriorly just distal to the tight cordlike coccygeus–sacrospinous ligament complex. We begin by placing a 1-0 Vicryl suture brought from outside the vaginal wall into the peritoneal cavity (in the area of the ligated uterosacral–cardinal ligament complex). Instruments are switched to a long-handled needle driver and long gastroplasty forceps to place that same suture in figure-of-eight fashion in the coccygeus–sacrospinous ligament complex on the corresponding side. The direction of the needle must be horizontal, since one can easily damage the nearby neurovascular structures and ureters. It helps to carefully palpate and identify the tight cordlike sacrospinous ligament structure in the substance of the coccygeus prior to suture placement. The same suture is then exited through the vaginal wall just above the area of the uterosacral–cardinal ligament complex and tagged separately. A second 1 Vicryl suture is placed on the contralateral side in the exact same fashion.

Two purse-string sutures of 0 Vicryl are now placed to close the cul-de-sac. These sutures incorporate the prerectal fascia, the uterosacral–cardinal ligament complex, the broad ligaments, and the perivesical fascia (Fig. 48.17). It is important to stay in the midline when incorporating the perivesical fascia to avoid ureteral injury. The purse-string sutures are tagged at this time. The sutures of the previously ligated pedicles of the broad ligaments and the uterosacral–cardinal ligament complex are identified on each side and tied in the midline. The purse-string culdoplasty sutures are now cinched and tied. If simultaneous repair of other prolapse is planned, it is now performed. The sacrospinous ligament vault suspension sutures are tied last after any cystocele repair and vaginal cuff closure. It is important to push down the vault to the sacrum while tying down the vault suspension sutures to achieve optimal vaginal depth.

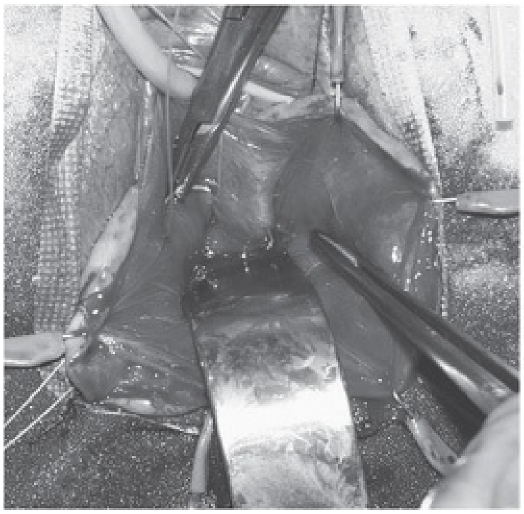

FIGURE 48.17 Placement of purse-string culdoplasty sutures. Inside the peritoneal cavity, two 1 Vicryl purse-string sutures are placed to obliterate the cul-de-sacs and approximate the prevesical and prerectal fascia.

Cystoscopy is performed routinely after giving indigo carmine to assess for a healthy jet stream of urine from the ureteric orifices. If there is any question of ureteric injury, gentle passage of a ureteral catheter or retrograde pyelography may be performed. If obstruction is encountered, the repair is taken down systematically starting with the vault suspension sutures.

Transvaginal Enterocele Repair

Posthysterectomy vault prolapse usually has an enterocele component that will be corrected first. The surgeon may choose to open the enterocele sac for an intraperitoneal repair or elect an extraperitoneal repair. Placement of vault suspension sutures can be daunting regardless of the chosen approach. It is important to understand where it is safe and where it is dangerous to place sutures. Sutures can be safely placed in the uterosacral ligament, the sacrospinous ligament, or the anterior longitudinal fascia of the sacral promontory. For vaginal ligament suspension, the needle should be directed downward rather than laterally or superiorly where other important structures lie (see Fig. 48.5). It is imperative to avoid going cephalad to the sacrospinous ligament, as the lumbosacral plexus can be injured or trapped with a suture. The ureter can be damaged, as can the pudendal nerve, if the needle is placed laterally at the time of uterosacral or sacrospinous fixation.

The patient is placed in the dorsal lithotomy position and prepped appropriately. A Scott ring retractor (Lone Star Medical Corp) is commonly used to aid with exposure; some authors also advocate for the use of rectal packing. The bladder is drained with a urethral catheter. The prolapsed vaginal wall is infiltrated with normal saline or lidocaine-epinephrine solution for hydrodissection, and incision is made along the length of the enterocele (Fig. 48.18). The vaginal wall is carefully dissected away from the peritoneal sac. Dissection in the proper avascular plane is performed with blunt dissection using a sponge and sharp dissection in the areas where sac is densely adherent to the vaginal epithelium. Dissection proceeds until the neck of the sac is reached (Fig. 48.19). The enterocele sac is opened at this point. Next, we proceed with the retraction of the peritoneal contents in order to place sutures for the enterocele sac closure. Retraction is best achieved using pediatric lap pads and a Haney or a narrow Deaver retractor (Fig. 48.20). Closure of the sac is performed with a 0 or 1 polyglycolic acid (PGA) suture.

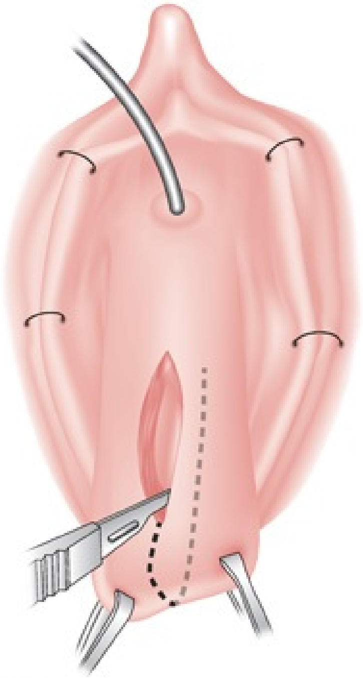

FIGURE 48.18 The vaginal wall is grasped with two Allis clamps and brought outside the vaginal introitus. A midline incision is made and opened on the dotted line.

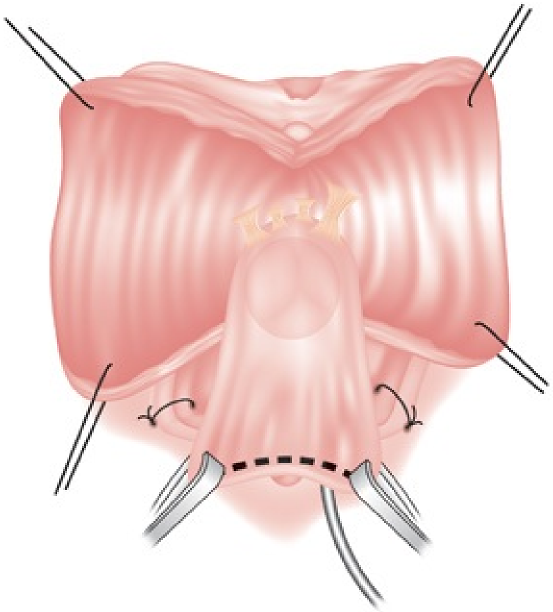

FIGURE 48.19 Enterocele sac completely dissected to its neck and opened on the dotted line.

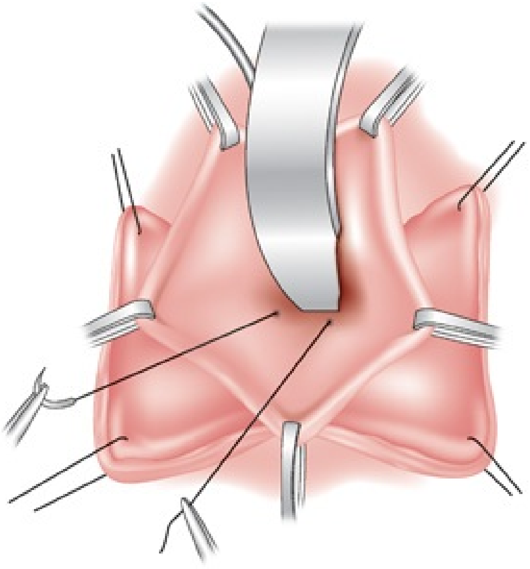

FIGURE 48.20 A Deaver retractor is used to retract abdominal contents so that purse-string sutures can be placed.

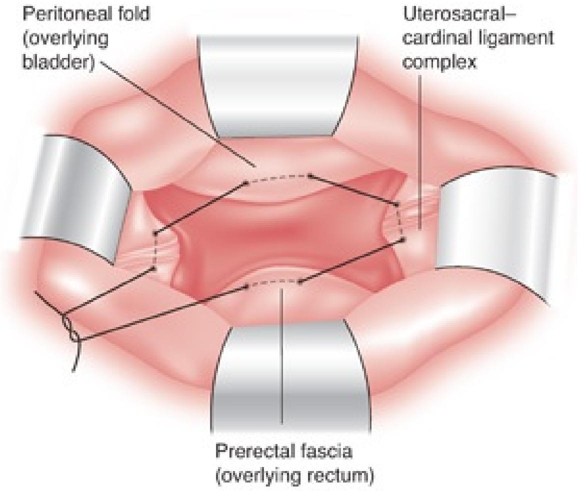
The enterocele repair begins posteriorly, whereas the abdominal contents are retracted anteriorly. The suture is first placed through the peritoneum and into the prerectal fascia that overlies the rectum (see Fig. 48.20). A circumferential closure of the defect is then performed by placing the purse-string suture laterally in the right uterosacral–cardinal ligament complex, anteriorly in the peritoneum overlying the base of the bladder, laterally on the left in the uterosacral–cardinal ligament complex, and finally again posteriorly in the prerectal fascia (Fig. 48.21). A second suture can be placed in close proximity to the first suture incorporating the same components. When no vault suspension is planned, the uterosacral–cardinal ligament complex needs to be incorporated into the repair to support the vaginal apex. The depth of the suture placement is an important determinant of the postoperative depth of the vaginal vault and needs to be carefully planned. Cystoscopy is performed to confirm no injury to the bladder and to observe ureteral jets after previously administered indigo carmine.



Peritoneal fold (overlying bladder)
Uterosacral–cardinal ligament complex
Prerectal fascia (overlying rectum)

FIGURE 48.21 Placement of purse-string sutures.

Several approaches for apical vault suspension are available and chosen based on patient's anatomy and surgeon's training and expertise. Most commonly performed are the McCall culdoplasty, the uterosacral ligament suspension, and the sacrospinous ligament fixation.

McCall Culdoplasty

McCall (25) first described a technique that used the uterosacral ligaments for support and correction of enterocele in 1957. Despite several modifications, the basic principles remain the same. The internal “McCall sutures” are passed through the uterosacral ligament; most proximal being placed 2 cm above its cut edge. After stitching the uterosacral ligament, several bites of posterior peritoneum are taken in 1 to 2 cm intervals until the contralateral uterosacral ligament is reached. The suture is not tied, and additional sutures are placed in a similar fashion as needed (Fig. 48.22). Next, the external McCall sutures are placed just lateral to the midline, through the proximal posterior vaginal wall and peritoneum. Similar to the internal McCall sutures, successive passes are made through the posterior peritoneum until the contralateral uterosacral ligament is reached. The internal sutures are each tied, followed by the external sutures, which suspend the vaginal wall at the level of the uterosacral ligaments.

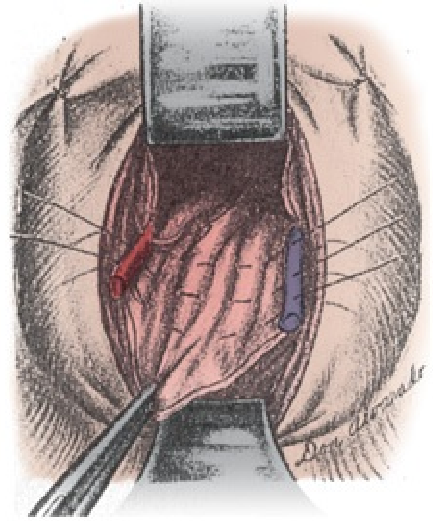


FIGURE 48.22 Placement of internal McCall sutures. (Reprinted with permission from McCall ML. Posterior culdoplasty: surgical correction of enterocele during vaginal hysterectomy: a preliminary report. *Am J Obstet Gynecol* 1957;10:595–602. Copyright © 1957 Elsevier.)

Uterosacral Ligament Fixation

Suspension of the vaginal vault to the uterosacral ligaments, as described by Shull et al. (26), provides a more natural vaginal axis than the sacrospinous ligament fixation. A vertical midline incision is made in the vaginal epithelium. The vaginal wall is then carefully dissected away from the enterocele sac, and the sac is opened to pack the bowel away as described earlier. It is useful to place a marking suture at 3 and 9 o’clock position at the vaginal apex (prior site of the uterosacral ligament attachment). As Shull et al. (26) originally described (Fig. 48.23), the remnants of the uterosacral ligaments are identified posterior and medial to the ischial spines at approximately the 4 and 8 o’clock positions. An Allis clamp can be used to apply traction to the tissue and the uterosacral ligament can be palpated toward the sacrum.

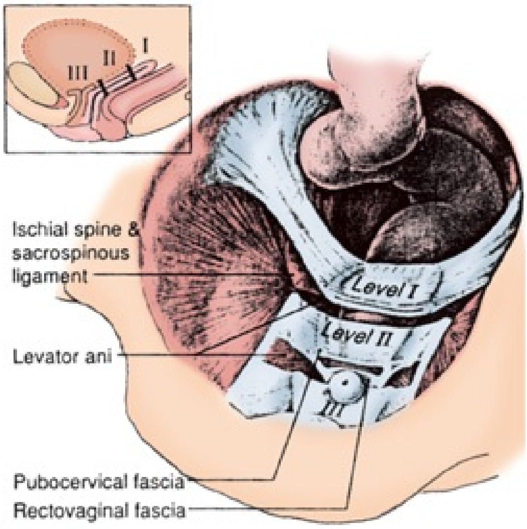

FIGURE 48.23 Level I (suspension) and level II (attachment). In level I, the paracolpium suspends the vagina from the lateral pelvic walls. Fibers of level I extend both vertically and also posteriorly toward the sacrum. In level II, the vagina is attached to the ATFP and superior fascia of levator ani. (Reprinted with permission from DeLancey JOL. Anatomic aspects of vaginal eversion after hysterectomy. *Am J Obstet Gynecol.* 1992;166:1717–1728. Copyright © 1992 Mosby. Published by Mosby, Inc. All rights reserved.)

Two or three delayed absorbable or permanent double-armed sutures are placed through the uterosacral ligaments on each side. First suture is placed at the level of the ischial spine. Subsequent sutures are placed proximal to the last. Sutures should be passed lateral-to-medial to avoid ureteral injury. The double-armed sutures are placed through the pubocervical and rectovaginal fascia (Figs. 48.24 and 48.25) (26). The most proximal sutures are sewn to the most medial aspect of the pubocervical and rectovaginal fascia. More distal sutures are placed more laterally (see Fig. 48.24). An anterior colporrhaphy may be done at this point if necessary. Intravenous indigo carmine is administered. The vaginal epithelium is then closed and the suspension sutures are tied but left long and tagged. Cystoscopy is performed. Once the ureteral patency is confirmed, sutures are trimmed.

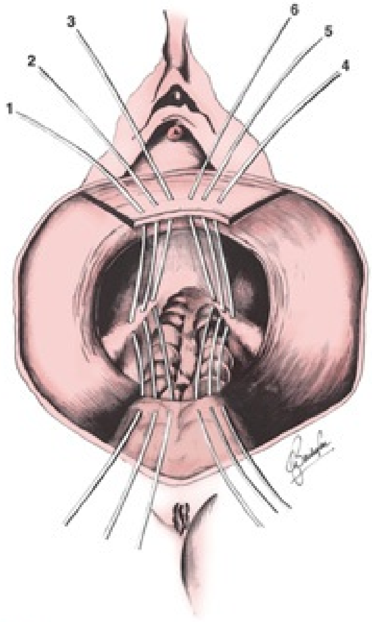

FIGURE 48.24 Sutures are placed in uterosacral ligaments bilaterally. One arm of each suture is placed in the pubocervical fascia and the other in the rectovaginal fascia. Sacrospinous Ligament Fixation

Sacrospinous ligament fixation was introduced in Germany by Amreich and Richter (27) in 1951 and made popular in the United States by Randal and Nichols (28). This approach fixes apex unilaterally or bilaterally to the sacrospinous ligament. The sacrospinous ligament stretches from the ischial spine to the sacrum and is covered by the coccygeus muscle. The posterior vaginal wall is incised in the midline and dissected laterally. The sacrospinous ligament is identified and reached. This is achieved by penetrating the rectal pillar (pararectal fascia) near the ischial spine using blunt and sharp dissection. Blunt dissection of the pararectal space can be performed with a combination of finger dissection and the use of deep Breisky-Navratil retractors. The rectum is retracted medially, and bladder anteriorly. (Fig. 48.26).

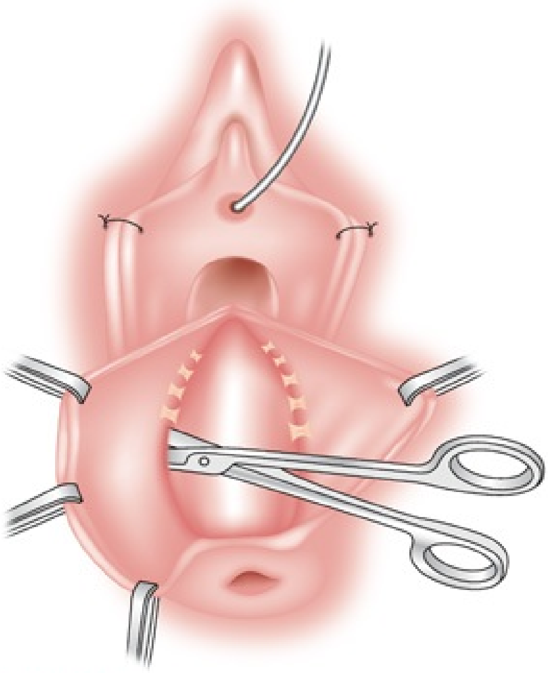

FIGURE 48.26 Dissection for SSLF. The rectal pillars are sharply penetrated and the pararectal space is entered. The space is widened with blunt dissection to expose the superior surface of the pelvic diaphragm. The sacrospinous ligament can then be palpated and the coccygeus muscle overlying it can be seen.

This dissection is performed until the sacrospinous ligament is palpated and the overlying coccygeus muscle is seen. We carefully dissect over the ligament using a spreading motion of the Metzenbaum scissors. This is done to ensure that a strong portion of the ligament under the coccygeus muscle is incorporated as the suture is placed. A permanent 1-0 braided suture is placed into the well-identified and dissected ligament–muscle complex 2 cm medial to the ischial spine. It is important to place the suture in this position to avoid injury to the pudendal nerve and vessels, which run posterior to the ischial spine as they enter Alcock canal. Visualization of the ligament itself helps avoid incorrect placement of the sutures. Several devices have been developed to aid with the suture placement into the ligament, including the Deschamps ligature carrier, nondisposable Miya hook (29), and a disposable Capio transvaginal suture-capturing device (Boston Scientific). These instruments aid with the suture placement and retrieval in this deep and narrow space. Tension should be placed on the suture to ensure its strong placement in the ligament. A second suture should be placed adjacent to the first. Each of these sutures is then placed through the vaginal wall, excluding the epithelial layer at the level of the apex, approximately 1 cm apart, and left untied. If a rectocele is present, it is repaired at this time. The apex of the vagina can be directed under finger guidance to the deepest possible portion, where it will be fixed. The vaginal wall is then closed with a running interlocking 2-0 PGA suture, and then the previously placed sacrospinous ligament fixation sutures are individually tied. Modifications of anterior approach (30) and bilateral fixation have been developed to potentially reduce anterior compartment recurrence.

Augmentation of the apical prolapse repair with synthetic material became increasingly popular in the early 2000s. It was motivated in part by the presumed reduction in the incidence of anatomical recurrence following the primary repair. Complications related to the use of synthetic mesh such as dyspareunia, mesh extrusion, and erosion led to the release of several statements by the U.S. Food and Drug Administration (FDA) (31). In addition, a widespread publicity campaign targeted women with previously placed vaginal mesh for POP as well as instances of litigation have resulted in fear and confusion among patients as well as providers. Minimally invasive abdominal approaches rapidly developed within the same timeframe and currently are favored by many providers. As a result, mesh augmented transvaginal repair is reserved for a minority of carefully selected cases. Nonetheless, even with transabdominally placed mesh, long-term follow-up suggests a >10% risk of vaginal mesh exposure (32).

Open Sacral Colpopexy

A transabdominal approach to apical repair can be performed by open, robotic-assisted laparoscopic and pure laparoscopic approaches. The principles of the operation remain the same regardless of approach, with the critical elements as follows:

- Permanent mesh (type I macroporous, monofilament) as graft material
- Secure suture fixation of the graft to the sacral promontory and vaginal cuff
- Complete enterocele reduction and culdoplasty
- Anti-incontinence procedure as indicated

The patient is placed in low lithotomy position to allow both transvaginal and transabdominal access. Typically, a Pfannenstiel incision is preferred by patients although visualization of the sacral promontory may be slightly more difficult. If one anticipates suboptimal exposure due to patient’s body habitus or prior surgical history (especially if prior mesh repair was performed), a low midline abdominal incision should be used. The following is a description of the operative technique of abdominal sacral colpopexy (ASC) and abdominal enterocele repair.

Once the incision is made and the peritoneal cavity entered, lysis of adhesions is performed as necessary and bowel is packed out of the pelvis above the level of the sacral promontory to achieve optimal exposure. Next, an incision is made in the posterior peritoneum over the sacral promontory, extending inferiorly along the right lateral aspect of the rectum (Fig. 48.27). Care is taken during fatty tissue dissection on the anterior surface of sacral promontory to avoid the middle sacral vein and presacral veins which can cause significant bleeding. Next, the peritoneum over the vaginal cuff is excised, and the peritoneum is dissected off the cuff of the vagina (Fig. 48.28).

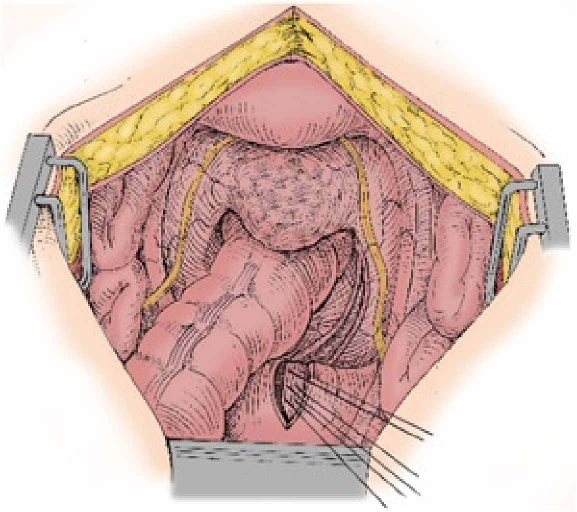

FIGURE 48.27 Incision of posterior peritoneum extending into pelvis lateral to rectum. Note secure suture placement into the sacral promontory.

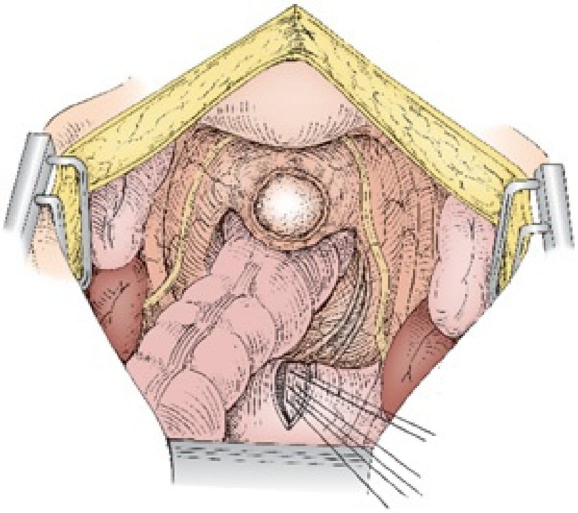

FIGURE 48.28 Peritoneum over vaginal cuff incised. Note: Dissection is made easier by use of EEA sizer.

The graft is secured to the vagina by folding over the cuff of the vagina and allowing the long end of the graft to exit posteriorly and extend to the sacrum. After placing an obturator in the vagina (large end-to-end anastomosis sizers are useful), the enterocele sac is identified and secured with an Allis clamp. If the enterocele is large, several purse-string sutures or linear 2-0 Ethibond sutures are placed into the enterocele sac to obliterate it (Fig. 48.29). This will reduce the cul-de-sac and facilitate the culdoplasty.

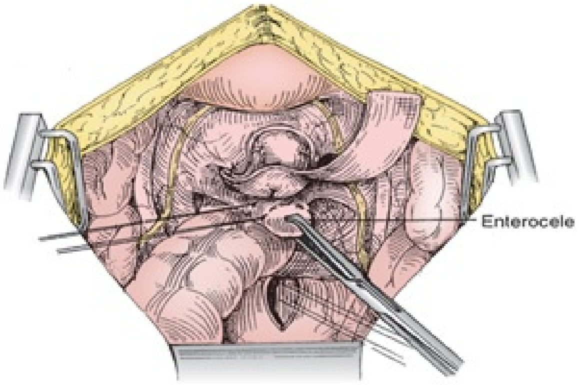

FIGURE 48.29 Isolation of enterocele from above. If enterocele is large, it may be reduced by plicating with purse-string sutures prior to cul-de-sac closure.

A Halban culdoplasty is performed by placing linear sutures (2-0 Ethibond) through the posterior peritoneum and on the outer surface of rectum up to the vaginal cuff (Fig. 48.30). The central sutures are placed through the obliterated enterocele sac to prevent recurrence of enterocele. Upward retraction of the graft will assist in exposing the cul-de-sac. Usually four to six sutures are used to complete adequate cul-de-sac closure.

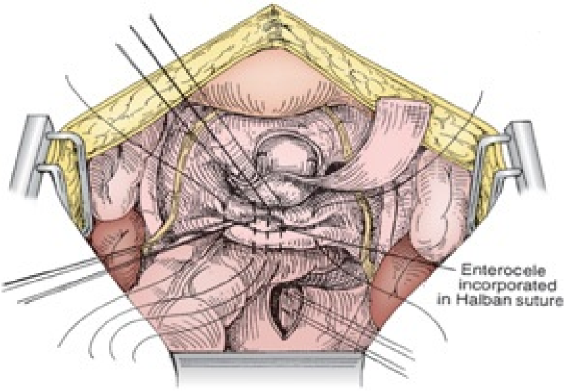

FIGURE 48.30 Halban culdoplasty. Longitudinal sutures placed to close cul-de-sac.

Next, the graft is secured to the promontory using 2-0 Ethibond sutures. Care must be taken to avoid excessive tension. Placing the obturator all the way into the vagina but not pushing the vagina upward establishes the proper length of the graft. The graft is placed around the right lateral aspect of the rectum. A space of two fingerbreadths between the graft and the rectum prevents compression of the rectum over the graft (Fig. 48.31). The excessive length of the graft is trimmed after fixation to the sacrum.

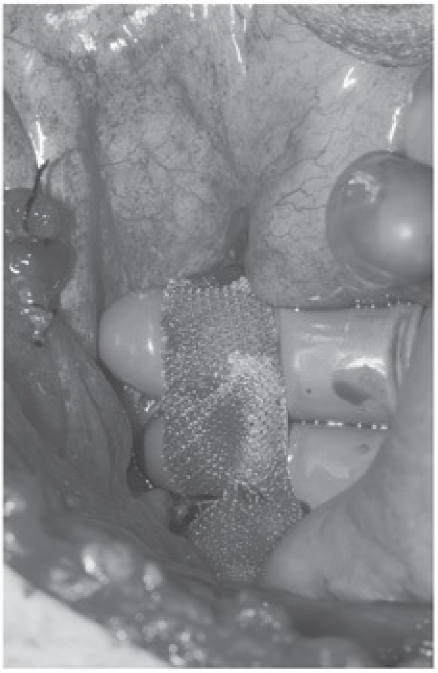

FIGURE 48.31 Intraoperative view: graft in final position. Note minimal tension placed on graft material. Incised peritoneum will be closed over graft after securing graft.

The graft is positioned in the retroperitoneal space by closing the presacral peritoneum over the graft and covering the graft on the vagina with the superior edge of the peritoneum over the vagina (Fig. 48.32). Stress incontinence procedures (if indicated) are then performed. The patient is then examined to determine if any ancillary prolapse repairs are needed.

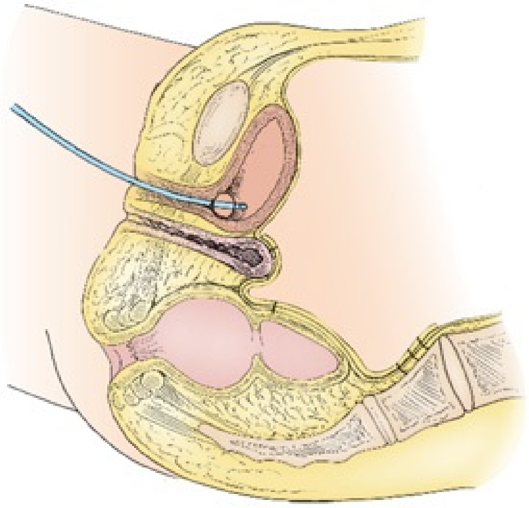

FIGURE 48.32 Final result. Graft positioned below posterior peritoneum by closing the previously incised peritoneum over the mesh.

Laparoscopic Sacral Colpopexy

Laparoscopic sacral colpopexy is very similar to the open technique. Peritoneal entry is achieved using Veress needle followed by CO_2 insufflation to pressure of 15 mm Hg. Five total laparoscopic ports are placed in the lower abdomen. Then lysis of adhesions, vaginal cuff dissection, and sacral promontory dissection are performed in sequence. After the vaginal cuff and sacral promontory are exposed, a 4 cm × 15 cm Y-shaped graft is constructed using monofilament nonabsorbable mesh. The two short arms of the Y-shaped mesh are sutured to the exposed vaginal cuff anteriorly and posteriorly using six sutures of 2-0 Ethibond (Fig. 48.33). Alternatively, absorbable sutures, such as

Vicryl or polydioxanone, may be used. Next, the long arm of the Y-shaped mesh is anchored to the sacral promontory in tension free fashion. The posterior peritoneum is closed over the entire length of the mesh to avoid any contact with the abdominal contents. Cystoscopy is routinely performed to ensure that there is no injury to the ureters and that there is no foreign suture or mesh material in the bladder.

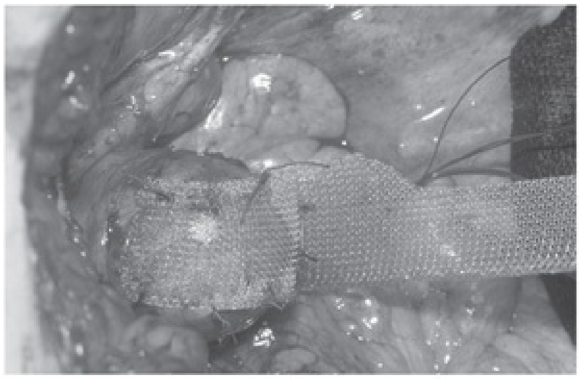

FIGURE 48.33 Intraoperative view: permanent graft secured to vaginal apex.

Robot-Assisted Laparoscopic Sacral Colpopexy

This technique is almost identical to the laparoscopic approach except the da Vinci robot is used to control the laparoscopic instruments designed for the da Vinci robot. It is believed that the sophisticated EndoWrist technology of the da Vinci robot allows for much faster intracorporeal suturing, less steep learning curve, and minimizes surgeon fatigue. However, these advantages must be weighed against the costly nature of da Vinci robot. Two studies evaluated the relative inpatient cost of ASC, laparoscopic sacral colpopexy (LSC), and robotic sacral colpopexy (RSC) and both concluded that ASC was the least costly inpatient option (33,34). Both models did not consider the potential benefits of minimally invasive approach and quicker recovery and return to work.

SURGICAL TECHNIQUES FOR ANTERIOR COMPARTMENT

Anterior prolapse can present as an isolated defect or as it frequently presents, in combination with the prolapse of the apex. Corrective techniques for the anterior defects can be used to repair the isolated defect or used in combination with apical procedures. These procedures can be performed using native tissues alone or augmented with either synthetic or biologic materials. Various commercial kits made of these synthetic and biologic grafts have been manufactured to improve the outcomes of anterior compartment prolapse repair. Detailed review of all the proprietary kits is beyond the scope of this chapter. One should note, however, that these devices apply similar anatomic principles as the procedures described in the following section and that a solid understanding of pelvic floor anatomy is paramount to successful restoration of POP. Furthermore, there is ongoing investigation by the FDA on the safety of transvaginal mesh devices and all comparative data on prolapse surgery outcomes should be interpreted with caution (31).

Anterior Colporrhaphy

After appropriate patient positioning and Foley catheter placement, the anterior vaginal wall is infiltrated with normal saline or lidocaine-epinephrine solution to facilitate hydrodissection. A midline incision extending from the bladder neck to the level of the vaginal cuff or to just above the cervix is made. Vaginal wall is dissected from the underlying pubocervical fascia. Countertraction by the index finger of the nondominant hand and traction on the Allis clamp helps to facilitate the dissection. The dissection continues laterally to the ischiopubic rami, apically to the level of the cuff and distally to the bladder neck (Fig. 48.34). The pubocervical fascia is plicated using a series of interrupted sutures across the midline. 2-0 PGA suture is commonly used. The cardinal ligaments first brought together in the most proximal aspect of the repair. Plication sutures are placed starting proximally and in 1-cm intervals toward the bladder neck. Sutures are tied after all the sutures have been placed. If a concomitant apical repair is performed, the apical plication sutures can be attached to the suspension sutures for additional support. If a synthetic midurethral sling procedure is planned as well, it is performed through a separate distal anterior vaginal incision. Cystoscopy is performed to ensure that the bladder is intact and ureteral efflux is present. Vaginal closure is then carried out using a running 2-0 absorbable suture.

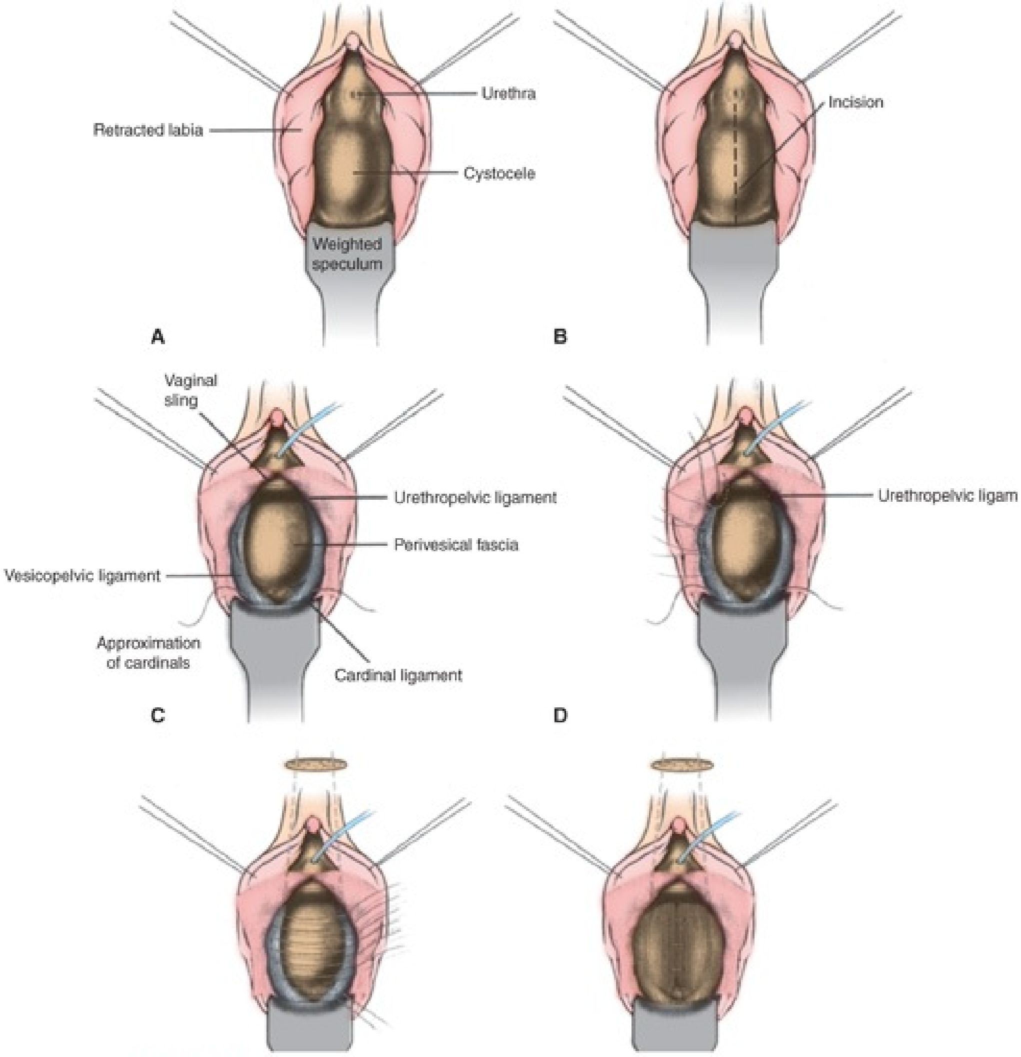

FIGURE 48.34 A: Demonstration of the central cystocele defect with preservation of the lateral vaginal sulci. B: A midline incision is created from the midurethra to vaginal apex in the vaginal wall. The retropubic space is developed on either side of the urethra and bladder. C: The vesicopelvic ligaments are identified, as are the cardinal ligaments. The cardinal ligament complex is reconstituted in the midline with sutures so as to provide apical support for the repair. D: For those repairs involving suture suspension techniques, sutures may be placed throughout the vesical pelvic ligament and transposed from the vaginal to suprapubic area for subsequent stabilization. These steps are repeated on the contralateral side. E: In those circumstances where plication alone is performed, sutures are placed across the base of the bladder from the vesicopelvic ligament on one side to the vesicopelvic ligament on the contralateral side and the two structures are reapproximated. F: Completion of combined plication repair with needle suspension of the proximal urethra and bladder neck.

Vaginal Paravaginal Repair

The paravaginal procedure performed through a vaginal incision exploits the ATFP as an anchoring point for sutures placed through the anterior vaginal wall on either side of the bladder base. The surgical field is prepared as discussed previously with dissection of the retropubic space, which frees up the base of the bladder from the pelvic floor. The dissection is extended laterally to the pubic ramus. Using blunt dissection, weak and attenuated attachments from bladder neck to the ischial spine are taken down. Once the dissection is complete, the bladder base is retracted medially with curved retractors to identify ATFP and/or obturator fascia. A 1-0 permanent suture is placed into the white line of the ATFP just distal to the ischial spine. A series of four to six 1-0 sutures are then placed in sequence toward the urethrovesical junction. These sutures are then passed through the pubocervical fascia. A small amount of lateral vaginal wall can also be incorporated. These steps are repeated on the contralateral side. The sutures are then tied distal to proximal and the cystocele is reduced. Cystoscopy is performed to ensure that the bladder is intact and ureteral efflux is present. Vaginal closure is then carried out using a running 2-0 absorbable suture.

SURGICAL TECHNIQUES FOR POSTERIOR COMPARTMENT

Although rectocele repair has been practiced for >100 years, the most effective surgical treatment remains undetermined. The three surgical routes described in the literature for repair of posterior wall prolapse are transvaginal, transanal, and abdominal. Among the different surgical routes, the transvaginal approach is the most commonly practiced approach. The transanal route was thought to be indicated for cases of small distal rectocele and is generally done by colorectal surgeons. Today, this is less commonly practiced because of the possible impairment of the anal sphincter as a result of its dilatation during the surgery. The abdominal approach is reserved for rare instances when there is associated rectal prolapse or advanced apical prolapse.

Although graft-augmented posterior repairs have been performed, they have fallen in popularity due to recent FDA warnings on the use of transvaginal mesh. Furthermore, several studies have shown little benefit to augmenting native tissue repair with biologic or synthetic mesh (35–37). We will therefore focus our discussion on commonly performed transvaginal techniques: posterior colporrhaphy, site-specific repair, and perineal reconstruction.

Posterior Colporrhaphy

Posterior colporrhaphy, also known as “traditional repair” is a transvaginal midline plication procedure commonly performed by general gynecologists and urologists. Prior to all pelvic reconstructive procedures involving the posterior compartment, bowel prep is recommended. Preoperative antibiotic with coverage of gram-negative organisms is given at the start of the procedure. Following the administration of general or spinal anesthesia, the patient is positioned in the high lithotomy position with care to ensure the neural safety of all four extremities. She is prepped and draped in a sterile fashion, and a Foley catheter is inserted. Exam under anesthesia is performed to reassess all compartments and ensure that the surgical procedures chosen are adequate (Fig. 48.35). A self-retaining vaginal wall retractor such as the Lone Star (Lone Star Medical Products) is placed. Some surgeons inject plain saline or epinephrine/saline solution diluted to 1/200,000 into the submucosal tissue to aid in the dissection and help with hemostasis.

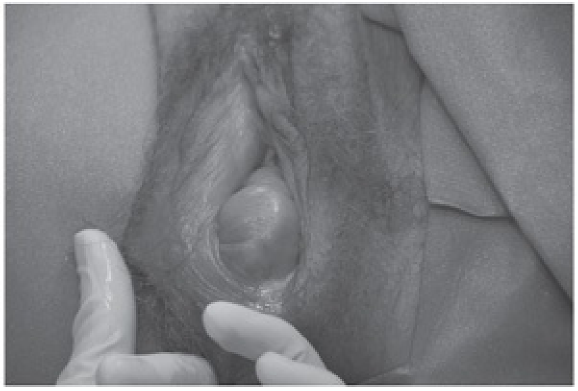

FIGURE 48.35 Rectal examination of a woman with a rectocele. The vaginal apex is 6 cm proximal to the hymen but the posterior vaginal wall distal edge protrudes past the introitus when standing. Notice how by placing the nondominant hand's third digit in the rectum, the thumb and index finger can still be utilized by the operating surgeon.

The posterior commissure of the vagina is clamped approximately 2 to 3 cm from the midline on the right and left with Allis clamps. A transverse incision is made in between the two Allis forceps. In cases where perineorrhaphy is performed concomitantly, an additional incision is made in the perineum to remove a triangular piece of skin, allowing exposure of the perineal body, as will be discussed in a later section. A vertical incision is made in the posterior vaginal mucosa from the middle of the transverse incision reaching the apex of the rectocele, which is held by an Allis clamp in the midline (Fig. 48.36). Using a Metzenbaum scissors, the vaginal mucosa is dissected from the underlying perirectal fascia using a "snip and push" technique. Once an avascular plane is established, an index finger wrapped with a moist vaginal laparotomy sponge can be used for further dissection, although this technique should be abandoned if significant tissue resistance is met. It is also important to do the dissection close to the vaginal wall side to avoid injuring the rectum. The dissection is extended upward in the midline to well above the bulge of the rectocele (Fig. 48.37). At this point, it is necessary to obtain sufficient hemostasis to identify the anatomic structures.

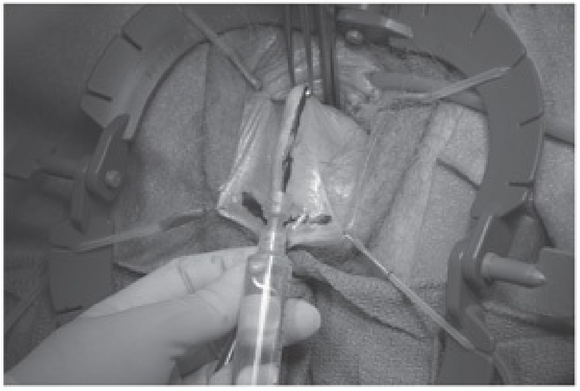

FIGURE 48.36 The proximal end of the rectocele is grasped with an Allis clamp and the midline and transverse incisions are marked. Injection of local anesthetic with epinephrine can help with developing a plane.

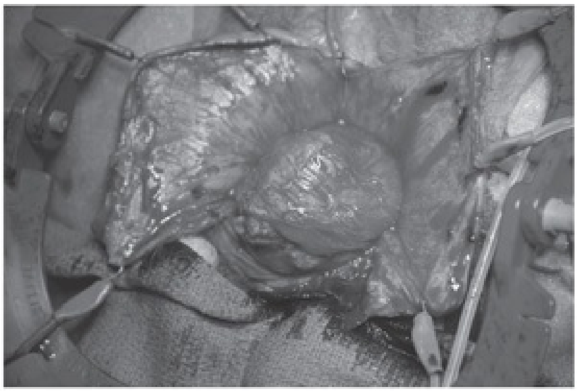

FIGURE 48.37 The vaginal epithelium overlying the rectocele is dissected off using a "snip and push" technique with Metzenbaum scissors held at a 90-degree to the vaginal epithelium. The excess epithelium is removed.

The surgeon then should insert the nondominant middle finger into the rectum, which allows the thumb and index finger to be available to the surgeon. The bulge is reduced to aid in the identification of the lateral rectovaginal fascia. Care is taken not to incorporate the levator ani (levator plication), since this can result in vaginal distortion, constriction, postoperative pain, and dyspareunia (38). The rectovaginal fascia is plicated to the midline using a series of interrupted size 0 polyglactin sutures (Fig. 48.38) that are initially tagged and then tied in succession. The distal end of the rectovaginal septum (imbricated rectovaginal fascia) is then attached to the reconstructed perineal body (perineorrhaphy) if this is performed. Any redundant vaginal epithelium that crosses the midline is excised, and the vaginal epithelium is closed with synthetic absorbable suture (Fig. 48.39).

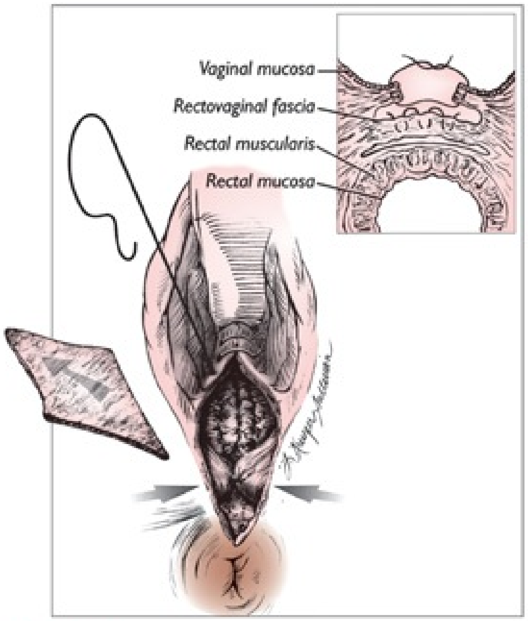

FIGURE 48.38 The rectovaginal fascia is identified lateral to the rectocele. Absorbable interrupted sutures are placed in the rectovaginal fascia bilaterally. The sutures are tied down in succession to re-approximate the tissue in the midline as indicated by the arrows above.

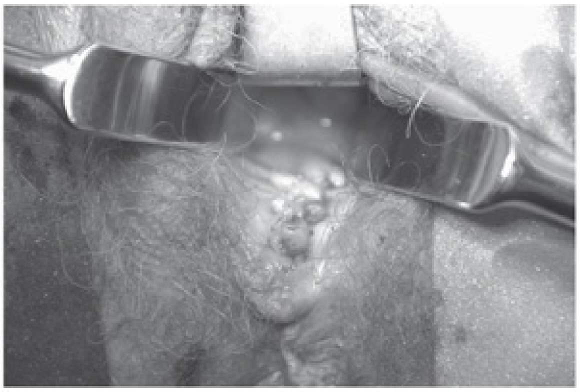

FIGURE 48.39 Examination of the posterior vaginal wall following the posterior repair

Site-Specific Rectocele Repair

The site-specific repair of rectocele was proposed by Richardson et al. (39) in 1976. This technique is based on Richardson et al.'s (39) observations during cadaveric dissection that rectoceles are the result of a specific defect in the rectovaginal fascia.

The initial steps of this procedure are similar to the classic posterior colporrhaphy. The vaginal epithelium is opened and dissected from the underlying rectovaginal fascia. A rectal examination assists in the identification of the edges of the defect, which are grasped with forceps. The defect is repaired with interrupted 0 polyglactin sutures (Vicryl); they are usually placed cranial to caudal, as opposed to the side-to-side placement in a posterior repair. Again, care is taken to avoid the incorporation of any healthy muscle that could result in dyspareunia. If indicated, the perineal body is reconstructed. The vaginal epithelium is closed as previously described.

Reconstruction of the Perineal Body

The perineal body is located between the vaginal introitus and the anus, and attached to it are the following structures: bulbocavernosus muscles, superficial transverse perineal muscles, levator ani muscles, the external anal sphincter, and the rectovaginal fascia (Fig. 48.40). Due to its lateral and superior support, there is limited downward movement of the perineal body. Rectoceles that recur or are symptomatic with defecatory disorders may actually be disorders of exaggerated perineal descent due to the detachment of the perineal body to the rectovaginal septum.

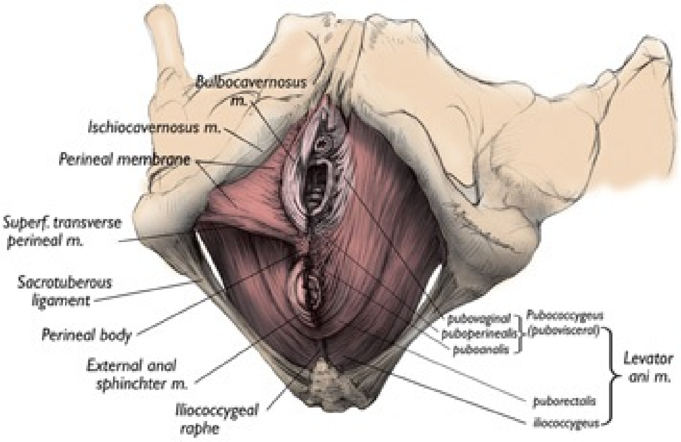

FIGURE 48.40 Inferior view of the pelvic floor. Superficial perineal muscles and perineal membrane have been removed on the left to show attachments of the levator ani (LA) muscles to the distal vagina, anus, and perineal body.

Reconstruction of the perineal body starts with placement of Allis clamps on the lateral edges of the posterior commissure of the vagina that also grasp the underlying bulbocavernosus muscles.

When brought together in the midline, they represent the lower edges of the reconstructed introitus. Care must be taken not to overly narrow the introitus especially because the relaxation of the pelvic floor during anesthesia can often lead to miscalculations in the resulting introitus. A triangular piece of vaginal epithelium is removed so as not to damage the underlying superficial transverse perineal muscles (Fig. 48.41). The bulbocavernosus muscles are plicated with midline interrupted size 0 polyglactin sutures (Fig. 48.42) and the epithelium is closed with a running absorbable suture. Preservation of the size of the genital hiatus is important for women who wish to remain sexually active.

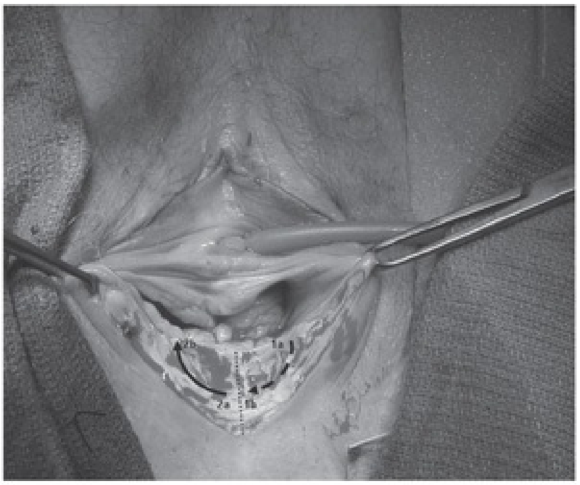

FIGURE 48.41 Perineorrhaphy incision. The perineorrhaphy incision is diamond-shaped and only the epithelium is removed. With a finger in the rectum, interrupted sutures are placed lateral to medial (*1*) with the first pass and then medial to lateral (2) and then tied down.

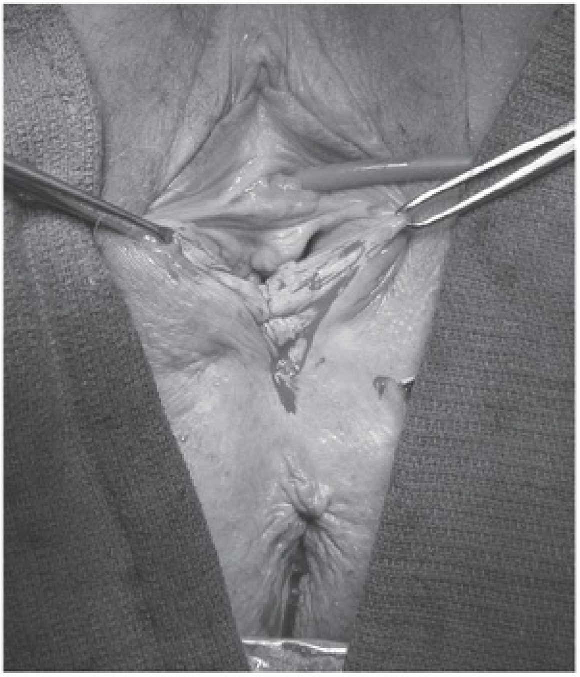

FIGURE 48.42 The perineum after three sutures are placed. The genital hiatus has decreased in size and the perineal body is reconstructed.

POSTOPERATIVE CARE

In our practice, women who have undergone a repair of a posterior vaginal wall defect are admitted to the hospital overnight for pain management and observation. An ice pack to the perineum every couple hours can reduce postoperative edema and pain in women who have had a perineorrhaphy. A voiding trial is typically performed the day of discharge (most often postoperative day 1). A repeat voiding trial is performed by a visiting nurse 3 or 4 days later in the patient's home for those who fail initially. Women are discharged home, to return in 2 weeks, with a bowel regimen consisting of fiber, stool softeners, and a "plan" if they have not had a bowel movement for a couple of days. Oral pain medications, including anti-inflammatory agents and narcotics, may be prescribed. We instruct all women that they are limited to no lifting over 10 pounds and "nothing in the vagina" for 6 weeks.

COMPLICATIONS

The major risks of transvaginally performed apical repair are bleeding due to vascular injury, nerve entrapment, ureteral injury or kinking, bowel injury, wound infection, and persistent or recurrent prolapse. During placement of the purse-string sutures of an enterocele repair, one needs to be aware of the ovarian vessels which lie near the uterosacral–cardinal complexes. The pudendal vessels and nerve, which lie posterior to the sacrospinous ligament, are at risk of injury during sacrospinous ligament fixation. Pudendal entrapment may occur if sutures are placed too laterally, whereas the sciatic nerve is at risk if the sutures are placed too cephalad. Pelvic and gluteal pain, although usually transient, can occur as a result of injury to these nerves. The intrapelvic ureter is intimately associated with the uterosacral ligaments but can be injured or kinked by any of the transvaginal vault suspensions. Administration of indigo carmine and observation of the bilateral efflux is a crucial step for identification of the potential ureteral problem and timely intervention. Ureteral injury or kinking in cases of vault suspension has a reported rate of 1% to 11% (40). Cystotomy, enterotomy, and ureteral injury are the main intraoperative complications specific to the transabdominal apical vault prolapse repair (41).Postoperative complications such as transvaginal mesh erosion, mesh erosion into the bowel, and bowel obstruction also have been reported. As was shown by the CARE trial, mesh erosion after abdominal sacrocolpopexy was 10.5% at 6 years (32).

Significant intraoperative complications occur relatively infrequently with anterior vaginal prolapse repairs. The most common complication seen with cystocele repair is injury to underlying structures such as the urethra, bladder, and rarely, other pelvic viscera, including bowel (42). Incidental cystostomy may be repaired with a layered closure with absorbable suture, and maximization of urinary drainage. Although reported to occur at an incidence of <2%, the prolapse surgeon must always be cognizant of the risk of ureteral damage or obstruction (43). Cystoscopic evaluation intraoperatively should indicate the possibility of ureteral obstruction with non-efflux from one side. Sutures may be removed at this time prior to completion of the procedure. Failure to recognize ureteral injury intraoperatively sets the stage for one of the most devastating complications of anterior or apical prolapse repair.

Postoperative voiding dysfunction may be caused by detrusor overactivity, urethral obstruction, or recurrence of the cystocele. Resolution of preoperative urgency will occur in up to 40% of patients (44); however, de novo detrusor instability will occur in approximately 7% to 12% (44) . Although degrees of urinary retention may occur in patients on a transient basis, prolonged obstruction manifests in <1% of women. Poor or inadequate detrusor contractility may be a reason for incomplete emptying and may be predictable on the basis of preoperative urodynamic evaluation. Persistent dyspareunia, pelvic pain, or vaginal stenosis may ensue from aggressive plication and/or excision of vaginal mucosa.

Constipation and pain are common in the postoperative period after posterior repair. Constipation needs to be addressed early because it may affect success of the surgery. Rectal injury, hematoma, and development of rectovaginal fistula are rare. The most important factor in preventing rectovaginal fistula formation is intraoperative recognition and repair. Dyspareunia was reported in

15% to 27% of cases following the posterior repair in some series (45), yet other studies showed significant improvement of sexual function after the posterior repair (36,46). New-onset bowel dysfunction is reported in 11%.

OUTCOMES

Apical Prolapse Surgery

The results of apical prolapse repair are difficult to evaluate because the definition of success varies between studies and few studies report long-term follow-up. Colombo and Milani (47) found no statistical difference in recurrence of vault prolapse in a retrospective study comparing sacrospinous ligament fixation and McCall culdoplasty (8% versus 3%, respectively). Shull et al. (26) reported "optimal anatomic outcomes" in 87% of patients undergoing uterosacral fixation, whereas Karram et al. (40) reported that 89% of women expressed satisfaction following the procedure. Success rates ranging from 8% to 97% have been reported for traditional sacrospinous ligament fixation (48,49). Shull et al. (50) and Meeks et al. (51) reported 95% and 96% cure rates following iliococcygeus fixation, whereas more recently, Maher et al. (52) reported equal efficacy when comparing the iliococcygeus fixation to sacrospinous ligament fixation.

There are numerous reports by multiple authors that confirm the success of ASC. Success rates >90% have been reported and the durability of this procedure has also been documented (52–54). There are several randomized, prospective trials comparing sacrospinous ligament fixation (SSLF) with ASC (55). In a comparative study between ASC versus vaginal repair, Benson et al. (53) reported a lower success rate with vaginal repair and an equivalent hospital stay between the two groups. Lo and Wang (54) reported on their results of ASC versus SSLF at a duration of 2.1 years: 94.2% success with ASC compared to 80% with SSLF. Maher et al. (56) reported on a comparative study between ASC and SSLF. At 2 years of follow-up, symptoms and anatomic success were equivalent, but asymptomatic failures to introitus and recurrent cystoceles were less after ASC. Overall, vaginal procedures have a higher rate of recurrent anterior defects even when performed in the setting of a concomitant anterior repair (colporrhaphy).

Anterior Prolapse Surgery

Long-term results for these procedures are still undergoing evaluation, but the recently updated Cochrane review provides insightful comparative data on various anterior prolapse repairs (57). Anterior colporrhaphy using native tissue alone is noted to be successful (80% to 100% in some retrospective series) but has high recurrence rate (58–61). Risk factors for operative failure may include advanced age, hormonal depletion, inadequate preoperative identification of all anatomic defects, incomplete surgical reconstruction, or technical failure (62). In addition, obesity, chronic pulmonary disease, bowel dysmotility, and genetic predisposition have also been implicated in surgical failure. Some studies have reported that interpositional grafts convey a significant reduction in prolapse recurrence, with plication repairs demonstrating only a moderate success rates (35,63); however, other authors have found similar objective anatomic outcomes (64,65). Several randomized clinical trials have demonstrated improved anatomic and subjective outcome with synthetic graft augmentation of native tissue repair (66–68). However, these results did not translate to functional outcome using validated questionnaires or reoperation rate. Furthermore, mesh repair was also associated with longer operating time, greater blood loss, and a nonsignificant tendency toward higher cystotomy, de novo dyspareunia, and de novo stress urinary incontinence rate compared with anterior colporrhaphy. However, the possibility of serious mesh complication must be carefully discussed with each patient prior to making any decision in surgical management of anterior compartment prolapse.

Vaginal paravaginal repairs have reported success rates from 67% to 100% at 1 year (69–73). Significant complications have been reported recently with vaginal paravaginal repairs including bilateral ureteric obstruction, retropubic hematoma requiring surgery, vaginal abscesses, and transfusions.

Posterior Prolapse Surgery

Despite the fact that transvaginal posterior colporrhaphies have been the preferred surgical procedure for rectocele repair among gynecologic surgeons for over 100 years, there are few data regarding the long-term anatomic success. In different case series, the anatomic cure rate ranges from 76% to 96% for posterior and from 56% to 100% for site-specific defects (74). One retrospective study compared posterior colporrhaphy and site-specific repair for posterior compartment and noted significantly higher recurrence rate of rectoceles following site-specific repair (32% versus 13% following posterior colporrhaphy) (75). A recent Cochrane review of the surgical management for prolapse reported that transvaginal repair is superior to a transanal approach for posterior vaginal wall prolapse in terms of objective and subjective outcomes (57). The updated Cochrane review also concluded that there was no benefit of mesh augmented repair of posterior compartment.

Posterior colporrhaphy was found to be effective in alleviating symptoms of vaginal bulge (4% to 64%), constipation (22% to 100%), and fecal incontinence (4% to 36%). Thus, the functional improvement is not always correlated with anatomic success.

CONCLUSION

POP is a common yet complex medical condition characterized by herniation of pelvic organs affecting multiple vaginal compartments. Successful restoration of anatomic defects requires expert knowledge of the pelvic floor anatomy and various surgical techniques that can be tailored to meet the needs of each patient.

SECTION V■ TESTIS, EPIDIDYMIS, VAS DEFERENS, AND SEMINAL VESICLES

Section Editor: MARC GOLDSTEIN

CHAPTER 49■ANATOMY OF THE EPIDIDYMIS, VAS DEFERENS, AND SEMINAL VESICLE

AKANKSHA MEHTA

It is well known that spermatogenesis, the development of germ cells into structurally mature sperm, occurs in the seminiferous tubules of the testis through a series of ordered and well-regulated processes. Less well appreciated is the fact that testicular sperm are functionally immature and therefore incapable of fertilizing an oocyte without direct intracytoplasmic injection (ICSI). Sperm maturation occurs as sperm migrate out of the testis and travel through the male reproductive tract. In their journey, they are supported and stimulated by the distinct microenvironments of the epididymis and vas deferens and bathed in the secretions of the prostate, seminal vesicles, and accessory glands before eventually exiting the male urethra during ejaculation. Physiologic changes that sperm undergo during migration include plasma membrane remodeling, changes in intracellular signaling transduction, and the acquisition of progressive motility, all of which contribute to ultimately rendering spermatozoa capable of oocyte penetration and fertilization. The unique anatomy of the excurrent ductal system, both gross and microscopic, is optimally suited to ensure that sperm maturation progresses in as efficient and as effective a manner as possible. An appreciation of this anatomy is key for understanding not only normal male reproductive physiology but also male factor infertility.

EPIDIDYMIS

Physical Examination

Careful assessment of the epididymides during the physical examination of an infertile patient is as important as the testicular evaluation. The size and consistency of the epididymis can help differentiate between obstructive and nonobstructive etiologies of azoospermia. An enlarged and indurated epididymis suggests obstruction of sperm outflow, whereas a flat epididymis suggests impaired spermatogenesis. Pain upon palpation of the epididymis is concerning for inflammation or infection due to chemical, viral, or bacterial causes, depending on the patient’s history and risk factors. Palpation of a cystic structure originating from the caput epididymis is suggestive of a spermatocele, a diagnosis that is confirmed by documenting the presence of sperm in the aspirate. Although rare, solid tumors originating from the epididymis have been described (1). These may be primary or secondary, benign or malignant, and warrant surgical excision. Absence of the distal epididymis on physical examination should alert the clinician to the possibility of ipsilateral absence of the vas deferens, which, when noted bilaterally, should prompt an evaluation for cystic fibrosis.

Development

The development of the epididymis from the wolffian or mesonephric duct occurs between the 8th and 12th week of gestation under the influence of testosterone produced by fetal Leydig cells (2,3). Specifically, the proximal portion of the wolffian duct differentiates into the epididymis, whereas the distal portion gives rise to the vas deferens. As the cranial end of the wolffian duct degenerates, it leaves behind a small remnant of tissue called the appendix epididymis. During the 9th week of gestation, 5 to 12 nephric ducts in the region of the epididymis make contact with the developing sex cords of the future rete testis. It is not until the third month of gestation, however, that these tubules establish a communication with the rete testis as the efferent ductules (2,4). In humans, the epididymis is well developed by 16 weeks of gestation, and secretory activity of the epididymal cells has been observed by 25 weeks of gestation (5).

The major morphogenic event in epididymal development is the elongation and coiling of the wolffian duct, a process that is likely the combined product of cell proliferation and directed cell rearrangements, and interactions between wolffian duct epithelium and surrounding mesenchymal cells (6).

Anatomy

The epididymis lies posterior and slightly lateral to the testis. It is invested by the tunica vaginalis, which is continuous with the tunica vaginalis covering the testis. Laterally, a deep groove, termed the *sinus epididymis*, marks the boundary between the testis and epididymis. Extensions from this connective tissue sheath enter the interductal spaces, forming septa that divide the tubule into histologically similar regions (7).

Antoine De Graaf, the famous 17th century anatomist, reported his dissection of the human epididymis in 1668, likening the epididymis to a “thin thread which gradually enlarges until it attains the thickness of a piece of string and constitutes the vas deferens” (8). It is estimated that the uncoiled human epididymis measures between 6 and 7 meters in length.

Anatomically, the epididymis is divided into three regions: the caput (head), corpus (body), and cauda (tail) (Fig. 49.1). The caput epididymis is formed by 8 to 12 efferent ducts that originate from the superior pole of the testis and drain into the epididymis. Each efferent duct is 15 to 20 cm in length and opens into an individual epididymal tubule. The epididymal tubules anastomose with one another along the length of the epididymis, eventually becoming a single, coiled tubule in the corpus epididymis. The epididymal tubules are surrounded by contractile smooth muscle cells, which increase in size and number in the distal epididymis. Peristaltic contractions generated by the smooth muscle propel the spermatozoa in an antegrade direction. At its distal end, the cauda epididymis becomes continuous with the convoluted portion of the vas deferens. Here, contractile cells are replaced by smooth muscle organized in three layers—inner longitudinal, intermediate circular, and outer longitudinal—that thicken and continue into the vas deferens.

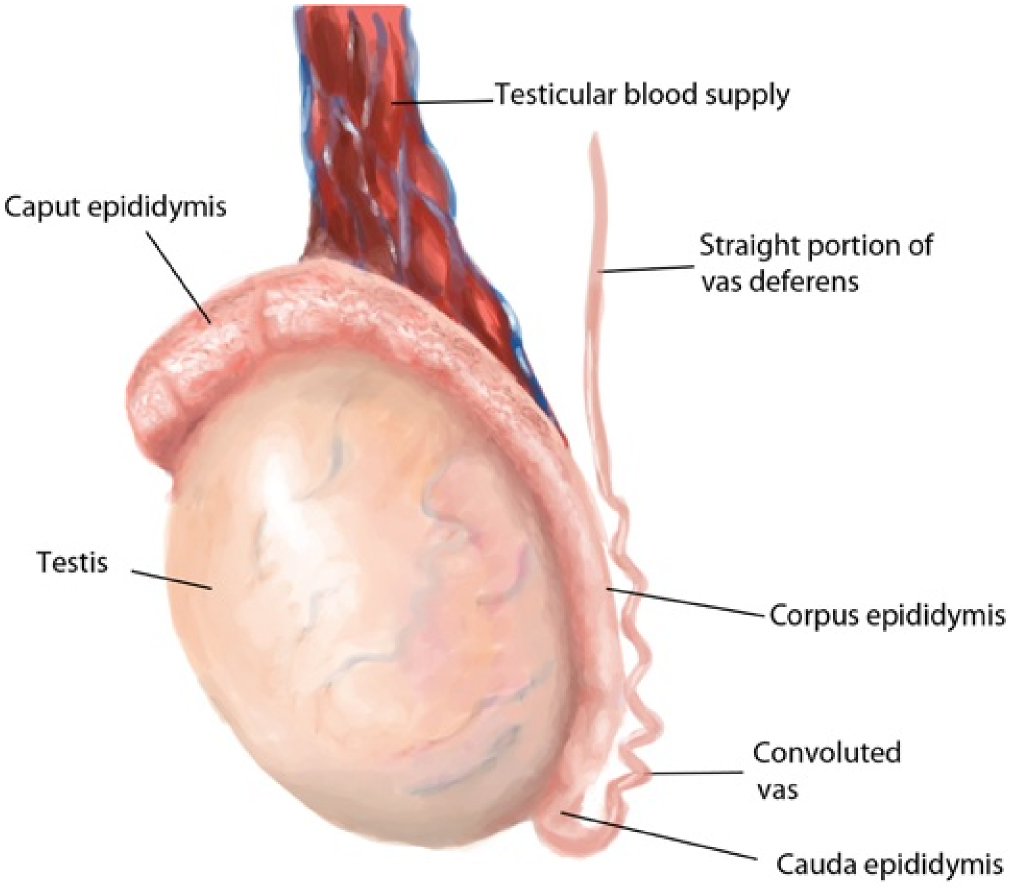

FIGURE 49.1 Anatomy of the testis and epididymis.

The luminal shape and size on cross section of the epididymis varies from the irregular stellate shape in the efferent ducts to the regular, oval, or round shape in the corpus epididymis to the wide irregular shape in the cauda epididymis. Variability in luminal appearance correlates with the different functions performed by each segment of the epididymis and with the different cell types found along its length.

The lumen of the epididymis is lined by nonciliated pseudostratified columnar epithelium and contains four major cell types: principal, basal, apical, and clear cells. Principal cells are tall, columnar cells with basally located, oval nuclei. They bear long stereocilia (15 μm) and function to resorb testicular fluid; approximately 90% of the total secretory fluid volume is absorbed in the epididymis. Principal cells also endocytose other components of seminal fluid and produce glycoproteins that are essential for sperm maturation. Basal cells lie between the principal cells, at their base, and are thought to be precursors of principal cells. Apical and clear cells are far less common than principal and basal cells. Apical cells are rich in mitochondria and most abundant in the caput epididymis. In contrast, clear cells are columnar and most abundant in the caput epididymis. They have few microvilli but numerous endocytic vesicles and lipid droplets. The exact functions of apical and clear cells are unknown.

The composition of epididymal fluid varies along the length of the epididymis, giving rise to several distinct microenvironments within the tubule (9). These are maintained by the active secretion of proteins by the epithelium, fluid reabsorption, and exchange of molecules between the lumen and the circulation. Exchanges are selectively regulated by the blood–epididymis barrier, which is formed by tight apical junctions between adjacent principal cells (10).

The delicate structure of the epididymis makes it vulnerable to iatrogenic injury during procedures such as hydrocelectomy, spermatocelectomy, and orchidopexy, especially if the epididymis is adherent to the tunica vaginalis (11). Additionally, trauma, infection, inflammation, and even prolonged obstruction of the vas deferens, as, for example, after vasectomy, can cause an increase in intraluminal pressure, leading to microscopic ruptures with sperm leakage, sperm granuloma formation at the site of the rupture and, consequently, secondary obstruction of the epididymis.

Blood Supply

The primary arterial supply to the epididymis derives from the testicular artery, with small contributions from the deferential and cremasteric arteries. The testicular artery (also called the internal spermatic artery) arises from the abdominal aorta and courses inferolaterally, under the parietal peritoneum and along the psoas major, toward the pelvis. As the right and left testicular arteries enter the pelvis, they lie anterior to the genitofemoral nerves, ureters, and external iliac arteries. Both arteries then enter the deep internal inguinal ring and travel with the ipsilateral spermatic cord in the inguinal canal to the scrotum. In its course to the testis, the testicular artery branches into an internal artery and an inferior testicular artery and into branches supplying the caput, corpus, and cauda epididymis (12). The level at which this branching occurs is variable; in 31% to 88% of cases, it occurs within the inguinal canal (13,14).

The deferential artery is a branch of the superior (and occasionally inferior) vesical artery, which, in turn, arises from the internal iliac (hypogastric) artery. The cremasteric artery (also called the external spermatic artery) is a branch of the inferior epigastric artery, which accompanies the spermatic cord and supplies the cremaster muscle and other coverings of the cord and the tunica vaginalis surrounding the testis. Both the deferential and the cremasteric arteries enter the inguinal canal at the deep inguinal ring and travel the length of the spermatic cord along with the testicular artery and veins within the scrotum. Rich vascular anastomoses occur at the head of the epididymis, between the testicular and epididymal arteries, and at the tail of the epididymis between the testicular, epididymal, cremasteric, and deferential (vasal) arteries.

Innervation

Sympathetic nerve endings are concentrated in the corpus and cauda epididymis and increase in density in the proximity of the vas deferens, consistent with their role in promoting epididymal contractility. During ejaculation, the distal portion of the epididymis demonstrates intermittent contractions, in contrast to the peristaltic activity of the proximal epididymis (15).

Function

The mean transit time for sperm in the human epididymis is approximately 12 days (16). In addition to providing sperm storage and facilitating sperm transport, the epididymis plays an important role in sperm maturation. Here, spermatozoa undergo a number of physiologic changes, rendering them capable of oocyte penetration and fertilization within the female reproductive tract. The majority of these changes have not been reproduced in vitro, indicating that their triggers have an epididymal origin. Importantly, sperm maturation within the epididymis has been shown to be androgen-dependent (17).

Human spermatozoa acquire an increased capacity for motility as they migrate through the epididymis, which is manifested not only as a quantitative increase in the percentage of spermatozoa with motile tails but also as a qualitative change from an immature to a more mature pattern of motility. Spermatozoa in the proximal epididymis demonstrate high-amplitude, low-frequency tail movements, producing little motion. In contrast, spermatozoa in the cauda epididymis, demonstrate low-amplitude and high-frequency tail movements, resulting in considerably greater forward progression (18). However, the extent to which motility is dependent of the interaction of spermatozoa with a particular section of the epididymis is unknown. In patients with congenital absence or obstruction of the vas deferens, spermatozoa in the distal epididymis demonstrate worse motility compared to spermatozoa in the proximal epididymis (19,20). Therefore, intrinsic sperm processes and the epididymal microenvironment both appear to play an important role in the acquisition of progressive sperm motility.

Sperm undergo restructuring and modification of surface membrane glycoproteins as a result of their interaction with secretory proteins in the lumen of the epididymis (21). These modifications facilitate sperm–zona pellucida binding and the sperm acrosomal reaction (21). Additional morphologic changes, such as migration of the intracellular cytoplasmic droplet, also occur, with important implications for fertility (22).

After microsurgical vasoepididymostomy for epididymal obstruction, pregnancy rates after distal anastomoses are significantly higher than corresponding rates after anastomoses to the caput epididymis (23). Epididymal maturation of sperm therefore appears to be an essential posttesticular stage for acquisition of fertility by the male gamete. Understanding the detailed contribution of the epididymis to sperm function remains an area of active research.

VAS DEFERENS

Physical Examination

The most important aspect of the physical examination of the vasa deferentia is to simply confirm their presence. Approximately 95% of men with cystic fibrosis have congenital bilateral absence of the vas deferens (CBAVD) (24). This condition is characterized by azoospermia and low semen volume (typically less than 1 mL) due to absent or obstructed ejaculatory ducts or hypoplastic seminal vesicles. However, spermatogenesis in these men is usually normal. Absent vasa in these men is usually the only manifestation of cystic fibrosis. In the subset of men with CBAVD who do have a palpable vasal segment in the scrotum, surgical exploration usually reveals a fibrous cord or nonpermeable duct (25,26).

It is recommended that all couples with CBAVD undergo genetic testing, as the vast majority of affected men (70%) have mutations in at least one allele of the cystic fibrosis transmembrane conductance regulator (CFTR) gene that is detectable by routine testing methods (24). Additionally, renal agenesis has been reported in 74% of men with congenital unilateral absence of the vas deferens and in 12% of men with CBAVD (27). Therefore, a renal ultrasound should be performed in the setting of unilateral or bilateral impalpable vasa.

Development

The vas deferens, or ductus deferens, is a tubular structure derived from the mesonephric duct. Normal differentiation of the vas requires exposure to testosterone during embryogenesis. Although vasal agenesis is the most common congenital anomaly, duplications, interdeferential communications, and deferentiomegaly have also been described (28).

Anatomy

As it arises from the cauda epididymis, the vas is tortuous, or convoluted, for the first 2 to 3 cm of its length. Beyond this convoluted segment, the vas lies posterior and parallel to the vessels of the spermatic cord, passes through the inguinal canal, and emerges in the pelvis lateral to the inferior epigastric vessels. At the internal ring, the vas diverges from the testicular vessels, coursing medial to the structures of the pelvic side wall, in order to reach the base of the prostate posteriorly. Here, the vas once again becomes tortuous and dilated, within the segment known as the ampulla of the vas deferens, before culminating at its junction with the seminal vesicle duct, forming the intraprostatic ejaculatory duct (Fig. 49.2).

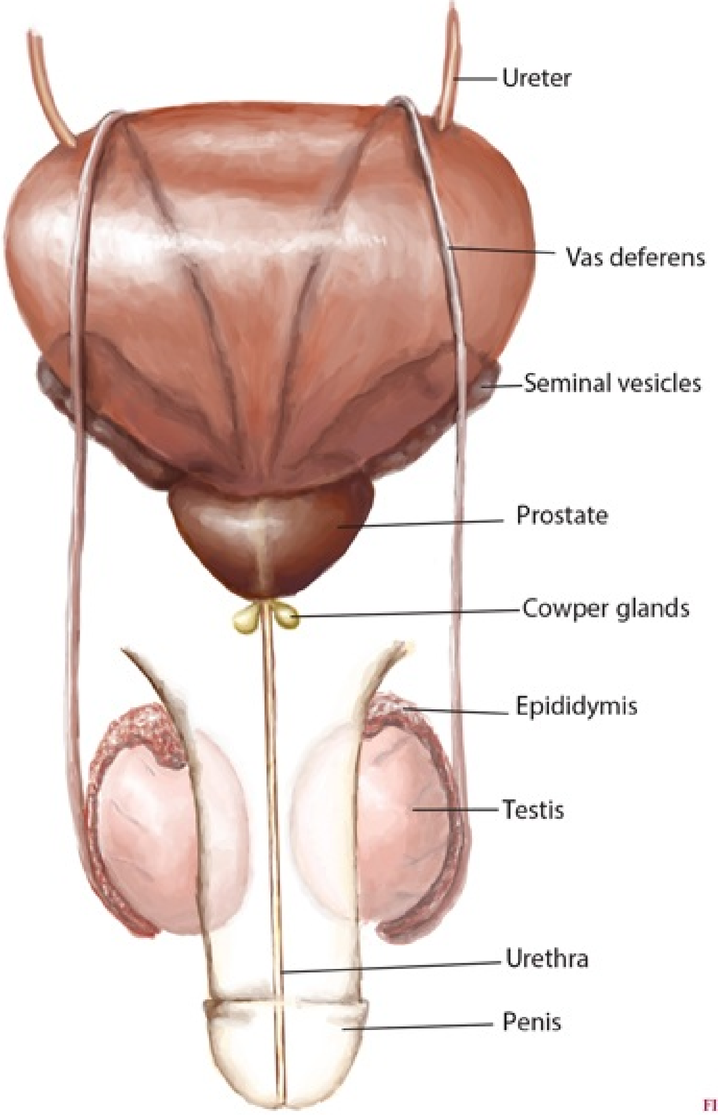

FIGURE 49.2 The male reproductive tract.

In humans, the vas is 30 to 35 cm in length and 2 to 3 mm in outer diameter but with a luminal diameter of only 300 to 500 microns. In cross section, the vas consists of an outer adventitial sheath containing blood vessels and nerves, a thick, muscular wall of outer longitudinal and inner circular smooth muscle lined by elastin, and an inner mucosal lining of pseudostratified columnar epithelium with nonmotile cilia. As such, the vas deferens has the greatest muscle to lumen ratio (approximately 10:1) of any hollow viscous in the human body. During ejaculation, the smooth muscle layers contract reflexively, propelling the sperm in an antegrade direction.

The vas is vulnerable to injury along its entire length, particularly during its course through the inguinal canal. Inguinal hernia repair in adults and children, with and without the use of mesh, is the most common cause of vasal obstruction, with renal transplantation, appendectomy, and hydrocelectomy being other risk factors (29).

Blood Supply

The vas deferens is supplied by the deferential artery, which is usually derived from the superior vesical artery, and occasionally from the inferior vesicle artery, both of which are branches of the internal iliac (hypogastric) artery. Rarely, the deferential artery is derived directly from the internal iliac artery. The deferential artery is surrounded by a dense adrenergic network, and it contracts and relaxes in response to different agonists, demonstrating that it plays an active role in regulating the vasal blood supply (30). Veins from the vas drain into the pelvic venous plexus.

Innervation

The vasa deferentia are innervated by a rich autonomic plexus of primarily sympathetic fibers, which derives from the pelvic plexus. Sympathetic input is important in regulating vasal contraction during ejaculation. Cholinergic nerve fibers supplying the mammalian vas deferens have also been described, albeit lower in density that sympathetic fibers (31). The functional contribution of the cholinergic input to the vas deferens is not well understood at present.

Function

The primary function of the vas deferens is the transport of sperm from the epididymis to the urethra, although absorptive and secretory functions have also been described (32).

SEMINAL VESICLE AND EJACULATORY DUCT

Physical Examination

Palpation of the seminal vesicles provides important information for urologists, both when assessing their involvement in prostate cancer and when assessing for ejaculatory duct obstruction in men with azoospermia and low-volume ejaculate (<1.0 mL). Transrectal ultrasonography can also be used to assess for dilatation of the seminal vesicles, as well as other signs of ejaculatory duct obstruction, such as dilatation of the ejaculatory duct, calcifications within the duct, and the presence of midline cysts. When transrectal ultrasonography is suggestive of ejaculatory duct obstruction, vasography is the only option for confirming the presence of sperm in the vas, confirming the absence of epididymal obstruction, and determining whether or not the obstruction is resectable (Fig. 49.3). Vasography should only be performed at the time of possible reconstruction or transurethral resection of the ejaculatory duct(s).

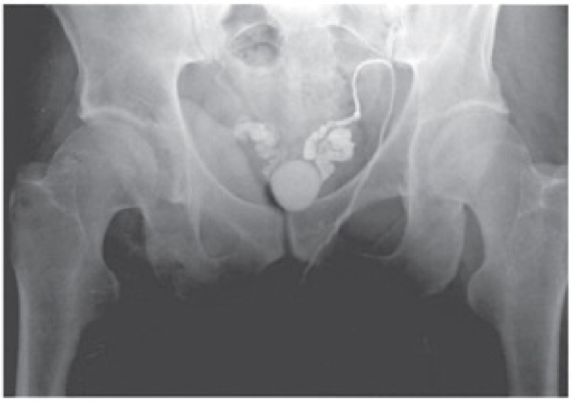

FIGURE 49.3 Intraoperative vasogram demonstrating contrast in the left vas deferens, seminal vesicle, and bladder, indicating patency of the left excurrent ductal system. Residual contrast is seen in the right seminal vesicle from previous performed right vasogram.

Development

The seminal vesicles develop from the caudal end of the wolffian or mesonephric ducts. This simple tube branches into a lobular structure during its development, organizing into a collection of ducts that drain into a principal excretory duct. In humans, the seminal vesicles are relatively undifferentiated during infancy and adolescence. Following puberty, under the action of circulating testosterone, their cuboidal epithelium is replaced by glandular epithelium, which is reflective of their secretory role and contribution to the composition of semen volume.

Anatomy

The seminal vesicles are paired glands positioned below the bladder and lateral to the vasa deferentia (Fig. 49.4). In adults, the seminal vesicle measures between 5 and 10 cm in length, and 3 and 5 cm in diameter, with an average volume capacity of 13 mL (33). In the majority of men, the right seminal vesicle is slightly larger than the left; however, the size of both glands decreases with age.

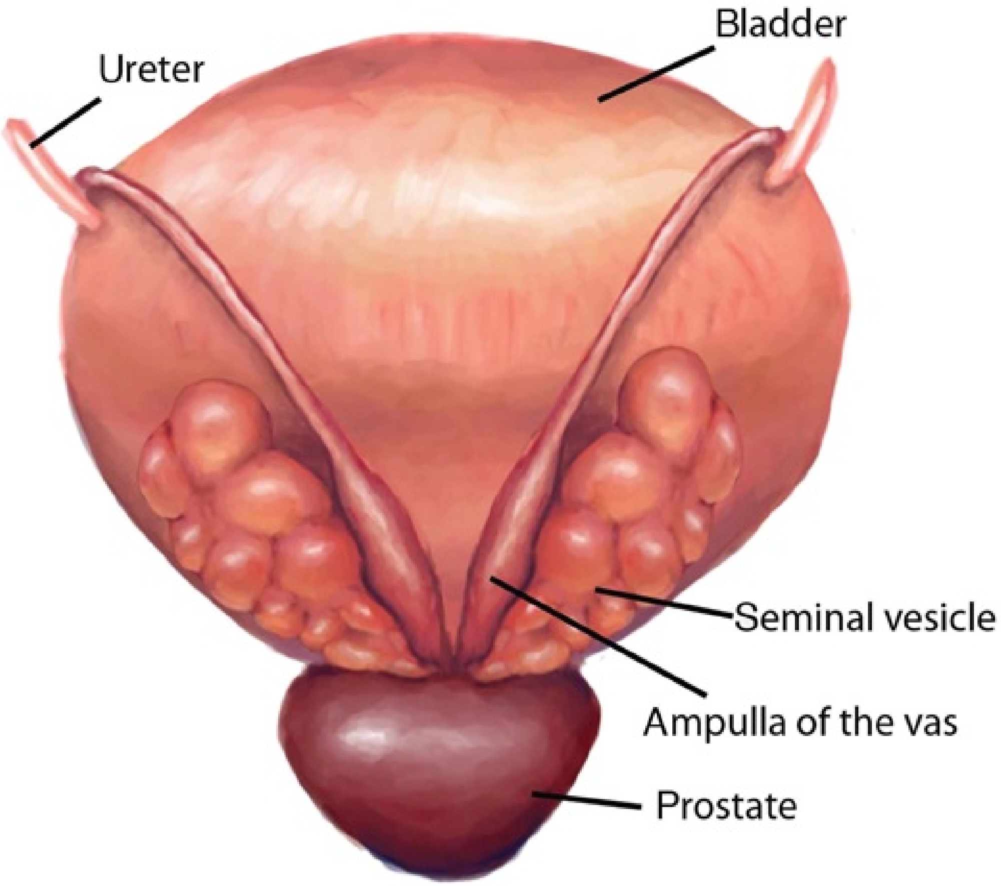

FIGURE 49.4 Posterior view of the bladder and seminal vesicles.

In essence, each seminal vesicle is a coiled tube with irregular diverticula, contained within a dense, fibromuscular sheath and partly covered by peritoneum. The wall of the seminal vesicle is composed of an external connective tissue layer, a middle smooth muscle layer (significantly thinner than the corresponding layer in the vas deferens), and an inner mucosal layer with a highly folded, labyrinthine structure. The mucosal layer is lined by cuboidal to pseudostratified columnar epithelium, featuring typical protein-secreting cells.

The upper pole of the seminal vesicle is a cul-de-sac, whereas the lower pole narrows to a straight duct, which, along with the vas deferens, culminates as the ejaculatory duct. The seminal vesicles are intimately associated with the prostate and bladder anteriorly, the distal ureter superiorly, and the rectum and Denonvilliers fascia posteriorly. The ampullae of the vas deferens lie along the medial margins of the seminal vesicles, whereas the veins of the prostatic venous plexus lie laterally.

The duct of the seminal vesicle unites with the ampulla of the ipsilateral vas, giving rise to the paired ejaculatory ducts. Each ejaculatory duct is approximately 2 cm in length and extends from the base of the prostate, between the median and lateral lobes, toward its opening on the verumontanum. The ducts diminish in size and converge toward their ends. Ejaculatory duct obstruction, although rare, can lead to oligospermia or azoospermia. Causes of ejaculatory duct obstruction include congenital cysts, such as müllerian duct cysts, chronic or acute severe prostatitis, or iatrogenic injury during urethral manipulation or even prostate biopsy.

In contrast to the walls of the vas and seminal vesicles, the walls of the ejaculatory ducts are thin. They contain an outer fibrous layer, which decreases in thickness upon their entry into the prostate, a thin layer of smooth muscle fibers arranged in an outer longitudinal and inner circular orientation, and a mucosa lined by columnar epithelium. The ducts dilate during ejaculation. Normal luminal and wall dimensions of the ejaculatory duct are remarkably uniform among men (34). A luminal diameter of greater than 2.3 mm defines a dilated or obstructed efferent duct (34).

Blood Supply

The primary blood supply to the seminal vesicles is from the vesiculodeferential artery, a branch of the umbilical artery (35). A second source of blood supply is the inferior vesical artery, which arises from the internal iliac (hypogastric) or the inferior gluteal artery. Venous drainage is provided by the vesiculodeferential veins and the inferior vesical plexus.

Innervation

The seminal vesicles receive parasympathetic input from the pelvic nerve and both sympathetic and parasympathetic input from the hypogastric nerve.

Function

The seminal vesicles produce a viscous white-yellow fluid, which contributes to at least two-thirds of the total ejaculate volume. The secreted fluid is rich in fructose, coagulation proteins, and prostaglandins, with a pH in the neutral to alkaline range. Seminal vesicle secretions play an important role in sperm motility and metabolism. Specifically, seminal plasma prevents sperm agglutination, promotes semen coagulation, stabilizes the sperm cytoplasmic membrane and sperm chromatin, and suppresses immune activity in the female reproductive tract (36). Contrary to what their name suggests, the seminal vesicles are not reservoirs for spermatozoa, except in cases of ejaculatory duct obstruction. They contract during ejaculation to release secretions into the ejaculatory duct.

ACCESSORY GLANDS

Prostate

Although an important organ of the male reproductive tract, the prostate is featured in its own chapters and will not be reviewed here.

Bulbourethral (Cowper) Glands

The bulbourethral glands, also known as Cowper glands, are small, round, yellow, lobulated structures, measuring approximately 1 cm in diameter. They lie lateral to the membranous urethra and superior to the perineal membrane (Fig. 49.5). They are drained by long excretory ducts, each duct being almost 3 cm in length, which pass obliquely and anteriorly from the region of the membranous urethra, penetrate the perineal membrane, and open on the floor of the bulbar urethra, approximately 2.5 cm below the perineal membrane (37).

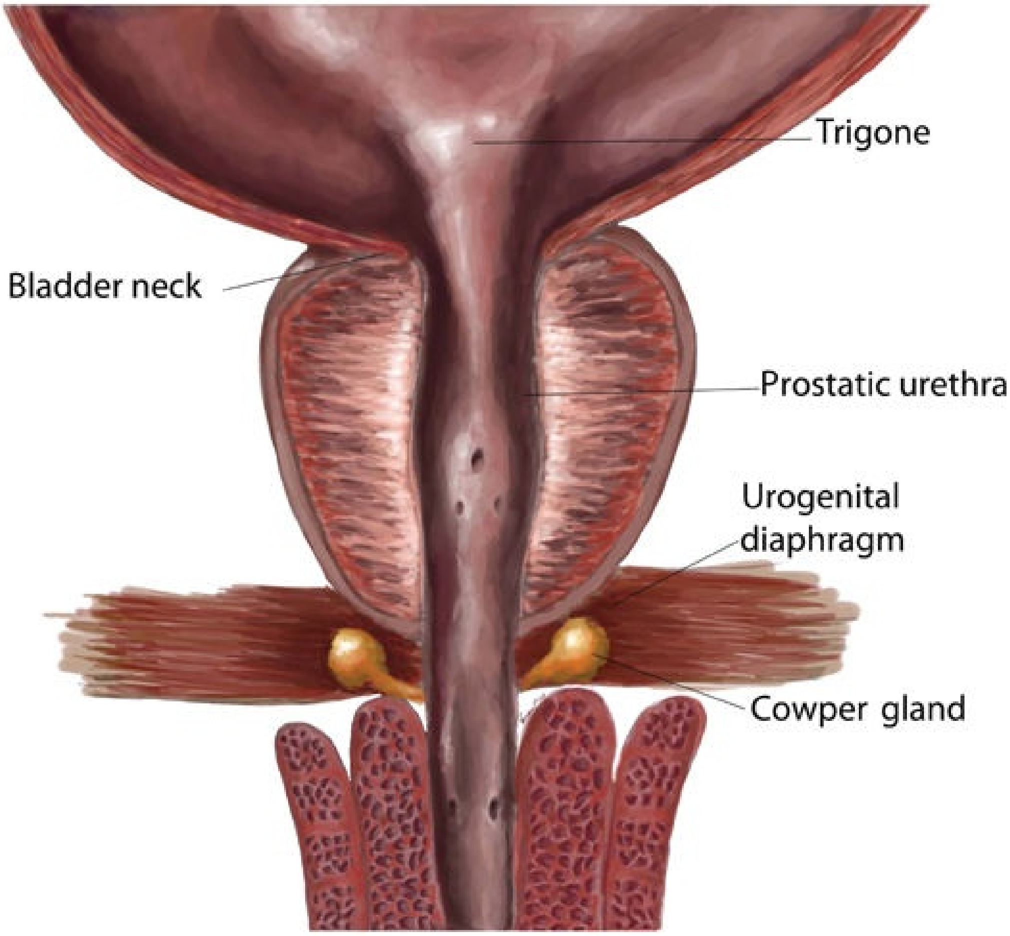

FIGURE 49.5 Anatomy of the urethra.

The glands themselves are surrounded by fibers of the sphincter muscle. During sexual excitement, contraction of the sphincter muscle fibers leads to expulsion of clear mucus from the glands into the bulbar urethra. Secretions of the bulbourethral glands comprise 5% to 10% of the total ejaculate volume.

Each bulbourethral gland consists of several lobules held together by a fibrous capsule. The secretory units are tubuloalveolar in form. The glandular epithelium is columnar and secretes acidic and neutral mucins into the urethra prior to ejaculation. These secretions primarily have a lubricating function. Diffuse mucosa-associated lymphoid tissue (MALT) is associated with the glands (37).

Blood supply to the bulbourethral glands derives from the artery of the bulb of the penis as well as the internal pudendal artery, the urethral artery, and the perineal artery. Primary innervation of the smooth muscle of the accessory glands consists of adrenergic fibers arising from the ipsilateral pelvic plexus.

Periurethral Glands

The periurethral glands, also known as the glands of Littre, are most numerous in the penile urethra. Like the bulbourethral glands, these secrete mucus into the lumen of the urethra prior to ejaculation. Their secretions, too, primarily have a lubricating function.

SUMMARY

The anatomic features of the epididymis, vas deferens, and seminal vesicle reflect their function in male reproductive physiology. An understanding of the anatomy of the excurrent ductal system facilitates the physical examination, diagnostic workup, and medical and surgical management of male fertility disorders.

CHAPTER 50 SEMINAL VESICLE AND EJACULATORY DUCT SURGERY

BROOKE A. HARNISCH AND JAY I. SANDLOW

SEMINAL VESICLE SURGERY

The seminal vesicles are paired male organs with no female homologue. They develop as a dorsolateral bulbous swelling of the distal mesonephric duct at approximately 12 fetal weeks. The seminal vesicle and the ampulla of the vas join posteriorly and superiorly to the prostate to form the ejaculatory duct at 13 weeks of life. The blood supply to the seminal vesicle is from the vesiculodeferential artery, a branch of the umbilical artery. Venous drainage is from the vesiculodeferential veins and the inferior vesical plexus. The seminal vesicles are innervated by the pelvic nerve and the hypogastric nerve. The hypogastric nerve sends both adrenergic and cholinergic fibers to the seminal vesicles. Lymphatic drainage is via the internal iliac nodes (1).

Primary pathology within the seminal vesicles is rare; secondary lesions are more common. In the past, insufficient imaging methods led to infrequent definition of either primary or secondary seminal vesicle pathology. The use of transrectal ultrasonography (TRUS), computerized tomography (CT), and magnetic resonance imaging (MRI) has improved diagnostic visibility and facilitated the diagnosis and treatment of seminal vesicle pathology. The necessity of surgical intervention is rare, but indications include congenital cysts with infection and/or obstruction causing infertility, ureteral ectopy into a seminal vesicle with resultant obstruction or dysplasia of the ipsilateral kidney, and primary tumors, either benign or malignant. Surgical access to the seminal vesicles is mostly via routes familiar to the urologic surgeon, but surgery on the seminal vesicles alone (without adjacent organ removal) is a unique challenge.

Diagnosis

The normal seminal vesicle on TRUS is an elongated, flat, paired structure between the rectum and the bladder just superior to the prostate and is typically not palpable on digital rectal examination. The diagnosis of seminal vesicle neoplasms can be difficult because they often do not cause symptoms until late in their course. General symptoms that may occur include urinary retention, dysuria, hematuria, or hematospermia. A mass is often palpable above the prostate and is usually not tender. TRUS is usually the next step in diagnosis and may be accompanied by needle aspiration or biopsy for diagnosis. CT or MRI would then be appropriate to stage the patient and may also be used to stage solid lesions within the pelvis as well as to confirm the hemorrhagic nature of suspicious masses. Because prostate cancer may be mistaken for primary seminal vesicle cancer, serum prostate-specific antigen (PSA), as well as tissue immunohistochemical stains for PSA, should, if positive, help define the prostate as the site of primary malignancy. In infertile patients who present with azoospermia, or in patients with hematospermia or coital pain, TRUS is the initial imaging study. Contrast vasography accurately images the vas deferens and ampullary–seminal vesicle junction but is less reliable than TRUS for seminal vesicle pathology.

Alternative Therapy

There are relatively few alternatives to treatment of seminal vesicle masses, unless they are infected. Antibiotics may be utilized in this case. Many of the benign masses are asymptomatic and may be observed. Ejaculatory duct obstruction can also be observed if fertility is not an issue or if the couple desires sperm acquisition with in vitro fertilization.

Indications for Surgery

Treatments of conditions of the seminal vesicles alone are limited to (a) transperineal/transvesical aspiration of seminal vesicle cysts or abscesses, (b) transurethral unroofing of seminal vesicle cysts or abscesses, (c) laparoscopic or robotic dissection, and (d) open resection of one or both seminal vesicles.

Most procedures performed on the seminal vesicles are related to radical surgery for the treatment of urethral, prostate, bladder, or rectal cancer. Treatments specific to the seminal vesicle include transrectal aspiration of cysts or abscesses, transurethral unroofing of abscesses and obstructing cysts, and open resection for refractory infections, to excise an ectopic ureter or to remove benign or malignant masses.

If a solid lesion identified in the seminal vesicle shows no evidence of local spread and is benign on biopsy, treatment is dependent on symptoms. If the patient is asymptomatic, close follow-up consisting of repeat rectal examination and TRUS to determine subsequent growth of the tumor is reasonable. If the mass enlarges or if the patient has symptoms referable to the mass, simple seminal vesiculectomy is advisable. This may be accomplished through one of several routes described in the following text. If the mass is quite large and solid and demonstrates questionable margins, or if the biopsy shows malignant cells, the treatment of choice is quite different. Because fewer than 10 cases of primary tumors of the seminal vesicles have been treated at any one institution, it is difficult to define optimal treatment with any degree of certainty. Radical excision, which usually includes a cystoprostatectomy with pelvic lymphadenectomy, is the treatment of choice unless the tumor is extremely small. This recommendation is based on the extensive nature of the majority of the cancers when detected. The excision may include the rectum (total pelvic exenteration) if it is thought to be invading the surrounding structures. Adjuvant therapy has no proven efficacy, although the only long-term survivors in the literature received radical surgery with subsequent pelvic radiation therapy or androgen deprivation therapy. No chemotherapeutic regimen is known to be efficacious (2–4).

Surgery

The most useful open surgical methods include transperineal, similar to radical perineal prostatectomy; transvesical, achieved by incising through the posterior bladder wall; paravesical; retrovesical; or transcoccygeal. Over the past decade, the laparoscopic or robotically assisted approaches to benign seminal vesicle lesions have been found to be remarkably direct and associated with much less postoperative morbidity than the open surgical approach (5). The choice of surgical approach, of course, depends partly on the characteristics of the lesion to be treated but probably more on the experience and expertise of the surgeon. For the most part, congenital lesions require an abdominal approach so that the ipsilateral kidney can be dealt with concomitantly, if necessary. Such lesions may be dealt with by laparoscopic or open surgical intervention. Benign lesions may be approached perineally; however, the risk of impotence is high even if a nerve-sparing approach is attempted. Larger benign tumors or cysts are best handled by an anterior abdominal approach, although a transcoccygeal method may be as useful. Again, the transperitoneal or retroperitoneal laparoscopic approach has great merit for such lesions. Patients with malignancy require radical extirpation, which commonly includes cystoprostatectomy, seminal vesiculectomy, and pelvic lymphadenectomy. This operation is no different from a routine procedure for bladder cancer and thus is not described here.

Preoperative Preparation

Preoperative preparation for laparoscopic, robotic, or open seminal vesicle surgery depends on the extent of the pathology and the planned incision. Transperineal, transcoccygeal, and transvesical approaches should be prefaced by a complete bowel preparation. Most surgeons use a mechanical preparation with GoLYTELY orally the evening before surgery, followed by the standard antibiotic bowel regimen. Some method to prevent phlebothrombosis in the legs, such as use of intermittent compression stockings during and immediately after surgery, is advisable.

Surgical Technique

A variety of surgical approaches to the seminal vesicles have been described, of which the most useful are the transvesical, transperineal, and laparoscopic.

Transvesical Approach

The transvesical approach to the seminal vesicle has been described by numerous authors (6). It is often used for large benign/cystic masses and cases where there is an ectopic ureter draining into the seminal vesicle. It allows for easy accessibility to the kidney, ureter, and bladder. A midline extraperitoneal suprapubic incision is made up to the umbilicus, and the rectus muscles are separated on the midline. The space of Retzius is opened by downward displacement of the transverse fascia on the pubis, and an Omni retractor is placed to expose the anterior bladder wall. Care is taken during this dissection not to injure the epigastric vessels on either side of the pubis. The bladder is opened longitudinally approximately 7 to 10 cm, ending 2 to 3 cm away from the bladder neck. Moist 4 × 8 sponges are placed on the bladder wall laterally and at the dome of the bladder, and specialized blades are placed to put the open bladder on stretch. Although it is not necessary, it is preferable to place long 8Fr feeding tubes in the ureters at this point to define the orifices and to help with identification of the subtrigonal ureters to prevent their injury later in the dissection. Using a Bovie cutting stylet, a vertical incision is made through the trigone on the posterior midline approximately 5 cm in length

(Fig. 50.1A). Alternatively, a transverse incision just above the bladder neck can be used, but it is not preferred. The vertical incision is deepened through the bladder muscle, and the ampullae of the vas should be recognized directly beneath the bladder neck. They can be dissected by scissors down to their entrance into the prostate and then either ligated and divided or left intact, depending on the pathology, as described in the perineal approach. Just lateral to the ampullae on the prostate base, the seminal vesicles should be identified and the plane surrounding them entered easily unless there has been prior inflammatory disease (Fig. 50.1B). The seminal vesicles should be encircled and dissected completely free. Metal clips should be placed on the vascular pedicle and a 2-0 chromic tie on the distal end at the prostate. A clip is placed across the proximal end of the vas to prevent seminal vesicle contents from obscuring the field, and then the vesicle is transected and removed. If there is a moderate-sized cyst, the dissection is more involved but is usually made simple because the perivesical plane is usually more pronounced. The plane may be very difficult to establish if there was prior vesiculitis, and in this instance, the ureteral catheters are a welcome safeguard—care must be taken not to dissect completely through Denonvilliers fascia posteriorly and into the rectum. The posterior bladder incision is then closed with a running 2-0 absorbable suture in the muscle layer, followed by a running 4-0 absorbable suture in the mucosal layer. The ureteral stents and 4 × 8 sponges are removed, a 20Fr urethral catheter is placed, and the anterior bladder wall is closed similarly to the posterior wall. Suprapubic tube placement is an option but is not necessary. A suction drain is placed through a separate stab incision and positioned in the prevesical space away from the suture line. The urethral catheter is typically removed in 5 to 7 days. This approach is more prone to blood loss and ureteral injury than the perineal approach, but a rectal laceration is much less likely.

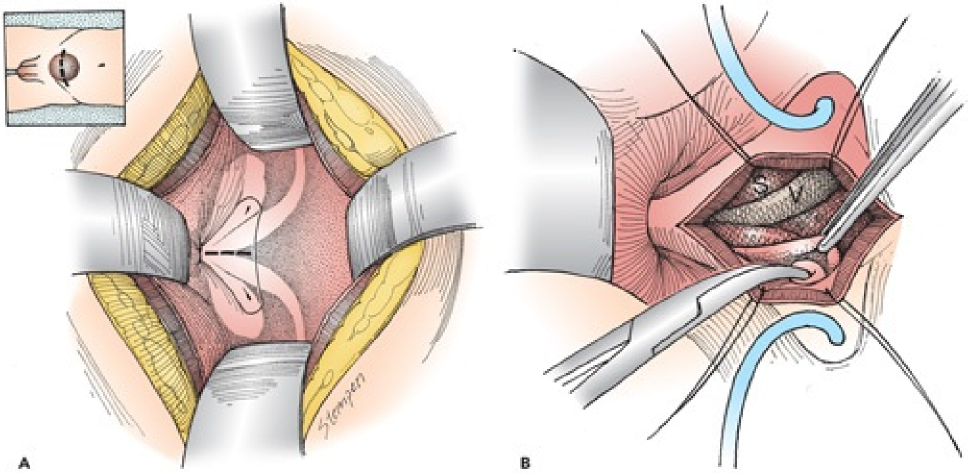

FIGURE 50.1 The transvesical approach to the seminal vesicle. A: Vertical incision in the trigone to expose the retrovesical seminal vesicle. *Inset*, line of incision. B: Dissection of the vas ampullae (*V*) and seminal vesicles (*S*).

Transperineal Approach

The transperineal approach to seminal vesiculectomy is virtually identical to radical perineal prostatectomy, described in Chapter 32. An exaggerated dorsal lithotomy position is used to elevate the perineum so that it is parallel to the floor. An inverted U incision is made in the perineum and the central tendon is divided (Fig. 50.2A). An anterior retractor stretches the rectal sphincter superiorly, allowing visualization of the glistening anterior rectal fascia fibers. The rectourethralis is divided near the prostatic apex and a weighted speculum is placed, dropping the tented rectum. To adequately expose the seminal vesicle, the rectum should be dissected off the posterior surface of the prostate to a point higher than that needed for perineal prostatectomy. Denonvilliers fascia is then incised transversely or in the midline (if nerve-sparing) on the prostate near the base of the seminal vesicles.

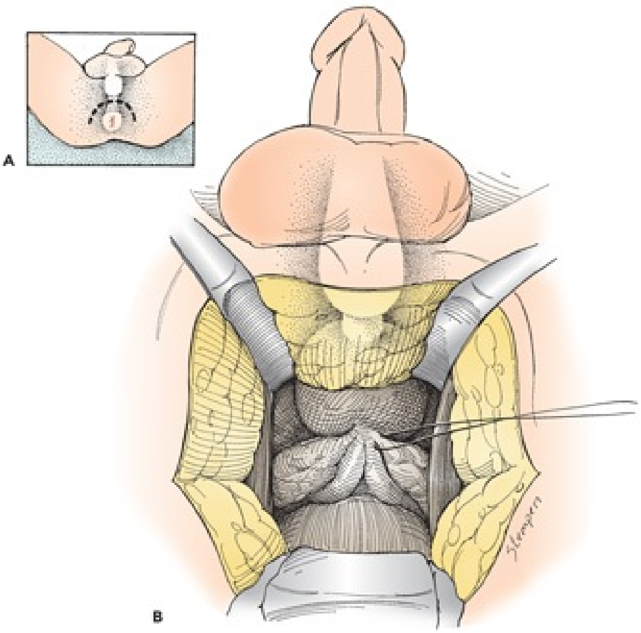

FIGURE 50.2 The transperineal approach. A: Inverted U-shaped incision in the perineum with takedown of the central tendon. B: Exposure and ligation of the seminal vesicles after incising Denonvilliers fascia.

Seminal vesicle dissection is facilitated by posterior traction on the prostate provided by placement of a Lowsley retractor in the bladder. Medially, the ampullae and seminal vesicles are apparent after Denonvilliers fascia is incised (Fig. 50.2B). The ampullae can be spared for the excision of a simple seminal vesicle cyst or small tumor but may need to be resected in the setting of cancer or infection. After dissection of the seminal vesicle at the prostatic base, an absorbable tie of 2-0 suture is used to ligate the gland (see Fig. 50.2B). Before division of the seminal vesicle, a clip is placed on the cut end of the organ to minimize spillage. An Allis or Babcock clamp is then placed on the freed base of the seminal vesicle to ease the apical dissection. The vascular pedicle at the apex of the gland is usually observed within 1 cm of the tip and is ligated with small metal clips, allowing gland removal. The wound is closed in layers as outlined for perineal prostatectomy. A Penrose drain is left in the area of dissection for 24 hours or until no drainage is noted. This approach is well tolerated, and patients are usually discharged within 24 to 48 hours of surgery.

Paravesical and Retrovesical Approaches

The paravesical incision is used in children, when there is a large unilateral cyst that lies lateral to and above the bladder and when nephroureterectomy is required. A midline or Pfannenstiel extraperitoneal suprapubic incision is made. The bladder is finger-dissected away from the lateral pelvic sidewall on the affected side. The vas deferens is identified, placed on tension, and dissected down toward the base of the bladder. If the seminal vesicle mass is distended, it should be visible rather quickly as the vas comes close to the bladder posteriorly. Placing a catheter in the bladder and emptying it usually allows the plane between the bladder and the cyst to be readily identified. The plane is incised with scissors, and the seminal vesicle cyst is carefully dissected away sharply. When the tip of the cyst is clearly identified, a 1-0 chromic suture is placed into it to provide traction, making further dissection easier. As the dissection proceeds, it must be remembered that the ureter crosses the vas and must be identified to prevent its injury. In addition, the superior vesicle artery and perhaps the inferior vesicle artery may be sacrificed to gain access to the base of the seminal vesicle. This will cause no harm and should be done without major concern. As the dissection proceeds, the bladder is progressively rolled over medially, and the mass is dissected away from the bladder laterally. The plane is easily maintained with sharp dissection. Any vessels feeding the seminal vesicles should be suture-ligated or metal-clipped. As the prostate is approached, caution must be used to stay directly on the mass so as not to injure the neurovascular bundle lying just lateral to the seminal vesicle. At the prostate base, the neck of the seminal vesicle is encircled and ligated with a 2-0 absorbable suture. A clamp is placed across just distal to the tie, and the seminal vesicle is severed. There may be no need to clip the vas. A suction drain is placed in the bed of the seminal vesicle and brought out through a separate stab incision. The wound is then closed in layers. Postoperative care is as previously described, except with this approach, the drain can be removed within 24 hours if there is no drainage, and the urethral catheter can be removed within 24 hours. The patient may be discharged within 2 to 3 days. Complications include ureteral injury and excessive blood loss. If the principles outlined earlier are followed, these are unlikely events.

The retrovesical approach should be considered in patients requiring bilateral excision of small seminal vesicle cysts or benign masses (7). A midline suprapubic incision is made into the peritoneal space (Fig. 50.3A). A catheter is placed, and the urine is evacuated. The reflection of the peritoneum over the rectum at the posterior bladder wall is incised transversely, with care taken not to incise into the rectum (Fig. 50.3B). The bladder is peeled back from the rectum progressively with sharp dissection until the ampullae of the vasa and the tips of the seminal vesicles come into view (Fig. 50.3C). The seminal vesicles are dissected down to the base of the prostate, much as described in the transvesical approach, and the neck of the seminal vesicle is ligated and divided bilaterally. The ampullae are usually not taken unless necessary. A suction drain is left in the area posterior to the bladder and brought out as before. Postoperative care is as per the description for a paravesical resection. Complications include rectal injury, bladder laceration, and hemorrhage. In this situation, a rectal injury would be within the peritoneum well above the levator ani muscles. After a two-layer closure as before, strong consideration should be given to placement of omentum over the closure between the bladder base and the rectum as well as to a temporary colostomy.

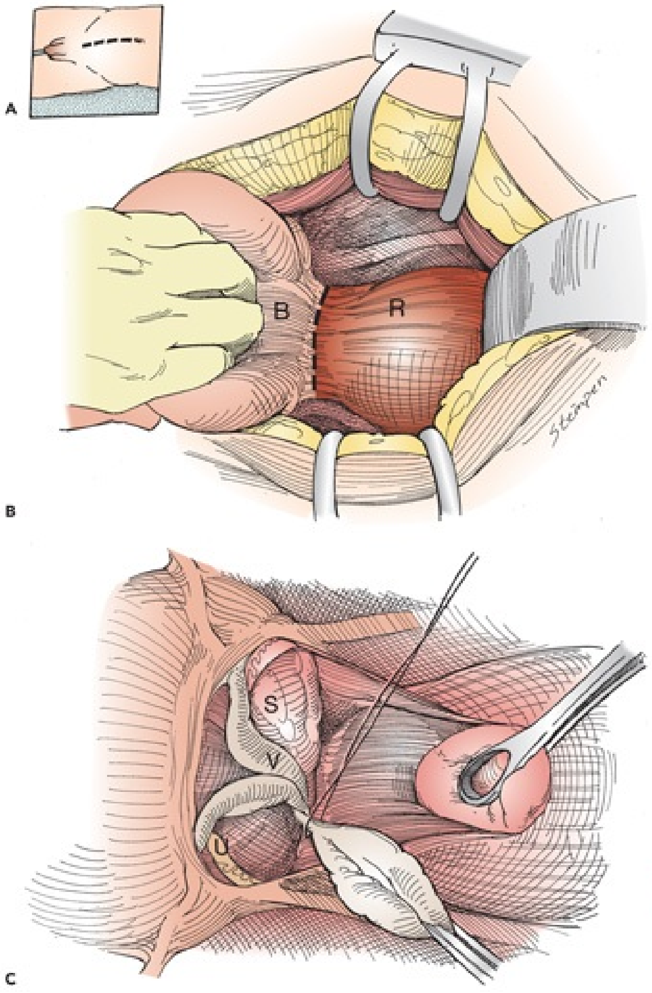

FIGURE 50.3 The retrovesical approach. A: Midline infraumbilical incision (*broken line*). B: Incision of the posterior peritoneum over the rectum (*R*) in the cul-de-sac. *B*, bowel. C: Exposure of the vas ampulla (*V*) and seminal vesicle (*S*) behind the bladder. *U*, ureter.

Transcoccygeal Approach

The transcoccygeal approach may not be familiar to most urologic surgeons and is unlikely to be a common choice owing to fear of rectal injury and impotence. In individuals for whom the perineal or supine position may be difficult to maintain, or who have had multiple suprapubic or perineal surgeries, the transcoccygeal approach may be very useful. The patient is placed on the table, ventral side down (prone), and in a relative jackknife position (8,9). The incision is made in an L shape from midway on the sacrum (10 cm from the tip of the coccyx) and angled at the tip of the coccyx down the gluteal cleft within 3 cm of the anus (Fig. 50.4A). The incision is carried down to the lateral side of the coccyx, which is dissected free from the underlying rectum and eventually totally removed. The gluteus maximus muscle layers are moved aside, and the rectosigmoid is encountered and dissected carefully from the underside of the sacrum. With careful dissection, the lateral wall of the rectum on the side of the lesion is dissected medially from the levator ani muscle and surrounding tissue until the prostate is encountered. It is possible that the neurovascular bundle will be recognized from this approach. Once the prostate is palpated, dissection of the tissue directly superior to the base on the midline should reveal the ampulla of the vas and, lateral to it, the seminal vesicle (Fig. 50.4B). If difficulty dissecting the rectum away from the prostate is encountered, a finger in the anus via an O’Connor sheath will allow the correct plane to be determined. Dissection and removal of the seminal vesicles should follow the principles outlined previously. A Penrose drain should be left in the area, exiting through a separate stab incision at closure. The rectum should be carefully scrutinized for injury; if any injury is found, it is closed in two layers. The wound is closed in layers as well. Postoperative care does not differ from that previously described; similar to the perineal approach, the patient should have a rapid and easy recovery. The drain should be removed within 2 to 3 days if there is no drainage.

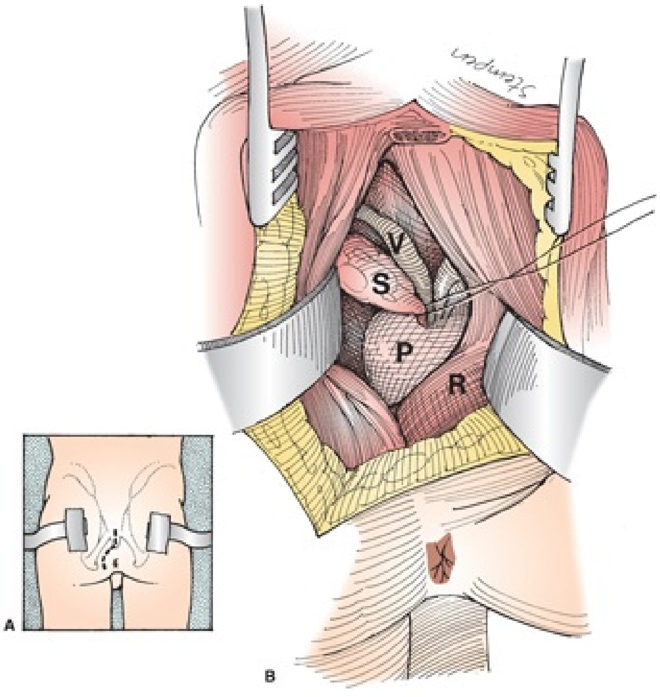

FIGURE 50.4 The transcoccygeal approach. **A:** The incision (*broken line*) is made over the coccyx and curved along the gluteal cleft. **B:** Denonvilliers fascia is incised deep to the rectum (*R*) to expose the prostate (*P*) and seminal vesicles (*S*). *V*, vas ampulla.

Laparoscopic Technique

Most laparoscopic surgery performed on the seminal vesicles has been in conjunction with radical prostatectomy, which was first described by Kavoussi et al. (10). It is known that dissection of the ampulla of the vas and seminal vesicles is a challenging part of a perineal prostatectomy, and thus, prior mobilization of these structures made this easier. Its application for benign seminal vesicle pathology is limited to case reports or small series (6).

Patients are placed supine with the arms carefully padded and tucked in by the sides. Access to the perineum is usually not necessary for benign seminal vesicle pathology, whereas if a laparoscopic or robotic prostatectomy will be performed in addition, the legs are abducted but left straight with the use of an operating table that allows a split-leg arrangement. If possible, the low lithotomy position is avoided so as to minimize the risk of lower extremity thrombosis or neuromuscular injury. Patients are carefully strapped to the operating table with wide cloth tape across the chest and thighs as steep Trendelenburg (approximately 20 degrees) is required for deep pelvic laparoscopic visualization. After the patient is prepared and draped, a Foley catheter is inserted into the bladder under sterile conditions. An orogastric tube placed in the stomach is optional.

A transperitoneal approach is preferred for benign seminal vesicle lesions. After establishing a suitable pneumoperitoneum up to 15 mm Hg with the Veress needle placed at the inferior or superior umbilical crease, four laparoscopic ports are usually adequate for seminal vesicle benign pathology excision. These ports, varying from 5 to 12 mm in size, may be placed in a diamond shape (Fig. 50.5) or a horseshoe shape. With the patient in steep Trendelenburg, the peritoneum just anterior to the rectum in the rectovesical pouch (pouch of Douglas) is incised transversely between the two obliterated umbilical ligaments. Large seminal vesicle cysts are usually easily visualized, and the dissection is carried close to the seminal vesicles so as to avoid injury to surrounding viscera and the neurovascular bundle. Use of bipolar coagulation is highly recommended over monopolar energy so as to minimize injury to these surrounding structures. The dissection can be completed using laparoscopic scissors and curved graspers using blunt and sharp dissection. The main arterial branch to the tip of the seminal vesicle is easily handled with bipolar coagulation, but a laparoscopic clip is also a good choice. The seminal vesicle should be dissected caudally down to its juncture with the ampulla of vas and then clipped en bloc. With completion of the dissection, the specimen is placed in an entrapment device (LapSac, Cook Urological Inc, Spencer, Indiana) or an Endo Catch bag (U.S. Surgical, Tyco Healthcare, Norwalk, Connecticut) and extracted through one of the larger laparoscopic ports. Large cysts may be aspirated prior to extraction so as to minimize the specimen size and obviate the need for enlarging the incision. Hemostasis and surrounding visceral integrity are assured and then the laparoscopic ports are closed in the usual fashion.

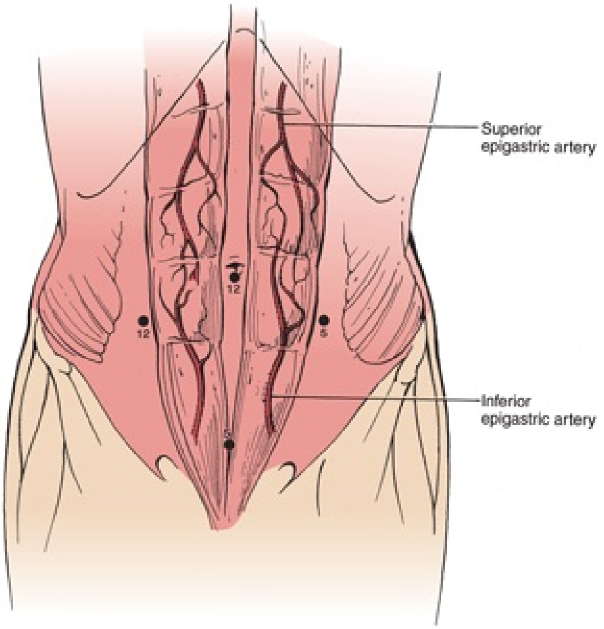

FIGURE 50.5 Optimal sites (*black spots*) of access for transabdominal laparoscopic seminal vesicle excision. Numbers represent trocar size in millimeters.

Laparoscopic/robotic approach to the seminal vesicles can also be approached in an extraperitoneal fashion. This technique was first described in the setting of radical prostatectomy. Despite being technically challenging, this method is often used in obese patients and those with prior abdominal surgeries. Patient positioning is similar to transperitoneal approach. However, a 1.5-cm paraumbilical incision is made and blunt dissection of the rectus muscle is completed, allowing for the initial preperitoneal space to be developed. A balloon trocar is then introduced and the preperitoneal space is further dilated under direct vision. A 15-mm trocar is inserted at the level of the umbilicus. Insufflation of the extraperitoneal space is achieved. The remaining trocars are placed similar to the description earlier. Seminal vesicle dissection takes place after the bladder neck dissection. The bladder neck is retracted cephalad, exposing the anterior layer of Denonvilliers fascia. A small incision is made at this layer approximately 5 cm from the base of the prostate. The ampulla of the vas deferens and seminal vesicles are then visualized, and dissection is initiated (11). In select cases, a concomitant ipsilateral nephroureterectomy may be required should an atrophic kidney have an ectopic ureter draining into the seminal vesicle. It is recommended that the laparoscopic nephroureterectomy be performed prior to the seminal vesicle dissection. Thus, the patient would begin the procedure in a modified lateral decubitus position and then the operating table would be rotated so as to bring the patient into a relative supine and Trendelenburg direction. The operative details of laparoscopic nephrectomy for benign disease are described in Chapter 124.

Laparoscopic robotic assistance for surgery of the seminal vesicles has usually been performed in conjunction with radical prostatectomy. This technique, with respect to port placement and approach, is almost identical to the standard laparoscopic route described (12).

Laparoendoscopic single-site surgery (LESS) is another minimally invasive technique that has been used for many urologic procedures. Recently, Jang et al. (13) used this approach to excise a seminal vesicle cyst. For LESS, the patient is positioned similarly to laparoscopic/robotic approaches discussed earlier. A 3-cm skin incision is made at the umbilicus. A multichannel trocar with three 12-mm ports and one 5-mm port is inserted under direct visualization. Pneumoperitoneum is established. A rigid 30-degree, 10-mm laparoscope; articulating laparoscopic instruments, including a dissector, monopolar hook, scissors, and needle holder; and standard straight working instruments are used. Incision in the retrovesical peritoneum allows for seminal vesicle cyst visualization. Dissection of the vas from lateral to medial allows for full exposure of cyst. The seminal vesicle cyst is then drained by aspiration followed by circumferential dissection. After the base is exposed, LigaSure vessel sealing system (Valleylab, Boulder, Colorado) is used to seal the neck of the cyst. The peritoneum is sutured closed (13,14).

Although the transperitoneal laparoscopic/robotic approach to the seminal vesicles offers improved visualization to the seminal vesicles, the latter’s close proximity to bladder, rectum, ureter, and neurovascular bundle must be appreciated by the surgeon. Transperitoneal incision in the pouch of Douglas, which is too anterior, may lead to perforation of the posterior bladder wall. Subtle hints that the surgeon may be dissecting too anterior would be the appearance of the detrusor musculature, which is quite vascular and tends to bleed easily. Should a hole be made in the bladder, it can be repaired laparoscopically or robotically without undue difficulty.

Similarly, the rectal wall may be incised at any point in the seminal vesicle mobilization. Assuming the patient has received a satisfactory bowel preparation, such rectal lacerations may be laparoscopically or robotically repaired in two layers. The anal sphincter is dilated at the termination of the procedure and the patient’s diet is advanced slowly. Electrocautery must be used judiciously when in close proximity to the rectum. Use of precise bipolar coagulation is recommended.

The distal ureter runs close to the tip of the seminal vesicle. Any tubular structure that is lateral to the seminal vesicle may be the vas arching upward toward the internal ring, but it also could be the ureter. The surgeon may easily become disoriented to which ampulla of the vas is being dissected, leading to the dissection shifting too far lateral and possibly injuring or transecting the ureter. Injection of intravenous methylene blue quickly confirms the ureteral injury. Should this unfortunate complication occur, the ureter could possibly be repaired by laparoscopic or robotic suturing.

However, an ureterovesical reimplantation may be required and necessitate open surgical conversion. Placement of a double-J ureteral stent following repair is wise, and a pelvic drain is strongly advised in the presence of any bladder, rectal, or ureteral injury that may have occurred during the course of laparoscopic or robotic seminal vesicle dissection.

Finally, the neurovascular bundle is just lateral to the tips of the seminal vesicles. Injury to this structure will impair erectile function and create a serious problem, especially to the potent patient who may be undergoing seminal vesicle excision for benign disease.

Although data are limited for laparoscopic and robotic excision of benign seminal vesicle pathology alone, this approach appears to afford superb visualization with minimal postoperative morbidity and shorter hospitalization compared to the open surgical alternatives (5). In most cases, the seminal vesicle is excised laparoscopically or robotically in conjunction with radical prostatectomy or cystoprostatectomy.

Endoscopic Treatment

Transurethral Resection. If the cyst or abscess is adjacent to the prostate (not in the middle or distal end of the seminal vesicle), it may be possible to unroof the cavity with a deep transurethral resection into the prostatic substance, just distal to the bladder neck at the 5 or 7 o’clock position. However, urinary reflux, with resultant postvoid dribbling, and infection are potential complications (15). Previous reports have detailed endoscopic treatment of seminal vesicle abscesses using semirigid ureteroscopes as well as drainage of a seminal vesicle cyst cystoscopically with an incision using a Collins knife (1).

Outcomes

Results

Resection of the seminal vesicles for cystic and inflammatory diseases is in general successful, although large case series are rare. Seminal vesicle extirpation for cancer has also been successful, but the rarity of this indication prohibits an accurate assessment of survival and cure rates. Strict categorization of the 100 reported cases of primary seminal vesicle cancer reveals that fewer than 50% are truly primary to the seminal vesicle (16).

Complications

Each approach to seminal vesicle surgery is associated with unique complications. The relative complication rates with these approaches are outlined in Table 50.1. Limited extraperitoneal rectal injuries can be handled with formal two-layer closure. Rectal injury with the retrovesical approach is intra-abdominal, however, and may require the placement of omentum over the repair or even temporary colostomy. Most bladder injuries can be closed primarily. The most important point about ureteral injuries is their recognition. Most ureteral injuries can be treated adequately with stents for 7 to 10 days.

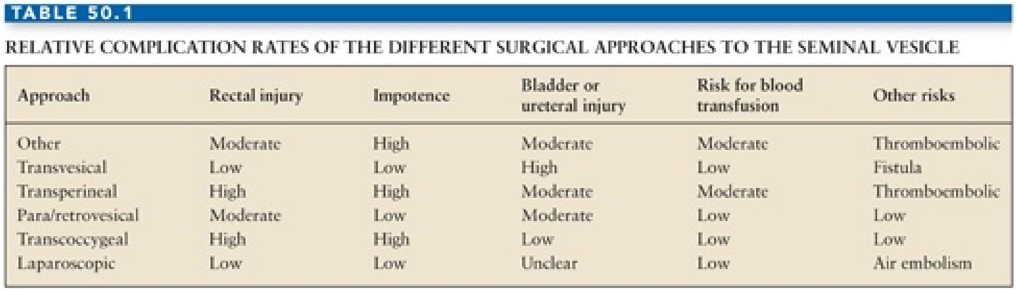

TABLE 50.1

RELATIVE COMPLICATION RATES OF THE DIFFERENT SURGICAL APPROACHES TO THE SEMINAL VESICLE

Approach	Rectal injury	Impotence	Bladder or ureteral injury	Risk for blood transfusion	Other risks
Other	Moderate	High	Moderate	Moderate	Thromboembolic
Transvesical	Low	Low	High	Low	Fistula
Transperineal	High	High	Moderate	Moderate	Thromboembolic
Para/retrovesical	Moderate	Low	Moderate	Low	Low
Transcoccygeal	High	High	Low	Low	Low
Laparoscopic	Low	Low	Unclear	Low	Air embolism

EJACULATORY DUCT SURGERY

The ejaculatory ducts are paired, collagenous, tubular structures that commence at the junction of the vas deferens and seminal vesicle, course through the prostate, and empty into the prostatic urethra at the verumontanum. There are three distinct anatomic regions to the ejaculatory duct: the proximal and largely extraprostatic portion, the middle intraprostatic segment, and a distal segment that is incorporated into the lateral aspect of the verumontanum in the prostatic urethra (17).

The duct consists of three histologic layers: an outer muscular layer, a collagenous middle layer, and an inner mucosal layer (18). The muscular layer is absent in the distal segment.

Indications for Surgery

Patients with ejaculatory duct obstruction sufficient to cause coital discomfort, recurrent hematospermia, or infertility should be considered candidates for transurethral treatment. Infertility with duct obstruction can present with low ejaculate volume and azoospermia or low ejaculate volume with decreased sperm density ($<20 \times 10^6$ sperm per Ml) or impaired sperm motility (<30% motility). Anatomic findings suggestive of obstruction and lesions located within approximately 1 to 1.5 cm of the verumontanum are usually amenable to transurethral management.

Diagnosis

Ejaculatory duct obstruction causes infertility in 5% of azoospermia cases. Duct obstruction can result from seminal vesicle calculi, müllerian duct (utricular) or wolffian duct (diverticular) cysts, postsurgical or postinflammatory scar tissue, calcification near the verumontanum, or congenital atresia (15). Classically, this condition presents as hematospermia, painful ejaculation, or infertility with azoospermia. Associated risk factors include evidence of prior urinary tract infection or trauma and perineal pain or discomfort. It is important to discontinue medications that may impair ejaculation. An abbreviated list of these medications is found in Table 50.2. Ejaculatory duct obstruction is suggested by finding enlarged, palpable seminal vesicles on rectal examination. The diagnosis is confirmed by a combination of findings:

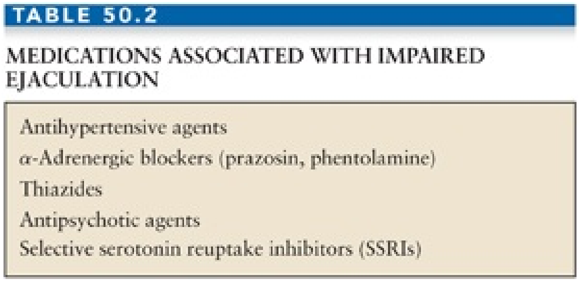

TABLE 50.2

MEDICATIONS ASSOCIATED WITH IMPAIRED EJACULATION

Antihypertensive agents
α-Adrenergic blockers (prazosin, phentolamine)
Thiazides
Antipsychotic agents
Selective serotonin reuptake inhibitors (SSRIs)

1. An ejaculate volume <1.0 mL and a pH <7.0 that contains no sperm or fructose (in the presence of palpable vas deferens)
2. A TRUS demonstration of dilated seminal vesicles (>1.5 cm in width) or dilated ejaculatory ducts (>2.3 mm) in association with a cyst, calcification, or stones along the duct

Recently, high-resolution TRUS has virtually replaced the more invasive vasography for this diagnosis. MRI with endorectal coil is recommended in suspicious cases without TRUS findings as it is excellent for the detection of small cysts. To complete the evaluation for infertility, it is important that the serum follicle-stimulating hormone (FSH) and testosterone levels be normal. Testicular volume should also be normal. A testis biopsy confirming ongoing sperm production may be helpful but is not always necessary.

Not all patients with ejaculatory duct obstruction have dilated seminal vesicles, and not all patients with dilated seminal vesicles have ejaculatory duct obstruction. This has led to refinements in diagnostic techniques. Jarow (17) found that seminal vesicle sperm aspiration with TRUS more accurately defined affected patients. Additionally, Engin et al. (19) reported that 55 (78.6%) patients had findings consistent with ejaculatory duct obstruction on diagnostic TRUS. However, obstruction confirmed by presence of sperm on aspiration was only found in 49.1% (27 of 55) of the patients, emphasizing that TRUS alone is not a reliable tool to diagnose ejaculatory duct obstruction (19). With a 30-cm, 21-gauge needle (Williams, Chiba, or oocyte retrieval needle), the seminal vesicles are aspirated transrectally or transperineally during TRUS (Fig. 50.6A). The aspirate is then examined under 400× phase microscopy for sperm. The finding of more than three sperm per high-power field is considered positive and suggestive of obstruction. Importantly, the duration of sexual abstinence prior to aspiration can influence the findings. Seminal vesicle aspiration should be performed with <24 hours of sexual abstinence. Despite the fact that aspiration does not anatomically localize the site of blockage or differentiate between physical blockage and functional obstruction, it confirms that spermatogenesis is ongoing and that epididymal obstruction is unlikely.

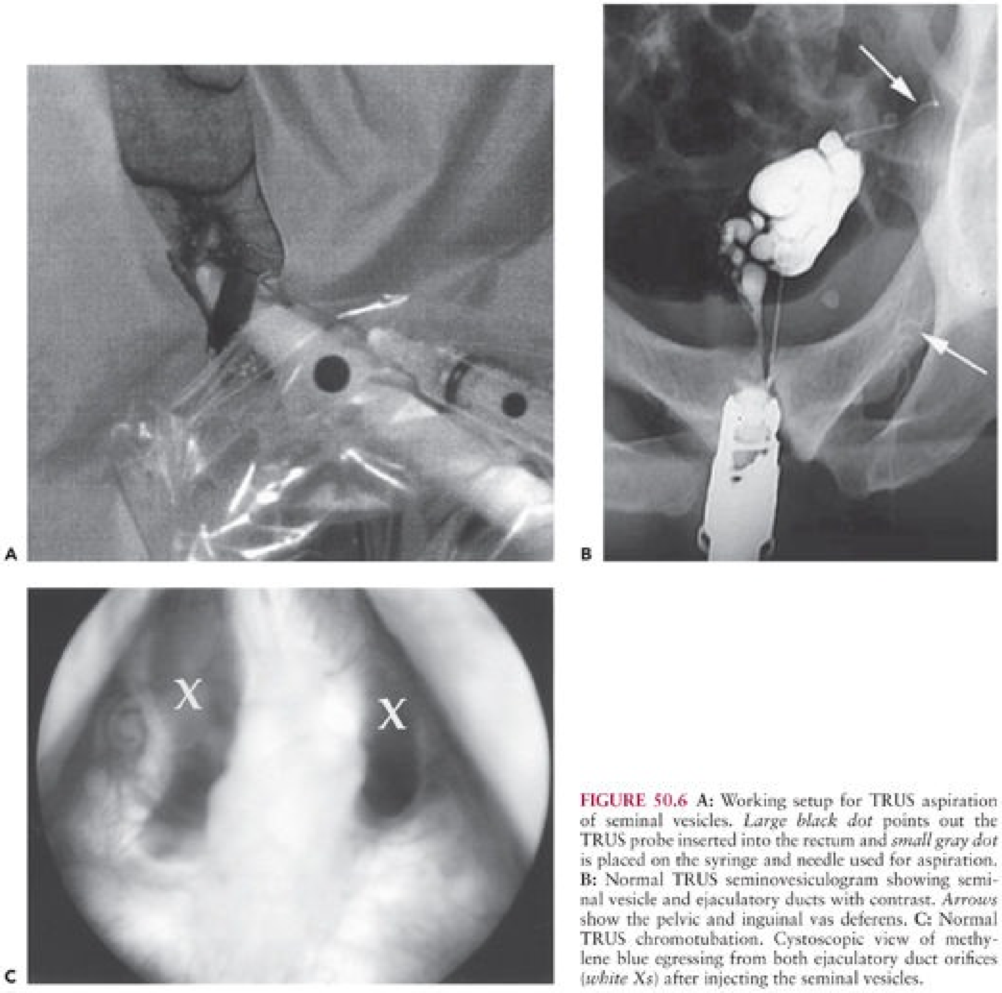

FIGURE 50.6 A: Working setup for TRUS aspiration of seminal vesicles. *Large black dot* points out the TRUS probe inserted into the rectum and *small gray dot* is placed on the syringe and needle used for aspiration. B: Normal TRUS seminovesiculogram showing seminal vesicle and ejaculatory ducts with contrast. *Arrows* show the pelvic and inguinal vas deferens. C: Normal TRUS chromotubation. Cystoscopic view of methylene blue egressing from both ejaculatory duct orifices (*white Xs*) after injecting the seminal vesicles.

Injection of nonionic contrast (50% Renografin) into the seminal vesicles after seminal vesicle aspiration, followed by formal radiographic imaging, can be a useful retrograde study of seminal vesicle and vasal anatomy in suspected obstruction (Fig. 50.6B). Also, a good-quality pelvic and inguinal vasogram can be obtained in most patients (see Fig. 50.6B). Fluoroscopy or a kidney-ureter-bladder (KUB) plain film is taken after the injection of 5, 10, and 20 mL of contrast to delineate excurrent duct anatomy. Helpful maneuvers include (a) having the patient in the 15- to 30-degree reverse Trendelenburg position for radiographs to “open up” the pelvic outlet and minimize overlying pelvic bone density and (b) placing a Foley catheter with 5 mL of water in the balloon on slight traction during contrast injection to reduce the spillage of contrast into the bladder that “clouds” the radiograph. As seminal vesiculography is more invasive than simple aspiration, it may require mild intravenous sedation and is best performed at the time of transurethral surgery.

Injection of diluted indigo carmine or methylene blue (1:5 dilution with saline) into the seminal vesicle with TRUS instead of contrast is termed *seminal vesicle chromotubation*. When performed with cystoscopy, it can assess whether or not there is antegrade flow of dye from the seminal vesicle into the prostatic urethra (Fig. 50.6C). In fact, “patency,” with chromotubation, defined by the presence of dye egressing from the ejaculatory duct orifices after seminal vesicle injection, may be the most accurate way to diagnose complete ejaculatory duct obstruction, unilateral, or bilateral (20).

Surgical Technique

Transurethral resection of the ejaculatory ducts (TURED) is performed in the outpatient setting. Following the administration of light general or regional anesthesia and a single dose of a broad-spectrum antibiotic, the patient is placed in the dorsal lithotomy position with a rectal drape

(O’Connor). Formal cystourethroscopy is performed. Careful examination is made of the areas lateral to the verumontanum within the prostatic urethra to visualize either ejaculatory duct orifice. A small resectoscope (24Fr) and electrocautery loop are inserted and the verumontanum is resected in the midline (Fig. 50.7). The resection is performed with pure cutting current to minimize cauterization of the delicate ejaculatory ducts. Often, several passes of the cutting loop are required to visualize the ejaculatory duct openings within the prostate. This can mean relatively deep dissection in a small prostate gland, a situation that can make even an experienced transurethral surgeon feel uneasy. At the correct level of resection, cloudy, milky fluid can usually be seen effluxing from the opened ducts. After resection, large bleeding blood vessels are lightly cauterized, with care taken to avoid fulguration of the duct openings. Because the area of resection is at the prostatic apex, near both the external urethral sphincter and the rectum, careful and constant positioning of the resectoscope is essential. A finger placed in the rectum can help avoid rectal injuries and assist in keeping the resectoscope tip proximal to the external sphincter. A small Foley catheter is placed for 24 to 48 hours and removed on an outpatient basis. Oral antibiotics are given while the catheter is in place. After such treatment for infertility, intercourse is resumed after 7 days, and a formal semen analysis is checked as early as 2 weeks and then at regular intervals thereafter, until semen quality stabilizes.

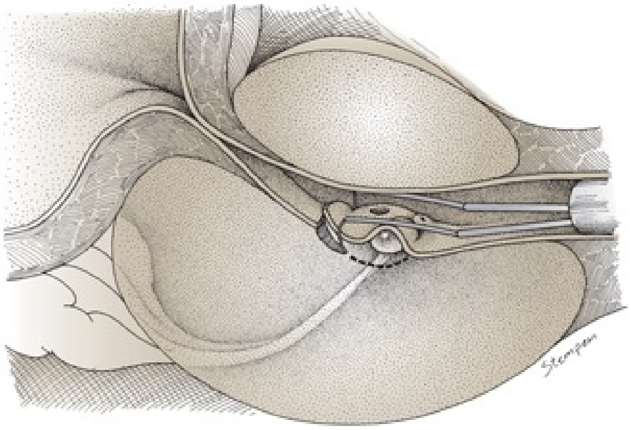

FIGURE 50.7 Transurethral resection for ejaculatory duct obstruction. Midline resection of the verumontanum is shown. Lateral and deeper resection may be necessary depending on the site and reason for duct obstruction. (Conceptualized by Paul Stempen.)

Several useful aids can ensure that the resection is performed safely and completely. With an endoscopic needle, the milky ejaculatory duct fluid can be sampled transurethrally during the procedure and inspected with microscopy for sperm. The use of simultaneous, real-time TRUS during the resection is a valuable addition to this procedure. The exact location of the lesion to be resected can be determined by TRUS and the depth of resection continuously assessed during the resection. Similarly, TRUS can be used to guide the instillation of indigo carmine or methylene blue into the seminal vesicles with a long, 20-gauge Chiba needle before the resection. The dye is subsequently visualized on relief of obstruction.

More recently, transurethral endoscopy and vesiculoscopy have been used to both diagnose and treat hematospermia and ejaculatory duct obstruction. This procedure is completed by passing a 6Fr or 7Fr ureteroscope retrograde through the orifice of the verumontanum over a 0.032 guidewire. The ejaculatory duct orifices are then visualized and the membrane covering the orifices is punctured with a guidewire. The ureteroscope is passed into the seminal vesicles. After this procedure, levofloxacin wash is directly injected into the seminal vesicles, and a Foley catheter is left for 24 hours (21,22).

Results

Long-term relief of postcoital and perineal pain after TURED can be expected in 60% of patients (22). Hematospermia has also been effectively treated with TURED, but the literature on this indication remains anecdotal. There is convincing evidence from several large series of patients treated for infertility that a 20% to 30% pregnancy rate can be expected from TURED (23,24). In one series, men treated for either low-volume azoospermia or low-volume oligoasthenospermia were equally likely (65% to 70%) to show improvements in semen quality after TURED (24). However, it appears that partial versus complete obstruction shows better improvement in semen parameters (100% versus 23.5%) (25). In one series, obstruction due to cysts responds better to TURED than that due to calcification (26).

Several caveats of TURED surgery should be emphasized to the patient preoperatively. Roughly, 13% of men treated by TURED for low-volume azoospermia will convert to normal-volume azoospermia. Among these patients, some have evidence of secondary obstruction at the level of the epididymis that requires epididymovasostomy. Epididymal obstruction may reflect the effects of time and blockage on other portions of the delicate male ductal system. Notably, 4% of patients treated for low-volume oligoasthenospermia may become azoospermic after TURED, presumably from scar tissue formation. We now recommend preoperative sperm cryopreservation if TURED is planned for this indication.

Regarding endoscopic therapy, there are limited studies. Liu et al. (20) studied 72 patients who underwent transurethral seminal vesiculoscopy for hematospermia. Symptomatic improvement occurred in 97% of these men. Furthermore, Wang and colleagues (21) completed seminal vesiculoscopy using a 6Fr endoscope in 21 patients with erectile dysfunction and infertility. Sperm was found in the ejaculate in 85% of patients. However, pregnancy rates were not reported. There were no intraoperative complications associated with this procedure (21,22).

Complications

The expected complication rate from TURED surgery is approximately 20% (15). The most common complications are self-limited hematospermia, hematuria requiring recatheterization, and urinary tract infection. More concerning, but less frequent, are epididymitis and a “watery” ejaculate. High-volume watery ejaculate is presumed secondary to the reflux of urine retrograde through the ejaculatory ducts into the seminal vesicles or into opened cysts, as suggested by the finding of creatinine in the ejaculates of TURED patients. In addition to the social implications of this, the exposure of sperm to urine may impair fertility potential. Several potentially major but rarely reported complications include retrograde ejaculation, rectal perforation, urinary incontinence, and recurrent seminal vesicle infection.

CHAPTER 51 VASECTOMY

DOUGLAS G. STEIN

As the most dependable method of contraception and one that requires virtually no compliance, vasectomy is an ideal choice for those men who have made a mature, informed decision to have no more children, and especially for men who have difficulty with compliance. As a result, 12% of the U.S. population relies on vasectomy as their primary method of birth control. National surveys of vasectomy providers indicate an incidence of vasectomy of 500,000 per year in the United States, but patient-based surveys would indicate an incidence of 175,000 to 300,000 (1). While it has been noted that vasectomy is the "most common procedure involved in malpractice claims against urologists" (2), vasectomy accounted for only 8 of 469 (1.7%) urology malpractice claims closed with indemnity payment between 1985 and 2004 (3). So, while urologists need not avoid vasectomy to decrease perceived high liability, they need to be thoroughly versed in the management of men seeking vasectomy. Vasectomy Guidelines were published by the American Urological Association (AUA) in 2012. From ~2,000 titles and abstracts, the AUA Guidelines Committee reviewed 900 articles and selected 275 to formulate 15 guidelines, which will be incorporated into this chapter. These guidelines with full explanations and references are available on the website of the AUA at http://www.auanet.org/education/guidelines/vasectomy.cfm.

DIAGNOSIS

The consultation visit should accomplish two objectives: (a) The patient should learn all aspects of vasectomy that constitute informed consent, including pre- and postvasectomy instructions, the benefits, the risks, and the alternatives, and (b) the doctor should assess the patient's social and medical histories and his genital anatomy to determine whether he is a good candidate for vasectomy and advise him accordingly. According to the AUA Guideline Statement 1 (expert opinion), this process may take place in person or through an electronic and telephone exchange of information, values, and opinions.

In-person consultations allow the vasectomist to examine the patient to determine whether there are features of the patient's anatomy or personality, which either (a) make him a better candidate for general anesthesia than for the more commonly used local anesthesia with or without oral or intravenous sedation, or (b) warrant referral to a more experienced vasectomy provider if general anesthesia is not desired or practical. Such features include incomplete testicular descent (either untreated or status post orchiopexy); scarring due to prior scrotal surgery; a small tight scrotum; obesity with thick spermatic cords; very thin vasa; large hydrocele, spermatocele, or varicocele; or extreme scrotal hypersensitivity. Guidelines Statement 2 (expert opinion) lists 11 "minimum and necessary concepts" which should be conveyed, whereas Guidelines Statement 3 (standard) indicates that there is no need to discuss those conditions once considered risks of vasectomy that have been proven to have no connection with vasectomy. This author prefers an electronic exchange of information via his website, in which the patient and his partner can read about vasectomy and watch a counseling video at their own pace, at a convenient time, and as often as they would find necessary to achieve full understanding. Patients preregister to provide the physician's office with (a) relevant medical and social information, which can be considered long in advance of the procedure, and (b) acknowledgment of understanding of all aspects of vasectomy including preparation and postoperative recommendations. Patients and doctor can opt for an in-person consultation if warranted by elements of the patient's history; for example, a history of prior orchidopexy, vasectomy/reversal, or obesity. Young men (<30 years) with fewer than two children are interviewed by phone to determine their motives, to explain reversible alternatives, and to confirm full understanding of the long-term implications of vasectomy. They are encouraged to consider sperm storage. Men who have never caused a pregnancy are asked to return a specimen mailer before the vasectomy to rule out azoospermia (avoid an unnecessary vasectomy) and to know about oligospermia, if present, in the event that they ever consider vasectomy reversal. The last 143 such cases included 4 with azoospermia and 6 with severe oligospermia (<25 sperm per high-power field [HPF]). The latter were offered formal semen analysis to establish a baseline.

The AUA Guidelines Committee includes the usual risks in the "minimum and necessary concepts" to be considered in the consultation exchange, namely, bleeding, infection, failure, and chronic pain. The guidelines also recommend that patients be "reassured" that there is no evidence of a cause-and-effect relationship between vasectomy and a change in sexual function. But through two large surveys of more than 100 respondents each, this author has learned that a small percentage of patients blame vasectomy for a diminution of libido, erectile function, or climax intensity. So this author includes those possibilities in his informed consent to avoid future legal problems.

INDICATIONS FOR SURGERY

While no strict criteria exist for determining which patient should be offered vasectomy, the Electronic Code of Federal Regulations for sterilization of persons in federally assisted family planning projects (Title 42 CFR Part 50 subpart B) specifies that the individual be at least 21 years of age and mentally competent when consent is obtained and that 30 days pass between the date of consent and the date of vasectomy.

ALTERNATIVE THERAPY

Especially because vasectomy should always be presented as a permanent form of contraception, a full disclosure of alternative contraceptive methods must be a part of informed consent. While condoms are the only other alternative available to males, men should have a thorough understanding of the options available to women, even though these provide less control for the male. When features of the male anatomy (obesity, tight scrotum, thin vasa, or scarring from prior scrotal surgery) would make vasectomy difficult for the vasectomist at his or her skill level, couples considering permanent contraception should be asked to consult with a more experienced vasectomist, as complications rates are lower for vasectomies performed by more experienced vasectomists (4). Although not guaranteed successful, patients should be counseled regarding sperm cryopreservation and storage as an insurance policy that may enable paternity after vasectomy without need for vasectomy reversal.

SURGICAL TECHNIQUE

Nearly all surgical procedures involve three steps: (a) anesthesia, to allow the procedure to proceed without pain, (b) access, or how the surgeon gets to the target organ, and (c) technique, how one manages the target organ, the actual occlusion of the vas deferens. Except for patients with comorbidities associated with a high risk of infection (e.g., diabetes, immunodeficiency, coexistent infection), the AUA Guideline Statement 4 recommends no preoperative antibiotics.

Anesthesia

AUA Guideline Statement 5 is an expert opinion that “vasectomy should be performed with local anesthesia with or without oral sedation . . . if the surgeon believes that local anesthesia with or without oral sedation will not be adequate for a particular patient, then vasectomy may be performed with intravenous sedation or general anesthesia.”

Despite the growing popularity of no-needle anesthesia since 2002 (5), especially appealing to men who “just hate needles,” administration of *anesthesia with a needle* is the most common and traditional technique, with a 2010 article (6) promoting a “mini-needle” technique. Using a three-finger no-scalpel vasectomy (NSV) technique to hold the vas beneath the median raphe, a 1-inch 30-gauge needle and 3 mL syringe are used to deliver 0.5 mL of 2% lidocaine to create a midline skin wheal through which an additional 0.50 to 0.75 mL is injected as close as possible and even into each vas in turn (Fig. 51.1). Vasectomy is started immediately on the first side injected.

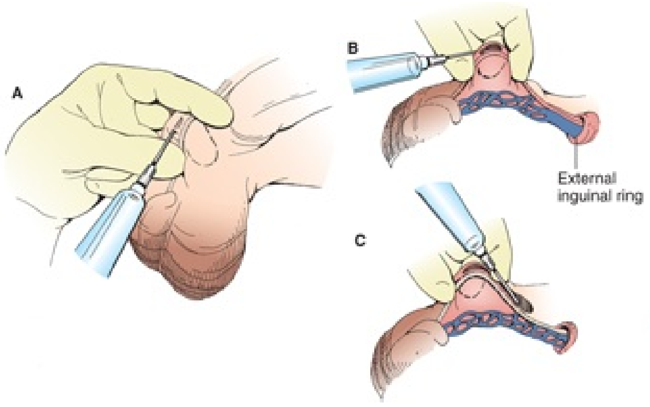

FIGURE 51.1 A and B: The vas deferens is lifted into position beneath the midline and anesthetic injected into the skin directly over it. C: Through the anesthetized skin, anesthetic is injected directly alongside the vas.

No-needle local anesthesia for vasectomy involves the use of a jet injector (or “spray applicator,” as this surgeon prefers to call it), the most popular of which is the MadaJet (MADA, Inc, Carlstadt, New Jersey). The spring-loaded MadaJet (Fig. 51.2) emits an extremely thin 0.1 to 0.2 mL stream of anesthetic (2% lidocaine, 0.5% bupivacaine or a mixture, depending on the duration of anesthesia desired) strong enough to penetrate the skin and underlying tissue to a depth of 2 to 5 mm, depending on the factory setting of the particular MadaJet. The vas is lifted into position beneath the skin at the preferred access site (anterior midline for NSV or lateral scrotal wall for traditional approach), the overlying skin is prepped with alcohol, the fluted spacer of the MadaJet is pressed over the vas (Fig. 51.3), and the release button is pressed to discharge the anesthetic through the skin and around the vas. The procedure may be repeated along the path of the vas at a 4- to 5-mm interval, but one application per vas is often adequate. Medication entry sites are barely visible as minute dots, surrounding which are 6- to 10-mm diameter areas of anesthetized skin. If the *right* vas is lifted to the midline and injected 2 mm to the *left* of the median raphe, and if the left vas is then lifted to the midline and injected 2 mm to the right of the median raphe, the patient develops an area of anesthetized skin about 5 mm on each side centered on the midline, and the scrotal septum receives all doses of the anesthetic. Through the anesthetized area, a minimally invasive vasectomy (MIV) is performed. (If anesthesia of the skin or vas is not adequate to perform a vasectomy without pain, supplemental anesthesia with a needle can be applied.) Because only the spacer touches the patient, it can be soaked in an antibacterial/antiviral antiseptic solution between cases, or a freshly autoclaved spacer can be used for each case.

Access

AUA Guideline Statement 6 states that an MIV technique (skin opening <10 mm and minimal dissection of the vas and perivasal tissues) should be used. Because this is a standard based on grade B evidence, the conventional vasectomy will not be described here. The guidelines specify that the classic Li NSV technique is one form of MIV. Any deviation from nine steps in the description of the Li NSV technique warrants that the method be described as an MIV. As long as the access technique, whether performed on the lateral scrotal walls or in the midline, uses a skin opening <10 mm and minimal dissection of the vas and perivasal tissues (with the Li NSV vas dissector and ring clamp or similar instruments), it can be considered an MIV.

The Li NSV technique (7) uses the vas dissector and ring clamp and a three-finger technique (Fig. 51.4) to access both vasa in turn via a single small opening in the anterior midline of the scrotal wall (anesthetized with needle- or spray-applicator-applied lidocaine). After the scrotum is formally prepped with povidone-iodine or chlorhexidine/alcohol and draped, needle anesthesia is used (see previously) or the pinpoint marks in the skin made by the spray applicator are located. In the Li technique, the vas, most commonly located on the posterior aspect of the spermatic cord, is swept medially and lifted into position beneath the median raphe (the site already anesthetized if the spray applicator was used) using a three-finger technique. The vas and overlying skin are grasped with the ring clamp (Fig. 51.5A), its tips applied at the left and right MadaJet application sites. If this is difficult, because the skin is thick or the vas thin, the surgeon may find it easier to puncture and spread the skin with the vas dissector then grasp the vas with the ring clamp through the opening thus created (Fig. 51.5B), still an MIV, but no longer a Li NSV, strictly speaking. MadaJet injection application sites can be difficult to locate, especially in dark-skinned men, so this step and the remainder of the vasectomy may be much easier with the magnification provided by 2.5× optical loupes. One tip of the vas dissector is introduced into the lumen of the vas and removed (Fig. 51.6). Both tips are introduced at the same spot and spread to twice the width of the vas (Fig. 51.7), splitting the vas open longitudinally and spreading all overlying layers. One tip of the vas dissector is then used to “hook” the vas (Fig. 51.8) and lift it from its sheath as the ring clamp is removed. The ring clamp is then used to grasp one wall of the vas and deliver a 1- to 2-cm loop of it from its sheath (Fig. 51.9).

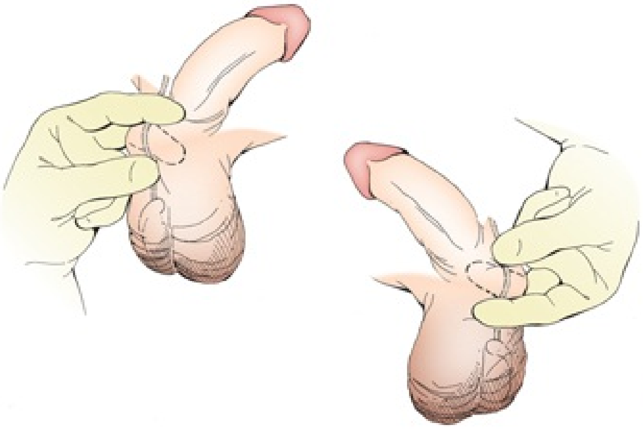

FIGURE 51.4 The three-finger technique for isolating the (**A**) right and (**B**) left vas deferens.

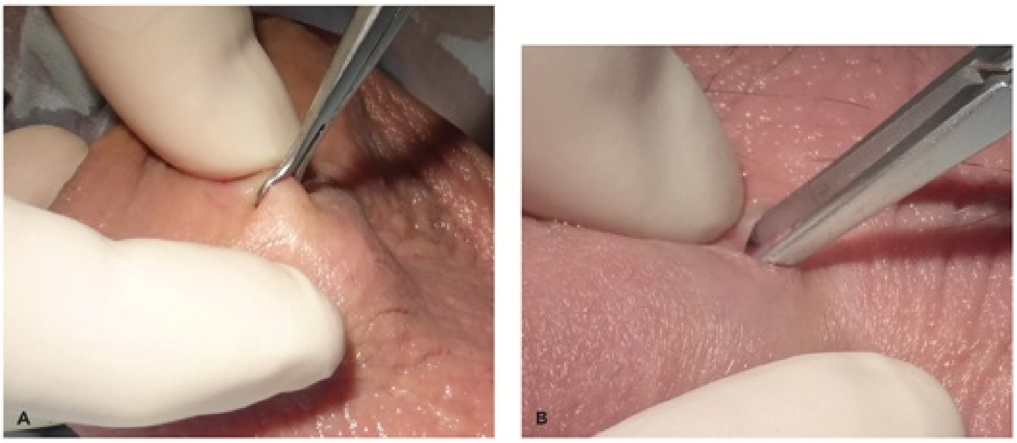

FIGURE 51.5 **A:** Held using the three-finger technique, the right vas is grasped with the NSV ring clamp, incorporating the skin. **B:** In some cases (e.g., thick skin or thin vas), it may be easier to grasp the vas through a skin opening made with the NSV dissecting clamp.

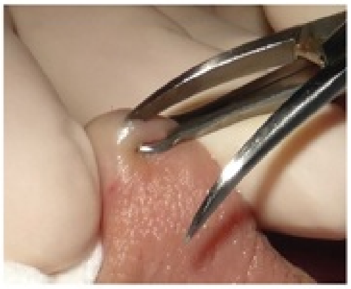

FIGURE 51.6 One tip of the NSV dissecting clamp is introduced into the lumen of the vas.

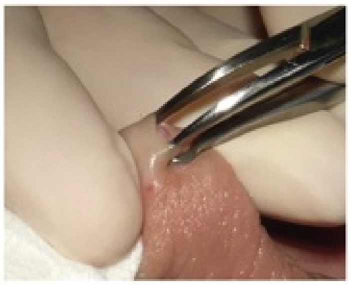

FIGURE 51.7 Then both tips are introduced, and all layers are spread to twice the diameter of the vas.

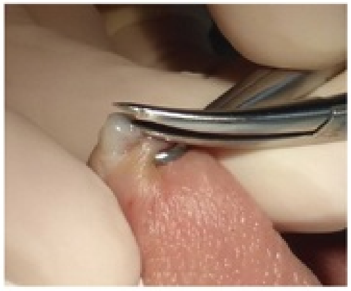

FIGURE 51.8 The split vas is hooked with the dissecting clamp and delivered while the ring clamp is released.

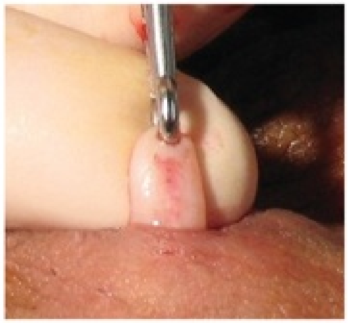

FIGURE 51.9 A loop of vas is delivered and grasped with the ring clamp, its mesentery still intact.

Occlusion

Numerous methods for obstructing the vas have been described, and most surgeons employ a combination of luminal cauterization, ligation, division, excision, and fascial interposition with either a suture ligature or hemoclip (8) (Figs. 51.10 to 51.13). The objective should be very low failure and low complication rates, without removing so much vas, especially in young patients, that vasectomy reversal is rendered extremely difficult. “Early” failure is said to occur when the postvasectomy patient has motile sperm or significant numbers (>100,000 per mL) of nonmotile in the semen 6 months after vasectomy. Recanalization within the tissue between the two severed ends occurs frequently during the 1 to 2 months following vasectomy but usually scars off (9). Early failure occurs when recanalization does not scar off but rather persists. “Late” failure is the return of motile sperm to the semen of a patient previously diagnosed as azoospermic, an event caused by delayed recanalization and usually discovered as a result of a surprise pregnancy.

Effectiveness of vasectomy using cautery. *BMC Urol* 2004;4:10, http://www.biomedcentral.com/1471-2490/4/10.)

There are numerous reviews of surgical techniques (8–10), and the AUA Guidelines Committee performed an exhaustive review of a total of 89 study arms worthy of inclusion, for a total of 126,821 patients. Techniques worthy of recommendation were those for which a fair number of studies (>3) with an adequate number of total patients (>1,000) all reported failure rates of less than 1%. (Other techniques were represented by studies that showed widely varying success rates or by studies that provided insufficient evidence of efficacy [e.g., only one study.]) One notable exception was nondivisional electrocautery technique of the Marie Stopes organization: only a single study but 41,814 patients across many centers and many clinicians with consistently low failure rates of 0.28% to 1.3%. Labrecque and Caron (11) were unable to duplicate this success rate with 1 cm of thermal mucosal cautery proximal and distal to a 0.5-cm segment of vas from which the anterior wall and mucosa had been completely removed/destroyed by thermal cautery, and they discontinued the study when preliminary results showed a failure rate of 14.8%. They surmised that the Marie Stopes electrocautery technique was more destructive (90% of the vas wall thickness as opposed to mucosa only) over a longer distance (3 cm as opposed to 2.5 cm). When a segment is not excised or fascial interposition used, the addition of division did not reduce the failure rate in a study of the effectiveness of various cautery techniques (9).

So, AUA Guideline Statement 7 is a “recommendation” (not a standard) that occlusion be accomplished by (a) division followed by (i) intraluminal mucosal cautery (MC) of both ends and fascial interposition, (ii) MC of both ends without fascial interposition, or (iii) MC of the abdominal end with fascial interposition; or (b) the Marie Stopes nondivisional method (not recommended by the author).

However, given the large numbers of surgeons who use ligatures or clips and the presence of some studies which show acceptably low failure rates with these techniques, the AUA Guideline Committee provided AUA Guideline Statement 8 as an “option” that the vas may be divided and the ends occluded by ligatures or clips by surgeons who consistently obtain satisfactory results with such methods.

Routine histologic examination of the excised vas segments is not required (AUA Guideline Statement 9, expert opinion).

Ligation without division has a high early failure rate, even when employing a specially designed clip rather than a suture ligature or hemoclip (12). A newly designed ligation clip is still marketed, but there are not enough studies with enough patients showing failure rates of <1% to recommend it at this time.

Early recanalization and failure rates are highest for ligation and excision without fascial interposition and lowest for thermal cautery with fascial interposition (6,9). This is the rationale for the following technique.

Preferred Anesthesia, Access, and Occlusion Technique

The no-needle minimally invasive (sometimes “no-scalpel” by the strictest definition) vasectomy with thermal cauterization and hemoclip fascial interposition is performed as follows.

An elastic lasso is applied at the coronal sulcus and an attached hemostat is snapped onto the shirt to keep the penis elevated. Most patients, coached by online instructions and telephone staff, shave the night before so that the skin is not so sensitive to the alcohol used to prep it for application of the no-needle anesthesia. If needed, the anterior scrotal wall is shaved with a single-edge shaver. No-needle local anesthesia is applied to each vas in turn at a midline location as described previously. The scrotum is then formally prepped with a mixture of 4% chlorhexidine, alcohol, and water (1:1:2) and draped with a fenestrated 18 inch × 24 inch drape. If no-needle anesthesia is not used, needle anesthesia is applied as described previously.

After local anesthesia, the no-scalpel technique described previously is utilized to deliver a loop of vas from its sheath (see Fig. 51.9). It is important that the vas be opened a few millimeters lengthwise to confirm complete penetration of the sheath and to allow grasping of the vas wall with the ring clamp. The vas dissector is passed along the undersurface of the vas at the apex of the loop (Fig. 51.14). The dissector tips may be gently spread to push the adjoining vessels away from a 1- to 2-cm segment of vas (Fig. 51.15), but this may sometimes promote bleeding and is not always necessary. A small vasotomy opening is made in the prostatic end with one tip of the vas dissector or with the tip of a battery-powered wire loop thermocautery unit as though one were draining a subungual hematoma. The tip of the thermocautery unit is then introduced into the abdominal end and advanced 5 to 10 mm (Fig. 51.16). It is activated just long enough to sear the mucosal lining of the vas so that it will seal off by scarring. If applied too long, causing the full thickness of the wall to blanch, the cauterized segment may slough, negating the effectiveness of cautery in contributing to obstruction of the vas. Then the thermocautery unit or a scissors is used to divide the vas where the vasotomy was made. The abdominal end slips up into the vas sheath and the margins of the sheath are brought together and tented over the buried end with a Halsted hemostat or the NSV dissecting clamp (Fig. 51.17). At this point, the testicular end is still secured with the ringed clamp. The hemostat is now brought down to a position below the ringed clamp (toward the foot of the table) and transferred to the nondominant hand (Fig. 51.18). A gentle “tear back” of the testicular end assures that the posterior aspect of the vas sheath is included in the fascial closure. Small vessels may be included in the hemostat if necessary to optimize fascial interposition or to provide hemostasis. A medium hemoclip (or suture tie) is applied to the tissue in the hemostat alongside the testicular end of the vas, drawing the sheath around the testicular end so that it cannot slip back inside. When the hemostat is removed, the clip (or tie) rotates back cephalad and sits parallel to the testicular end (Fig. 51.19) so that it will not hang up on scrotal wall fascia as it released back into the scrotum. The sheath may appear to be drawn tightly around the lower end if it indents the surface, but it is unclear whether this compromises blood flow to the segment outside the sheath. If there is concern that the lower end may slough, leaving the remaining stump inside the sheath and defeating the intent of fascial interposition, a gentle spread of the tight band with the dissector will suffice. An additional hemoclip may be applied for hemostasis if necessary. The ringed clamp on the testicular end is opened and the divided vas ends fall back into the scrotum. The testicular end is not ligated or cauterized, making this an open-ended technique, which may provide some advantages (4). No segment is removed. If the surgeon prefers to remove a segment, AUA Guideline Statement 9 offers the expert opinion that histologic examination of the excised segment is not required. The same procedure is repeated on the other side through the same midline skin opening.

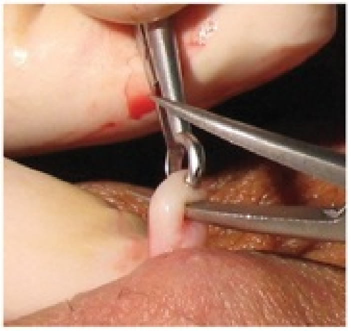

FIGURE 51.14 The NSV dissecting clamp is used to separate the vas from the underlying mesentery.

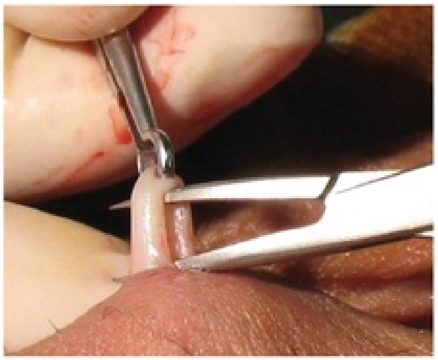

FIGURE 51.15 The NSV dissecting clamp may then be used to push back the mesentery and expose a longer loop of vas, but this sometimes causes bleeding and is not always necessary.

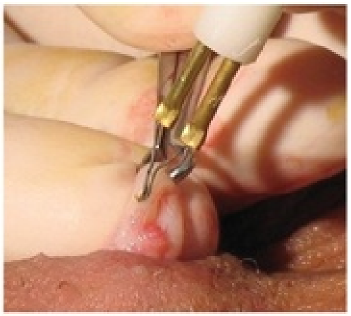

FIGURE 51.16 A thermocautery unit is introduced into the abdominal end only, if one prefers an "open-ended" vasectomy (testicular end not ligated or cauterized).

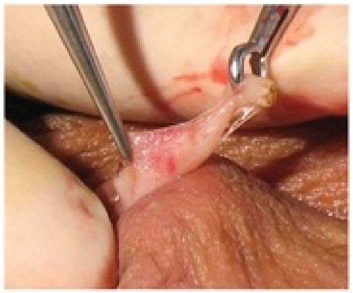

FIGURE 51.17 After the vas is divided with the thermocautery unit or with a scissors, the abdominal end slides into the vas sheath which is then closed over it with a Halsted hemostat or the NSV dissecting clamp.

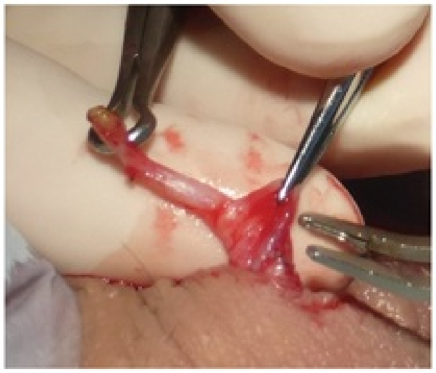

FIGURE 51.18 The closed sheath is rotated 180 degrees for easier application of a hemoclip while the testicular end is lifted to bring the underside of the vas into inclusion within the clip for more complete fascial interposition.

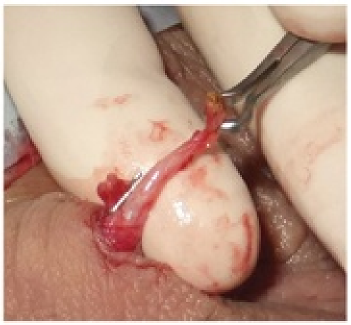

FIGURE 51.19 When the hemostat is removed, the hemoclipped sheath over the buried abdominal end rotates back to its original position, ready for return to the scrotum.

Tight underwear or an athletic supporter will hold a gauze pad in place and provide some comfort, or a Band-Aid can be used to cover the access site.

The patient is instructed to recline on the day of the surgery. Ice packs are recommended by some surgeons to decrease the risk of hematoma formation, but it is unclear whether the cold or the inactivity imposed by the ice pack provides the claimed benefit. On the day after surgery, patients may walk and drive ad lib but should avoid yard work, sports, and heavy lifting. They may shower, then continue use of scrotal supports for 2 more days. Two days after the vasectomy, patients may return to normal activities but refrain from ejaculation and limit aggressive athletic workouts until discomfort and tenderness have subsided.

Follow-up Semen Analysis

Postvasectomy semen analysis (PVSA) is used to confirm the effectiveness of a vasectomy postoperatively. AUA Guideline Statement 10 is the clinical principle that couples should use other contraceptive methods until success (effectiveness) is confirmed by PVSA. “Effectiveness” can be defined as either contraceptive effectiveness (absence of pregnancy) or occlusive effectiveness (ideally azoospermia). Some men fail to achieve azoospermia yet never cause a pregnancy, especially if their semen contains <100,000 nonmotile sperm per milliliter (“rare nonmotile sperm” or RNMS). The AUA Vasectomy Guidelines contain a long dissertation about the science of PVSA and emphasize the value of sperm motility as an indicator of vasectomy failure in those men with persistent seminal sperm 12 weeks after vasectomy. AUA Guideline Statement 11 offers the expert opinion that to evaluate sperm motility, a fresh semen sample should be evaluated within 2 hours after ejaculation.

If a *fresh* specimen contains fewer than 100,000 *nonmotile* sperm per milliliter (<1 sperm per three HPFs at 400× with many light microscopes), as will be the case for 95% at 12 weeks, no further testing is necessary, as 99.7% of these cases will achieve azoospermia or RNMS by 24 weeks (9) and the risk of pregnancy with fewer than 100,000 nonmotile sperm per milliliter is extremely low (13). So AUA Guideline Statement 12 is a recommendation that "patients may stop using other methods of contraception if one well-mixed, uncentrifuged, fresh post-vasectomy semen specimen shows azoospermia or only rare non-motile sperm (RNMS or <100,000 non-motile sperm per mL)."

Regarding the timing of the first semen evaluation, AUA Guideline Statement 13 (an option) states that "eight to sixteen weeks after vasectomy is the appropriate time range for the first PVSA. The choice of time to do the first PVSA should be left to the judgment of the surgeon." Ninety percent of men will achieve azoospermia or RNMS by 15 ejaculations (whichever comes first) after vasectomy.

In some cases, evaluation of a fresh semen sample is not logistically practical (patients who cannot get to a testing center within 2 hours and cannot produce a specimen at the center). If, at 12 weeks, a sample older than 2 hours (motility evaluation not reliable) shows azoospermia (an absolute value that may be a mathematical abstraction, but no sperm in 50 HPFs seems reasonable), the question of motility is moot. If any sperm are seen in 50 HPFs of a non-fresh specimen at 12 weeks, another container or mailer is provided. If any sperm are seen at 16 weeks in a second non-fresh specimen, evaluation of a fresh specimen is required despite logistical challenges. Labrecque et al. (13) propose a flow chart suggesting that testing be repeated every 4 to 6 weeks and that failure due to "persistent" recanalization (some cases will scar closed) be considered probable only if motile sperm persist beyond 6 months. When 100,000 or more nonmotile sperm per milliliter persist for over 6 months, failure should be considered, but even this is considered overly cautious by some (14,15). This data forms the basis of AUA Guideline Statement 14: "Vasectomy should be considered a failure if any motile sperm are seen on PVSA at six months after vasectomy," an expert opinion; and AUA Guideline Statement 15: "If >100,000 non-motile sperm/mL persist beyond six months after vasectomy, then trends of serial PVSAs and clinical judgment should be used to decide whether the vasectomy is a failure and whether repeat vasectomy should be considered," another expert opinion.

Compliance with PVSA (only about two-thirds of men return for at least one PVSA) may be enhanced by providing a specific appointment for the first PVSA. Home test kits are available (16), but improved compliance has not been studied or proven, and there is still insufficient data regarding the reliability of these kits in clinical practice.

When providing results, men should be reminded that vasectomy is *not* 100% *effective* even if azoospermia has been achieved because of the possibility of delayed recanalization, often detectable by simple semen analysis, unless the recanalization is transient, in which case DNA-documented paternity is possible even in the absence of detectable seminal sperm (17).

OUTCOMES

Results

Using fascial interposition with a hemoclip to bury the testicular end during the 16 years from 1990 through 2006, approximately 10,800 vasectomies were performed. An estimated 70% of men underwent postvasectomy semen testing. Of these 7,560, 4 patients (0.05%) experienced early failure (motile sperm at 4 months) and required repeat vasectomies, and 11 patients (of whom we are aware as of March 2014), or 0.1%, have experienced late failure: pregnancy and confirmation of motile seminal sperm or paternity more than 1 year after vasectomy (9 confirmed azoospermic after vasectomy and 2 not tested after vasectomy).

Starting in 2007, the author has buried the prostatic end of the vas, hoping for an even lower failure rate. From 2007 through 2013, 15,493 vasectomies were performed by the author with burial of the prostatic end, and 10,255 (66%) underwent postvasectomy semen testing. Of those tested, there have been six early failures (0.06%) (any motile sperm or >100,000 nonmotile sperm at >3 months, or a pregnancy sooner than 1 year in a man not tested after vasectomy). Of the entire group, there has been one late failure (0.0065%), but it is still too early to present a true rate of late failures (inadequate follow-up time) and to determine whether abdominal-end fascial interposition is superior to testicular-end fascial interposition.

Of interest is the fact that an associate trained by the author in the same technique had a higher failure rate in 911 cases over an 8-month period, of whom 659 patients (72%) underwent postvasectomy semen testing. There were six early failures (0.9%): five cases of motile sperm at >6 months and one case of >100,000 NMS at 10 months. This higher rate of early failure (over 10 times higher than that of the author) is evidence that subtle variations in even the same technique can result in different failure rates. It also makes a strong case for the need for every vasectomist to monitor his or her own rates of failure and modify his or her technique as needed to achieve an early failure rate of 1% or less.

Complications

Early

Three levels of hematoma are possible. Reported rates average about 2% but are higher (4.6%) for surgeons who perform few vasectomies (1 to 10 per year) and lower (1.6%) for surgeons who perform many vasectomies (>50 per year) (10). The incidence is lower with MIV (0.3% versus 1.4%) during which tissue is spread for exposure of the vas than with traditional vasectomy, during which tissue is cut for exposure of the vas (18).

Postvasectomy inflammation can occur anywhere from 3 days to years following vasectomy. Patients who have had little discomfort following vasectomy may “out of the blue” develop swelling and tenderness at the vasectomy site or within the epididymis and convoluted vas “upstream” from the vasectomy site. Most cases are unilateral and respond quickly to nonsteroidal anti-inflammatory drugs (NSAIDs).

Infection with conventional incisional vasectomy has been reported to occur in 1.4% of cases compared with a rate of 0.1% with NSV (18). In the absence of fever, it can be difficult to differentiate infection from common early postvasectomy inflammation, but infection should be considered in patients with swelling and tenderness that does not respond to NSAIDs. The most severe and obvious cases of infection develop into scrotal abscesses which require surgical drainage. There are two published reports of Fournier gangrene in healthy young men, with onset 1 to 2 days after vasectomy, both due to hemolytic strep, one case fatal (19,20).

Late

Sperm granulomas form at the vasectomy site to varying degrees in up to 60% of patients. A granuloma probably forms when sperm leak from the testicular end of the divided vas and incite the inflammation needed for their absorption, typically in the second or third week following vasectomy. This actually vents the congestion and inflammation that often occurs upstream in the proximal vas and epididymis and may enhance the prognosis for success with a future vasovasostomy. Open-ended vasectomy expectedly reduces the risk of pain due to congestive epididymitis but paradoxically does not increase the risk of tender sperm granuloma (21) and actually reduces it. For granulomas that are exquisitely tender, most patients will respond to nonsteroidal anti-inflammatories. Some may also respond to an injection of a steroid near the granuloma, but some will require surgical excision.

Chronic pain of the scrotal contents after vasectomy is a syndrome with various names: postvasectomy pain syndrome (PVPS), congestive epididymitis, postvasectomy orchialgia, and chronic testicular pain (22). In two studies conducted 7 to 12 months following vasectomy, 14.7% of men described some degree of chronic discomfort of the scrotal contents, approximately 1% described the pain as “quite severe and noticeably affecting quality of life” (23), and 1% to 2% expressed regret over having had the vasectomy because of pain. Rates were about the same at 10 years following vasectomy, indicating that the incidence does not increase or decrease with time. PVPS is thus defined as intermittent or constant unilateral or bilateral testicular pain for greater than 3 months following vasectomy, severe enough to interfere with daily activities and cause the patient to seek medical attention. There are no predictors as to which patients will develop it, there is no clear-cut etiology, and there is no best treatment. The syndrome is not due to infection, so antibiotics are not helpful. Medical treatment options include nonsteroidal anti-inflammatories, scrotal support, nerve blocks, and tricyclic antidepressants. Surgical treatments include conversion to open-ended vasectomy, vasectomy reversal, epididymectomy, orchiectomy (22), and microsurgical neurolysis (24).

Prolonged sexual dysfunction following vasectomy is rare.

Through the years, questions have been raised about an association between vasectomy and a variety of subsequently diagnosed disease states including atherosclerosis, prostate cancer, glomerulonephritis, and primary progressive aphasia. So far, reviews of the initial studies point out methodologic factors, and subsequent studies have not been able to support any association between vasectomy and any disease states (25). In fact, AUA Guideline Statement 3 is a standard: “Clinicians do not need to routinely discuss prostate cancer, coronary heart disease, stroke, hypertension, dementia or testicular cancer in pre-vasectomy counseling of patients because vasectomy is not a risk factor for these conditions.”

CHAPTER 52 VASOVASOSTOMY AND VASOEPIDIDYMOSTOMY

MATTHEW WOSNITZER AND MARC GOLDSTEIN

VASOVASOSTOMY

Approximately 500,000 vasectomies are performed annually in the United States (1). Up to 6% of men undergoing vasectomy will ultimately request vasectomy reversal for multiple reasons (2). Vasectomy reversal has evolved since its introduction in the early 1900s (3). Modern microsurgical reconstruction has been demonstrated as a safe and efficacious treatment for most cases of vasal or epididymal obstruction using vasovasostomy or vasoepididymostomy, respectively. The majority of patients with obstructive azoospermia postvasectomy maintain normal or near normal exocrine and endocrine function including sperm production in the testis (4). A precise, watertight, mucosa-to-mucosa, tension-free anastomosis of healthy tissue with excellent blood supply is critical to reestablish patency. Microsurgical reconstruction with vasovasostomy was initially described by Sherman Silber (5) and Earl Owen (6) in the 1970s and has been refined over the ensuing decades. Owen (6) reported a patency rate of 98% in his series of 50 patients, and patency rates have more recently approached 99.5% in some series with experienced microsurgeons (7). Cost-benefit analyses have characterized reversal procedures as the most effective and economic management of postvasectomy infertility (8), even in men with previous failed vasectomy reversal (9), demonstrating that microsurgical reconstruction is an important treatment option for appropriately selected patients (10).

Return of adequate numbers of motile sperm with good fertilizing capacity can take 3 to 18 months after a technically successful reversal. This is especially important for men with partners of advanced maternal age. For optimal outcomes, access to a microsurgeon trained in the vasovasostomy and vasoepididymostomy procedures is requisite. With widespread accessibility of in vitro fertilization (IVF) with intracytoplasmic sperm injection (ICSI) using aspirated sperm, the role for complex reconstructive procedures for postvasectomy infertility has been debated. For patients who either prefer to avoid surgical reconstruction or who, for a variety of reasons, may be poor candidates for reconstruction, motile sperm may consistently be retrieved preferably by microsurgical epididymal sperm aspiration (MESA) for IVF with ICSI (11).

Diagnosis

The preoperative workup for men electing vasectomy reversal includes confirmation of previous natural fertility. However, if the patient has no history of prior paternity or if he has obstructive azoospermia without a history of prior vasectomy, further workup is essential. The workup includes full medical and surgical history (see "Prognostic Factors" section) including survey for symptoms of hypogonadism, physical examination, and basic laboratory tests (see "Laboratory Evaluation" section) with semen analysis. The investigation of the male partner should be performed in conjunction with evaluation of the female partner.

Physical Exam

Physical examination provides important information regarding the likelihood for successful vasectomy reversal. This includes inspection for prior surgical scars in the pelvis and inguinal region, evaluation of vasa to rule out absence, and measurement of testicular volume and consistency (small and soft testes are indicative of impaired spermatogenesis). Testicular biopsy may be necessary in some ambiguous cases at the time of proposed reconstruction. Epididymal fullness, irregularity, induration, or ipsilateral hydrocele may predict presence of secondary epididymal obstruction, which necessitates vasoepididymostomy (see "Vasoepididymostomy" section). The vasectomy site should be examined to detect sperm granuloma, vasal gap length, and length of testicular vasal remnant to formulate a surgical plan. Sperm granulomas are detected in 10% to 30% of men undergoing reversal surgery and may serve as a pop-off valve protecting the epididymis from the adverse consequences of increased intratubular pressure (10,12). Presence of a granuloma on the testicular end of the vas is associated with improved intraoperative vasal fluid quality, decreased risk of epididymal obstruction, therefore predicting vasovasostomy instead of vasoepididymostomy on that side, and is a predictor of better microsurgical vasectomy reversal outcomes (12). Increased gap length between the obstructed vasal ends may require inguinal extension of the scrotal incision and additional dissection of the convoluted vas or epididymis to facilitate tension-free anastomosis (see "Vasovasostomy Surgical Technique" section). Testicular vas length is significant because vasectomy performed closer to the testis (in the convoluted vas for example) is characterized by increased intraluminal pressure and greater risk of secondary epididymal obstruction as compared to a vasectomy site further from the testis which theoretically results in decreased intraluminal pressure and therefore a lower risk of secondary epididymal obstruction (13).

Laboratory Evaluation

Semen analysis with examination of centrifuged pellet, to confirm azoospermia on two occasions, is the primary laboratory test obtained prior to vasectomy reversal. Up to 10% of patients will have sperm with tails in the centrifuged pellet at mean 10 years following vasectomy (14), indicating that sperm will be found in the testicular vasal lumen of at least one side which is associated with favorable outcomes. Low semen volume could indicate ejaculatory duct obstruction and should be investigated with transrectal ultrasound. Serum follicle-stimulating hormone (FSH) less than 7.6 IU per L and normal testosterone reflect intact Sertoli and Leydig cell function, respectively. Elevation of FSH suggests poor spermatogenesis in men with small, soft testes, which may require further diagnostic workup and increased requirement for assisted reproductive technologies following vasectomy reversal (15). In men with elevated serum FSH levels or in men without prior fertility, a positive serum antisperm antibody assay confirms active spermatogenesis obviating the need for testicular biopsy before reconstruction (16).

Indications of Surgery

Microsurgical reconstruction is performed for patients desiring additional children and for treatment of postvasectomy pain, iatrogenic (hernia or hydrocele repair, orchiopexy), infectious, or traumatic causes of vasal obstruction. In a series of 472 patients undergoing surgical exploration for obstructive azoospermia, approximately 7% had an iatrogenic injury secondary to inguinal hernia repair (frequently pediatric hernia surgery), renal transplantation, appendectomy, or spermatocelectomy (17). Such patients typically exhibit long vasal defects, impaired blood supply, longer obstructive duration, increased technical complexity of surgery, and poorer outcomes compared to vasectomy reversal patients.

Prognostic Factors

Multiple patient and partner factors affect the outcome of vasectomy reversal and should be assessed during preoperative evaluation. Factors include prior fertility, medical and surgical history subsequent to vasectomy (inguinal hernia repair, previous failed vasectomy reversal, presence of sperm granuloma), obstructive interval, and female partner's age/fertility status. The likelihood of successful pregnancy following vasectomy reversal decreases from 56% in patients whose partners are 20 to 39 years of age to 14% in those whose partners are age 40 years and older (18). Men with the same partners prior to and following vasectomy procedure also have better outcomes, perhaps from proven previous fecundity together and shorter time interval since vasectomy (19). Regarding time interval from initial vasectomy to subsequent vasectomy reversal, patency and pregnancy rates of 91% and 89%, respectively, were identified for obstruction interval of <5 years, whereas patency and pregnancy rates of 89% and 44% for obstruction interval of >15 years were identified (12). The Vasovasostomy Study Group demonstrated similar results with patency and pregnancy rates of 97% and 76%, respectively, for obstruction interval of <3 years, which declined to 71% and 30% for obstruction interval of ≥15 years (20). Determining when vasovasostomy or vasoepididymostomy is performed primarily depends on intraoperative vasal fluid findings.

Alternative Therapy

The alternative to reversal surgery is IVF with ICSI using retrieved sperm. Sperm retrieval is optimally performed by MESA with high yields of good quality sperm and excellent outcomes. Testicular aspiration typically yields motile sperm but far fewer in number and poorer in quality (4,11). Following sperm retrieval, there is no need to synchronize sperm and egg retrieval because outcomes with sperm cryopreservation are equivalent to fresh samples (21–23). Sperm retrieval rates for men with obstructive azoospermia using ICSI are high (96% to 100%) regardless of the etiology for obstruction or the use of testicular versus epididymal sperm (24,25).

Vasovasostomy Surgical Technique

Operating Room Setup

Dual-headed operating microscope with 6× to 32× power magnification is used with foot pedal controls allowing the surgeon to customize zoom and focus the field of view without interrupting surgery (Fig. 52.1). The patient is placed in supine position with all pressure points padded. Following incision and initial dissection, the microscope is used for the entire procedure until closure. Although the operation can be performed in the standing position if preferred, custom-designed microsurgical chairs increase stability of the surgeon's chest and arms (Fig. 52.2). By positioning the surgeon on the patient's right side, the right-handed surgeon is in the optimal location to place the more challenging abdominal end vasal sutures with the forehand.

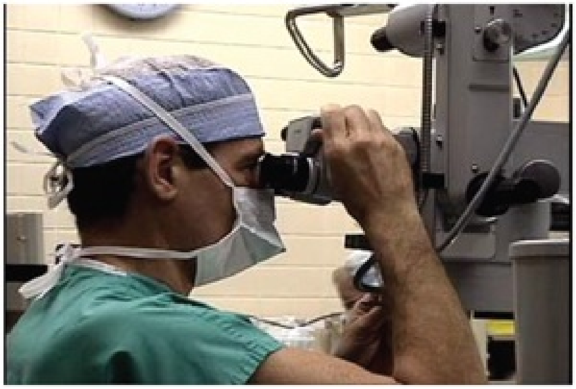

FIGURE 52.1 The operating microscope has two heads for the surgeon and the assistant. Microscope settings are checked before starting the procedure. (All photos courtesy of Marc Goldstein, MD, and Philip S. Li, MD.)

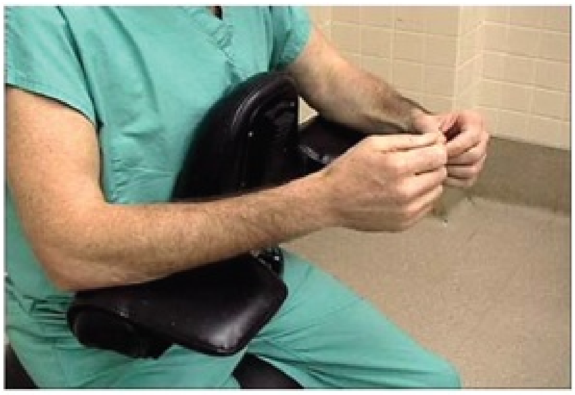

FIGURE 52.2 The specially designed microsurgical chair adjusts for optimal support of the chest and arms.

Anesthesia

Although local or regional anesthesia has been used for uncomplicated vasovasostomy, general anesthesia is preferred. The patient's ability to remain still and the surgeon's experience and comfort level should be considered in selecting the type of anesthesia.

Incision

Following intravenous cefazolin administration and standard surgical preparation of the groin and genitalia in the supine position, the external inguinal ring is marked on both sides (Fig. 52.3). Careful palpation of the vasectomy site assists in determining the required level of the incisions. Following demarcation of the external inguinal ring, high vertical scrotal incisions (at least 1 cm lateral to the base of the penis) provide optimal exposure and cosmetic results. The incision should be adequate to permit delivery of the testis; the tunica vaginalis should be maintained intact for optimal exposure of the vas deferens (Figs. 52.4 to 52.6). The incision may be extended as needed toward the external ring to compensate for high vasectomy site or large vasal gap. If the site of vasal disruption, however, is even higher (such as following inguinal obstruction from herniorrhaphy), an inguinal incision is preferred so that inguinal anastomosis may be completed without tension. Incision through the scar from the previous hernia surgery usually leads directly to the site of obstruction. With this incision, the epididymis may be exposed as needed by delivering the testis through the inguinal incision or via a separate scrotal incision.

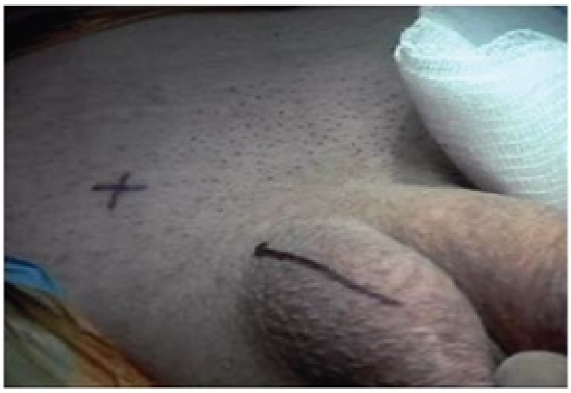

FIGURE 52.3 The right surgical incision is marked over the scrotal skin. The external inguinal ring is marked with an *X*. The incision is at least 1 cm away from the penis.

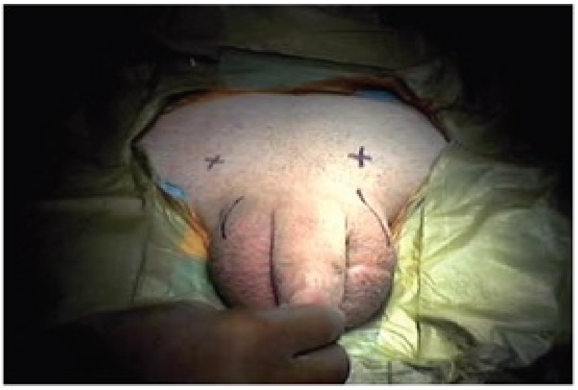

FIGURE 52.4 The skin incision is made with a no. 15 blade.

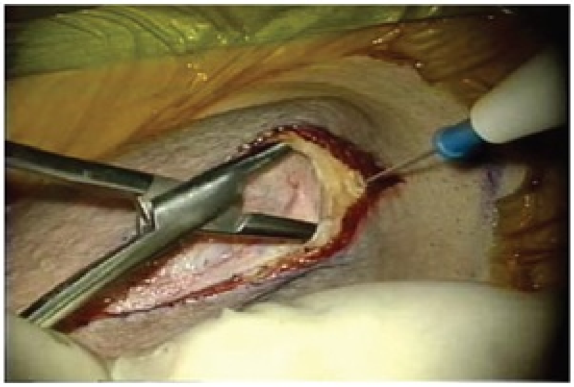

FIGURE 52.5 Electrocautery is used for the underlying dartos layer.

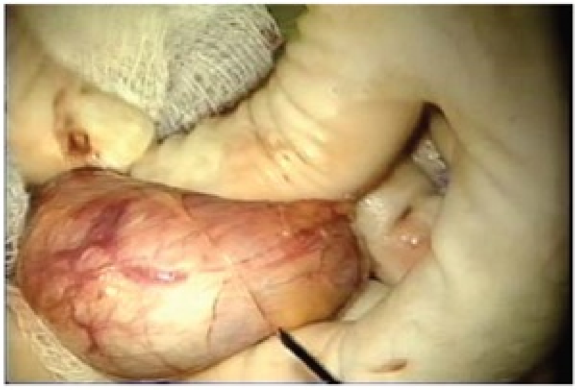

FIGURE 52.6 The testis is delivered into the field, with the tunica vaginalis intact.

Exposure of the Vasa Deferentia

Adequate exposure and meticulous mobilization of the vas deferens is essential for an eventual tension-free anastomosis (Fig. 52.7). To maintain the vasal blood supply, the optimal dissection plane must be established along the vasal sheath; venturing too close to the sheath risks injury to the periadventitial vasal blood supply, whereas too much distance from the sheath may threaten the testicular artery. Injury to the testicular artery may lead to testicular atrophy because the deferential artery likely was disrupted during vasectomy. Mobilization can be performed in part bluntly with a Kittner or gauze-encased fingertip. The operating microscope should be used for this dissection with at least 10× power magnification for sufficient visualization to minimize risk of stripping the vasal vessels. The deferential artery provides the blood supply to the vas deferens (along with the inferior epididymal artery derived from the deferential artery), which originates from the superior or inferior vesicle branches of the internal iliac (hypogastric) artery. Iatrogenic injury to the testicular blood supply (testicular, deferential, and cremasteric arteries) could lead to testicular atrophy.

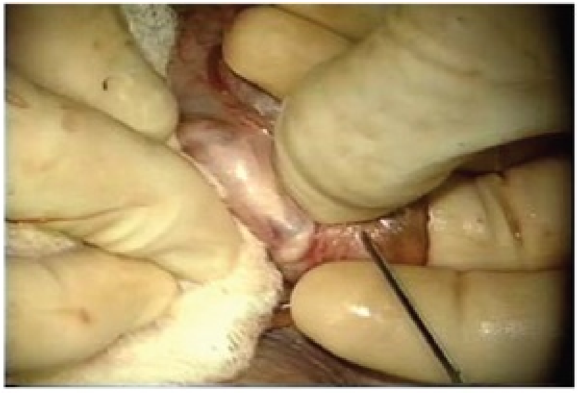

FIGURE 52.7 Blunt dissection with a gauze-covered finger releases the vas deferens from the surrounding tissue.

Following careful blunt dissection of the vas deferens, two Babcock clamps are placed above and below the obstructed segment (Fig. 52.8). With the clamps held with light tension, the proper dissection plane can be entered by transilluminating the sheath with the operating light (Fig. 52.9). Using a curved mosquito clamp, the spaces at two points on either side of the vasectomy site are punctured (Fig. 52.10), and two quarter-inch Penrose drains replace the clamp to serve as handles to manipulate the vas deferens on mild tension while gently separating the vas from surrounding tissue with both blunt and sharp dissection using small fine Metzenbaum scissors (Fig. 52.11).

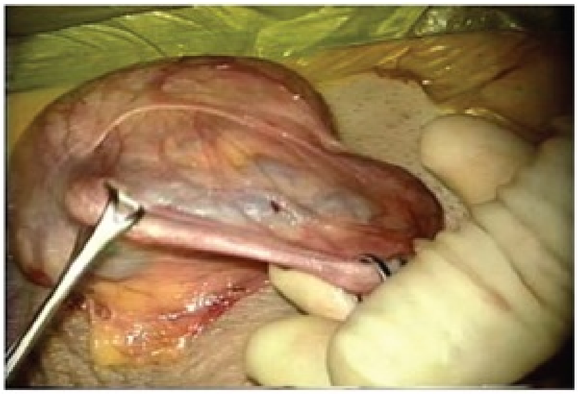

FIGURE 52.8 Two Babcock clamps are placed along the length of the vas deferens.

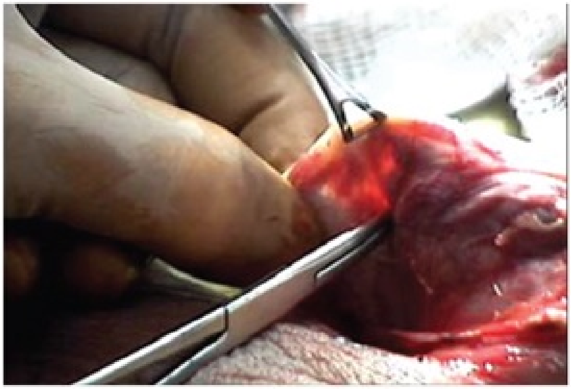

FIGURE 52.9 Transilluminating the tissue surrounding the vas deferens by bringing the operating light low helps to identify the correct dissection plane.

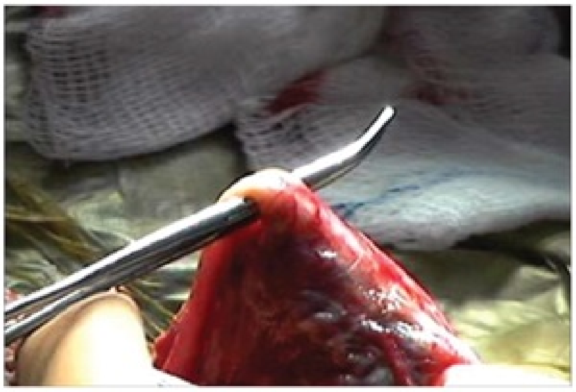

FIGURE 52.10 The plane between the vas deferens and the surrounding tissue is pierced with a Crile clamp.

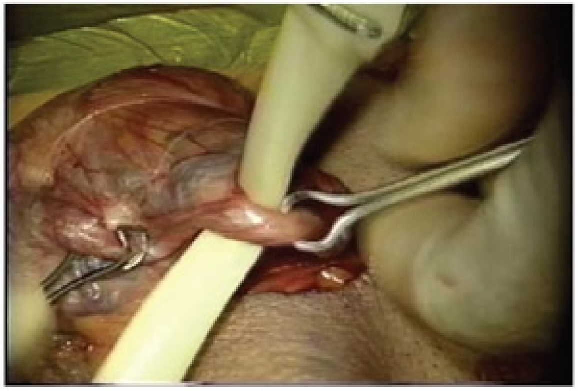

FIGURE 52.11 Quarter-inch Penrose drains are brought through the two openings made by transillumination. Using traction on the Penrose drains, the vas deferens is released using both blunt and sharp dissection.

Multiple techniques can achieve additional length when a long vasal gap would preclude tension-free anastomosis. Blunt dissection using the index finger through the external inguinal ring can free the abdominal vas deferens nearly to the internal inguinal ring level without opening the external oblique aponeurosis. Further, the convoluted vas deferens can be dissected from the epididymal tunica (Figs. 52.12, 52.13, and 52.14A). Up to 6 cm of additional length can be obtained by these techniques. An additional 4 to 6 cm can be released by dissecting the epididymis from the testis, up to two-thirds of the length of the epididymis to the level of the caput epididymis (Fig. 52.14B). During epididymal dissection, the epididymal blood supply (composed of the superior epididymal artery [originating from the testicular artery] and inferior epididymal artery [derived from the deferential artery]) should be recognized and preserved. Additionally, orchidopexy can be performed to reposition the testis higher in the scrotum. Lastly, laparoscopic or robotic mobilization of the intra-abdominal vas may be performed (26,27). The Prentiss maneuver, with placement of the vas medially to the inferior epigastric vessels, may deliver up to 10 cm of vasal length when used in combination with the other methodologies to facilitate subsequent inguinal vasovasostomy.

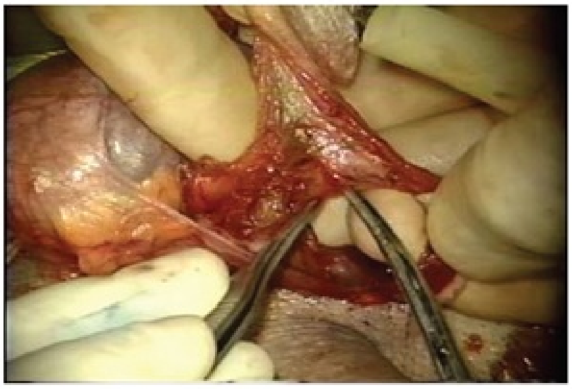

FIGURE 52.12 The vas deferens is freed distally to the level of the convoluted vas.

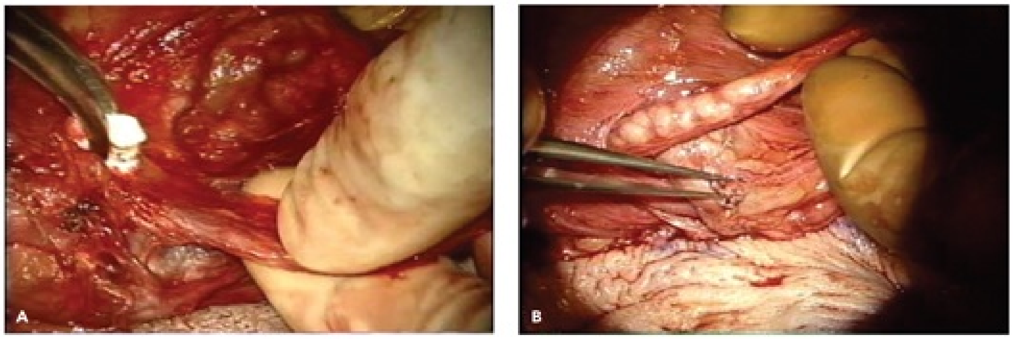

FIGURE 52.13 **A and B:** The convoluted vas deferens is fully exposed.

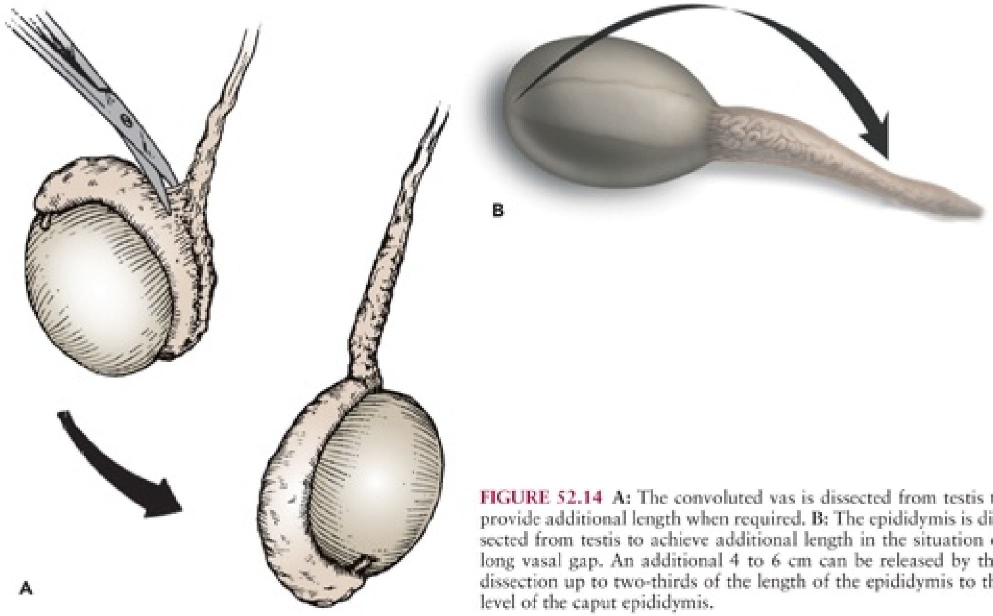

FIGURE 52.14 **A:** The convoluted vas is dissected from testis to provide additional length when required. **B:** The epididymis is dissected from testis to achieve additional length in the situation of long vasal gap. An additional 4 to 6 cm can be released by this dissection up to two-thirds of the length of the epididymis to the level of the caput epididymis.

Preparation of the Vasa Deferentia

The obstructed segment is excised including any associated vasectomy clips or sperm granuloma. Initial excision is performed on the testicular side with an ultrasharp knife and a slotted 2-mm, 2.5-mm, or 3-mm-diameter nerve-holding clamp (Accurate Surgical & Scientific Instruments Corp, Westbury, New York). The slotted nerve-holding clamp permits a perfect 90-degree transection (Figs. 52.14 to 52.16). Under 15× to 25× magnification, three distinct layers are visualized including the mucosa, muscularis, and adventitia. Healthy mucosa should be white and elastic and muscularis should be smooth and supple. Bleeding at each layer represents healthy blood supply. If the blood supply is in question, or if the muscularis is gritty and fibrotic, additional cuts in the same manner should be made until consistently healthy tissue is identified (see Fig. 52.16). The deferential artery and vein are ligated using 6-0 Vicryl. The micro-bipolar coagulation forceps, set at 2.5 to 3.5 watts, controls small bleeders, but caution should be exercised to avoid mucosal thermal injury.

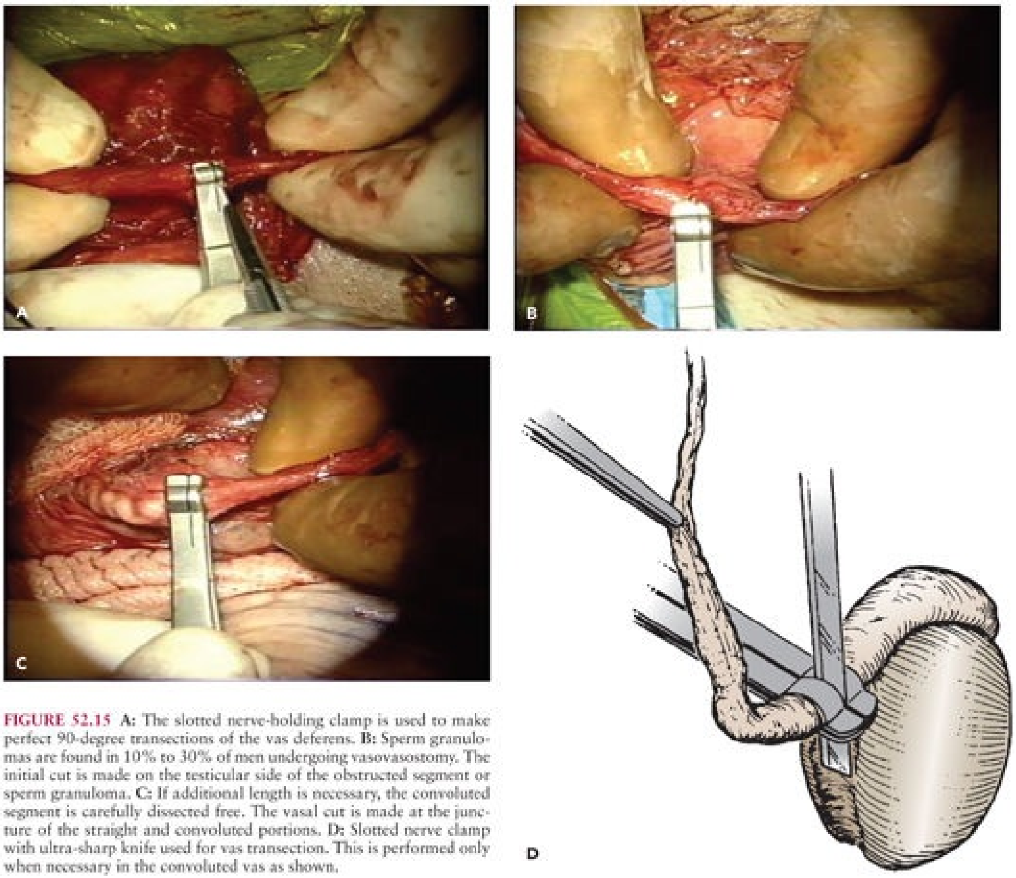

FIGURE 52.15 **A:** The slotted nerve-holding clamp is used to make perfect 90-degree transections of the vas deferens. **B:** Sperm granulomas are found in 10% to 30% of men undergoing vasovasostomy. The initial cut is made on the testicular side of the obstructed segment or sperm granuloma. **C:** If additional length is necessary, the convoluted segment is carefully dissected free. The vasal cut is made at the juncture of the straight and convoluted portions. **D:** Slotted nerve clamp with ultra-sharp knife used for vas transection. This is performed only when necessary in the convoluted vas as shown.

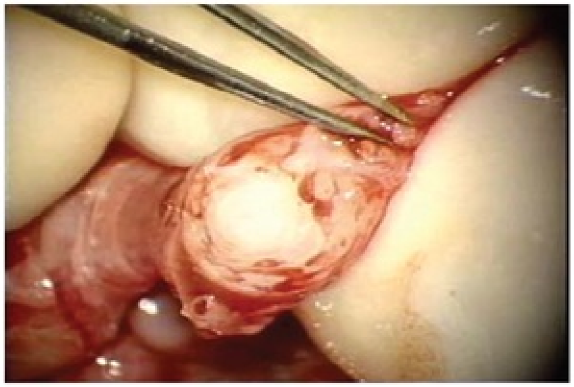

FIGURE 52.16 An unhealthy segment of vas deferens demonstrates white, avascular vasal layers surrounded by fibrotic scar tissue.

Examination of Vasal Fluid

The testicular end of the vas deferens is milked until fluid is expressed and a touch prep is completed using a glass slide (Fig. 52.17). The fluid is mixed with a single drop of lactated Ringer solution and a cover slip is mounted. The slide is immediately examined under 40× power magnification with a separate bench microscope setup in the OR (Fig. 52.18). The Practice Committee of the American Society for Reproductive Medicine (28) (ASRM Guidelines) grades the sperm quality of vasal fluid as follows: grade 1, mainly normal motile sperm; grade 2, mainly normal nonmotile sperm; grade 3, mainly sperm heads; grade 4, only sperm heads; and grade 5, no sperm. Vasovasostomy is the ideal approach for grades 1 through 4. If no sperm are identified in the vasal fluid (grade 5), the gross appearance of the vasal fluid is used to select between vasovasostomy and vasoepididymostomy (Table 52.1). Copious, crystal clear waterlike fluid squirting from the testicular end of the vas even when no sperm are found in this fluid initially is usually associated with return of sperm to the ejaculate after vasovasostomy. In fact, resampling of the fluid again just prior to tying the last mucosal suture often reveals rare long-tailed, even motile, sperm. Thick, white, water-insoluble toothpaste-like material indicates epididymal obstruction necessitating vasoepididymostomy (Fig.

52.19). Although a standard algorithm has not been established, vasovasostomy is completed when complete sperm or copious sperm heads, especially with occasional short tails, are identified in the vasal fluid or when fluid is copious and watery. Vasoepididymostomy should be elected if the vasal sperm is absent after barbitage or if the fluid is thick, white, and creamy and devoid of sperm or sperm parts. If no fluid can be expressed for evaluation, the testicular end of the vas deferens is barbitaged with 0.1 mL of saline using a 24-gauge angiocatheter sheath, and the expressed fluid is examined (Fig. 52.20). With large sperm granulomas, the testicular end of the vas is minimally dilated with very little or no luminal fluid; barbitage with milking often expresses a small amount of fluid containing long-tailed, even motile, sperm.

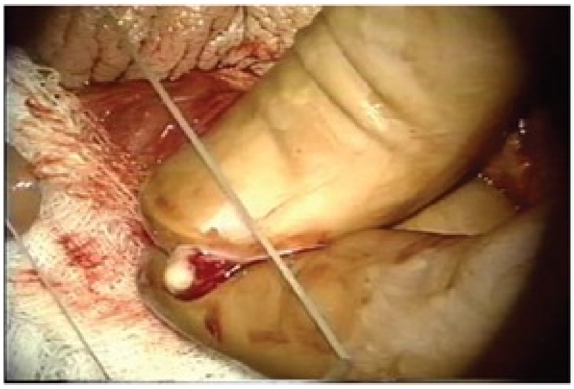

FIGURE 52.17 A touch prep of the vasal fluid is made by blotting the freshly cut testicular portion of the vas deferens onto a glass slide.

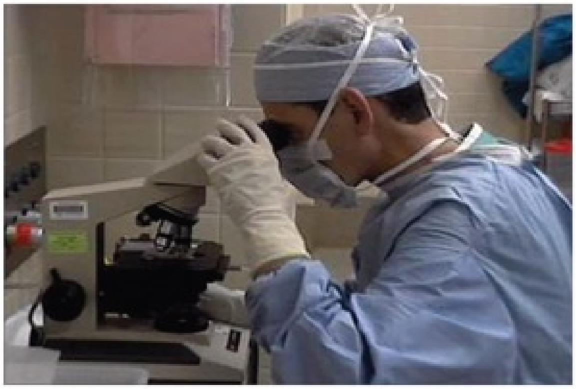

FIGURE 52.18 A separate microscope setup should be used to examine the vasal fluid under 40× magnification.

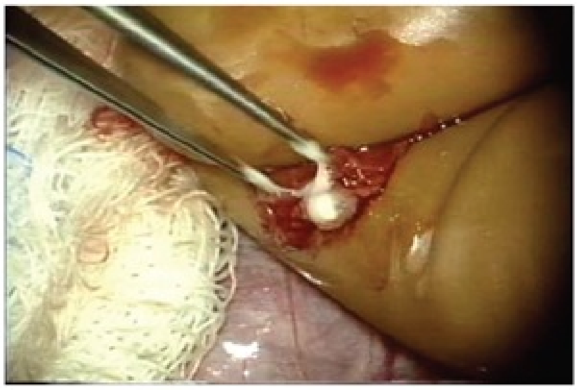

FIGURE 52.19 A thick, greasy, "toothpaste" consistency indicates a poor prognosis for sperm in the vasal fluid.

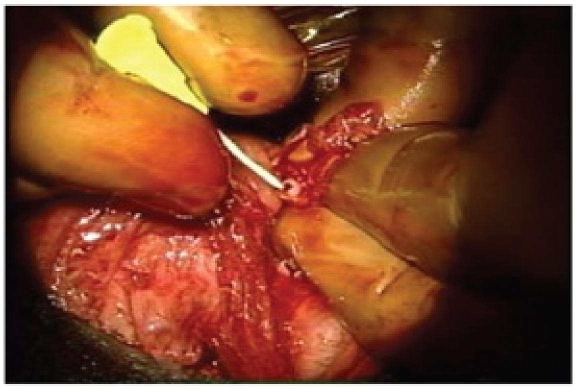

FIGURE 52.20 If the vas deferens is "dry," a 24-gauge angiocatheter sheath is used to barbitage the lumen with saline.

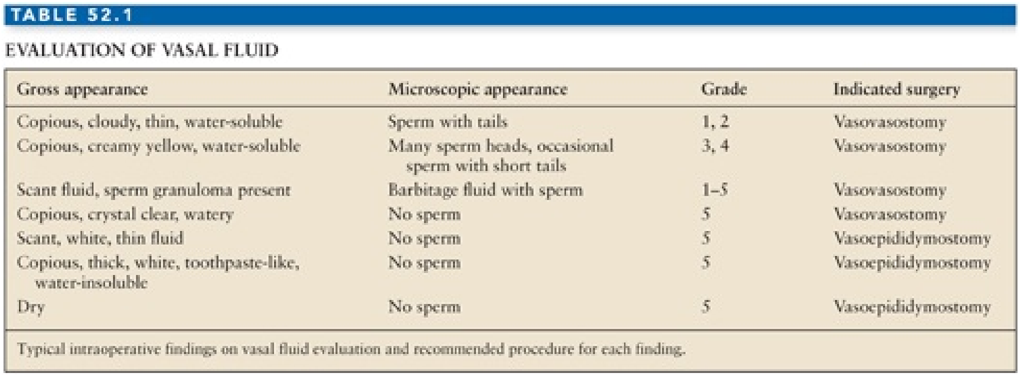

TABLE 52.1

EVALUATION OF VASAL FLUID

Gross appearance	Microscopic appearance	Grade	Indicated surgery
Copious, cloudy, thin, water-soluble	Sperm with tails	1, 2	Vasovasostomy
Copious, creamy yellow, water-soluble	Many sperm heads, occasional sperm with short tails	3, 4	Vasovasostomy
Scant fluid, sperm granuloma present	Barbitage fluid with sperm	1–5	Vasovasostomy
Copious, crystal clear, watery	No sperm	5	Vasovasostomy
Scant, white, thin fluid	No sperm	5	Vasoepididymostomy
Copious, thick, white, toothpaste-like, water-insoluble	No sperm	5	Vasoepididymostomy
Dry	No sperm	5	Vasoepididymostomy

Typical intraoperative findings on vasal fluid evaluation and recommended procedure for each finding.

The abdominal end of the vas deferens is similarly transected and inspected. The lumen is gently dilated with a microvessel dilator and approximately 1 mL of saline is gently injected with a tuberculin (TB) syringe attached to a 24-gauge angiocatheter sheath to confirm patency without resistance. If there is any question, a Foley catheter with 5-mL balloon (inflated with air) is placed gently against the bladder neck. One milliliter of indigo carmine (1:1 ratio with lactated Ringer) is injected into the abdominal vas, with blue urine confirming patency. Additional tests to identify obstruction location include passage of a 2-0 prolene suture (non-needle end) into the lumen of the abdominal vas (with a clamp placed on the suture when it meets obstruction) to calculate distance to the location of an inguinal obstruction. Finally, formal vasogram may be completed with 0.5 mL of injected water-soluble radiographic contrast injected using a no. 3 whistle-tip ureteral catheter to identify obstruction while a Foley catheter with 5 mL balloon is placed gently against the bladder neck. Vasography must be performed with microsurgical technique because poor vasotomy closure can result in stricture formation, sperm granuloma, or obstruction at the vasography site. In assessing patency of the testicular and abdominal ends of the vasa deferentia, the surgeon must assess both the left and right sides before proceeding with reconstruction. Often, a crossed vasovasostomy or vasoepididymostomy is the best solution for complex problems such as a patent abdominal vas on one side where there is also epididymal obstruction, or a nonfunctioning testis and an obstructed inguinal vas or ejaculatory duct on the contralateral side where sperm are found in the testicular vas.

Vasovasostomy: Anastomosis of the Vasa Deferentia

In preparation for the anastomosis, the two ends of the vas deferens are stabilized without tension with a microspike approximating clamp (Fig. 52.21) (29). A tongue blade encased in a 1-inch Penrose drain provides a suturing platform (Fig. 52.22). The entire setup is brought up through a slit in a rubber dam (Fig. 52.23). The rubber dam provides a contrasting field for the black suture visualization and prevents sutures from adhering to surrounding tissue.

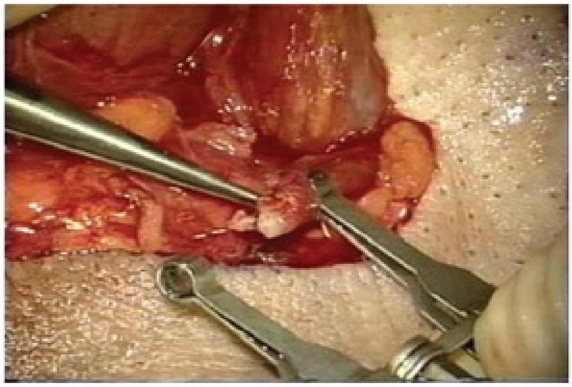

FIGURE 52.21 The microspike approximating clamp stabilizes the two ends of the vas deferens for suturing.

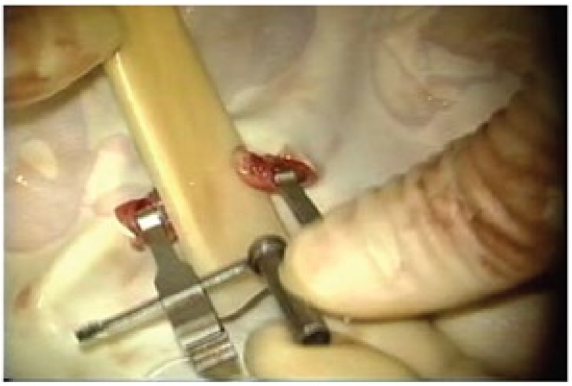

FIGURE 52.22 A tongue blade wrapped with 1-inch Penrose drain provides a platform for suture placement.

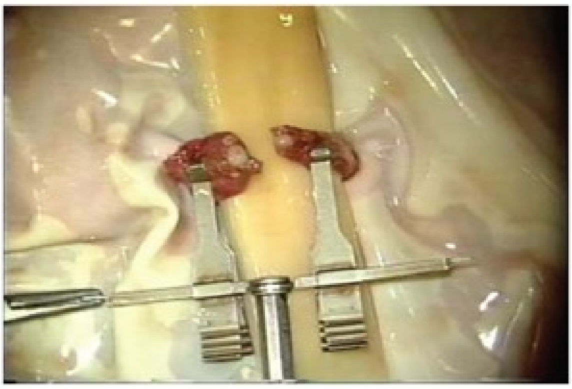

FIGURE 52.23 A rubber dam prevents sutures from sticking and getting lost in the surrounding tissue.

Microdot Technique for Multilayer Microsurgical Vasovasostomy

A microtip marking pen (Devon Skinmarker Extra Fine no. 151, Devon Industries, Buffalo, New York) is used to apply six equidistant dots on the face of each transected vas deferens; the dots of one vasal end should mirror those of the other end to obviate twisting or distortion of the anastomosis (Fig. 52.24A1, 52.24B, and 52.24C). The dots are made at 1, 3, 5, 7, 9, and 11 o'clock positions on the muscularis, approximately halfway between the adventitia and the mucosa. Unlike a single-layer anastomosis, this blueprint ensures precise suture placement and an ultimately watertight multilayer closure even with markedly discrepant luminal diameters (7,20).

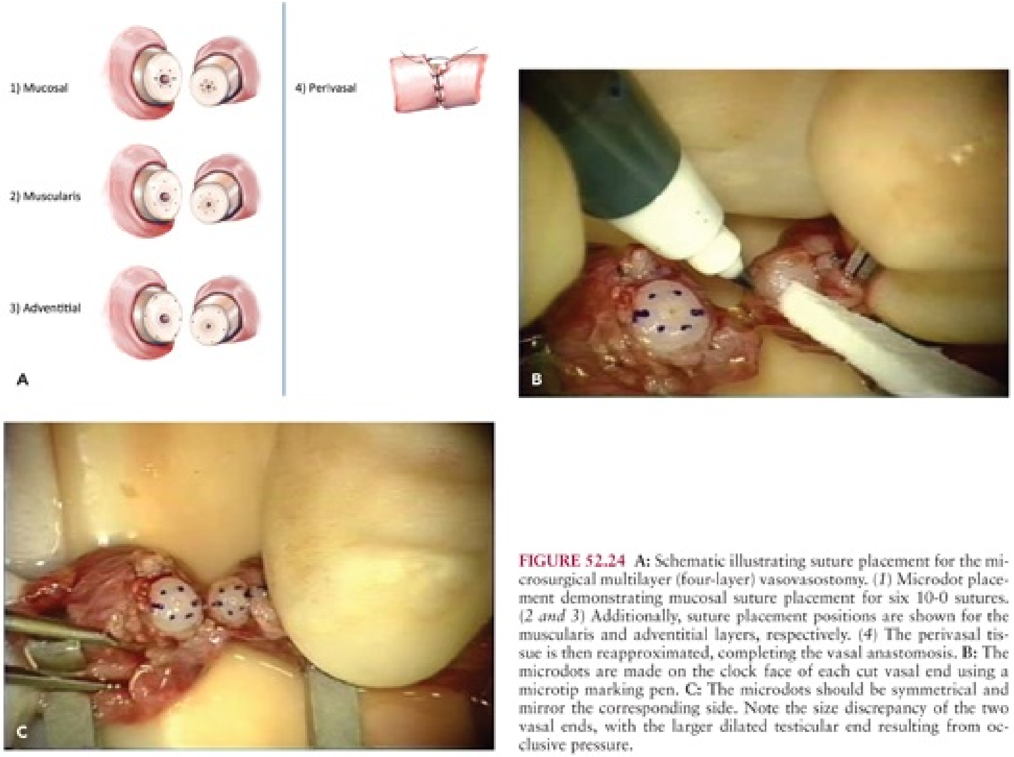

FIGURE 52.24 **A:** Schematic illustrating suture placement for the microsurgical multilayer (four-layer) vasovasostomy. (*1*) Microdot placement demonstrating mucosal suture placement for six 10-0 sutures. (*2 and 3*) Additionally, suture placement positions are shown for the muscularis and adventitial layers, respectively. (*4*) The perivasal tissue is then reapproximated, completing the vasal anastomosis. **B:** The microdots are made on the clock face of each cut vasal end using a microtip marking pen. **C:** The microdots should be symmetrical and mirror the corresponding side. Note the size discrepancy of the two vasal ends, with the larger dilated testicular end resulting from occlusive pressure.

Six monofilament 10-0 nylon double-armed sutures with 70-micron-diameter taper-point needles (Sharpoint, Surgical Specialties Corp, Reading, Pennsylvania, or Ethicon, Inc, Somerville, New Jersey) are placed initially at the three anterior positions in the mucosal layer (Figs. 52.25 and 52.26). Each suture begins within the lumen and exits at the dot. Such inside-out placement of the sutures minimizes mucosal manipulation and reduces risk of back-walling of the vas lumen. The mucosal lumen can be stained with indigo carmine and the tiny abdominal-side lumen gently dilated with the microvessel dilator just prior to suture placement (Fig. 52.27). Although methylene blue causes an immediate reduction in sperm motility and should be avoided in reversal surgery, indigo carmine may be safely used (30). Each suture should include a small amount of mucosa and one-third to one-half of the muscularis, with equal amounts of tissue included on each side. After the three anterior mucosal sutures are tied (Fig. 52.28A), the second layer of two monofilament 9-0 nylon deep muscularis sutures are placed in between these three, without including the mucosa, and tied (Figs. 52.24A2, 52.28B, and 52.28C).

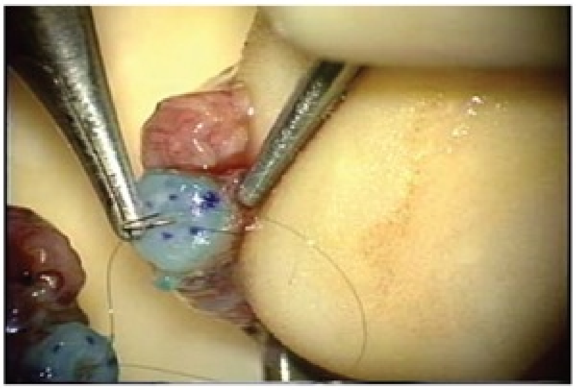

FIGURE 52.25 The placement of the 10-0 nylon mucosal sutures is guided by the microdots. Additional fine-tuning of the suture placements can be made at the surgeon's discretion.

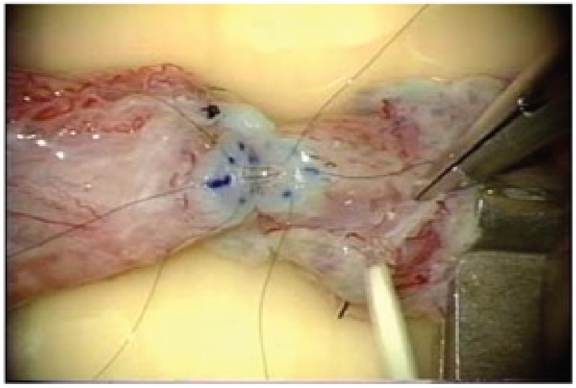

FIGURE 52.26 Three anterior mucosal sutures are placed and tied.

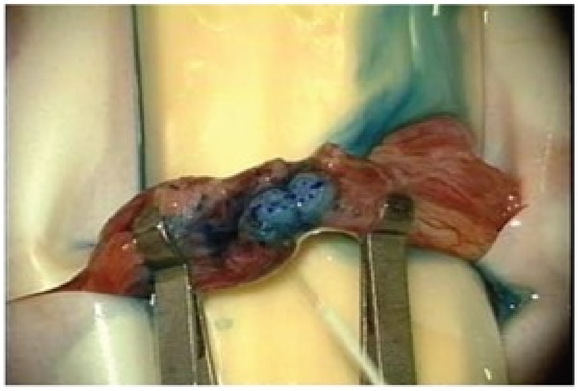

FIGURE 52.27 Visualization of the mucosal edge is improved with the application of indigo carmine.

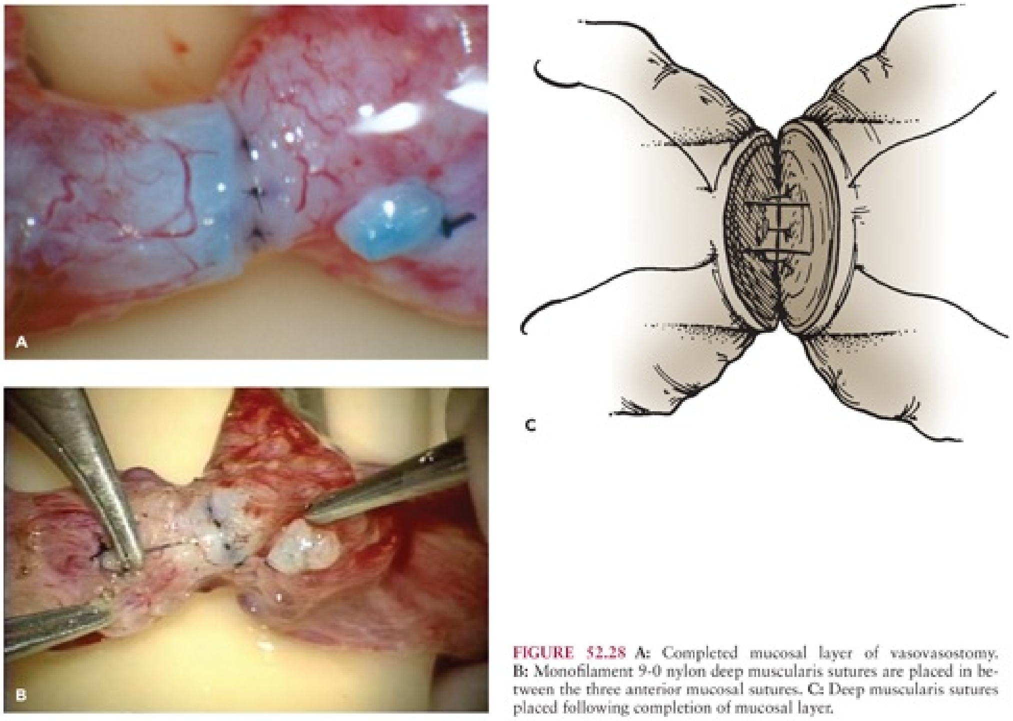

FIGURE 52.28 A: Completed mucosal layer of vasovasostomy. B: Monofilament 9-0 nylon deep muscularis sutures are placed in between the three anterior mucosal sutures. C: Deep muscularis sutures placed following completion of mucosal layer.

The vas deferens is then rotated 180 degrees and the remaining three mucosal sutures are placed in a similar fashion (Fig. 52.29A–C). Prior to tying of the final mucosal suture, the vasal lumen is irrigated with heparinized lactated Ringer solution to inhibit clot formation. Four deep muscularis 9-0 monofilament sutures are placed between the recently placed mucosal sutures for a circumferential two-layer closure (see Fig. 52.24A2). Four to six monofilament 9-0 nylon sutures placed between the deep muscularis sutures within the adventitia constitute the third layer of closure (Figs. 52.24A3, 52.30A, and 52.30B). Finally, the vasal sheath is reapproximated using six interrupted 8-0 nylon sutures which protect the anastomosis from tension and enhance vascularization across the anastomosis (Figs. 52.24A4, 52.30C, and 52.31).

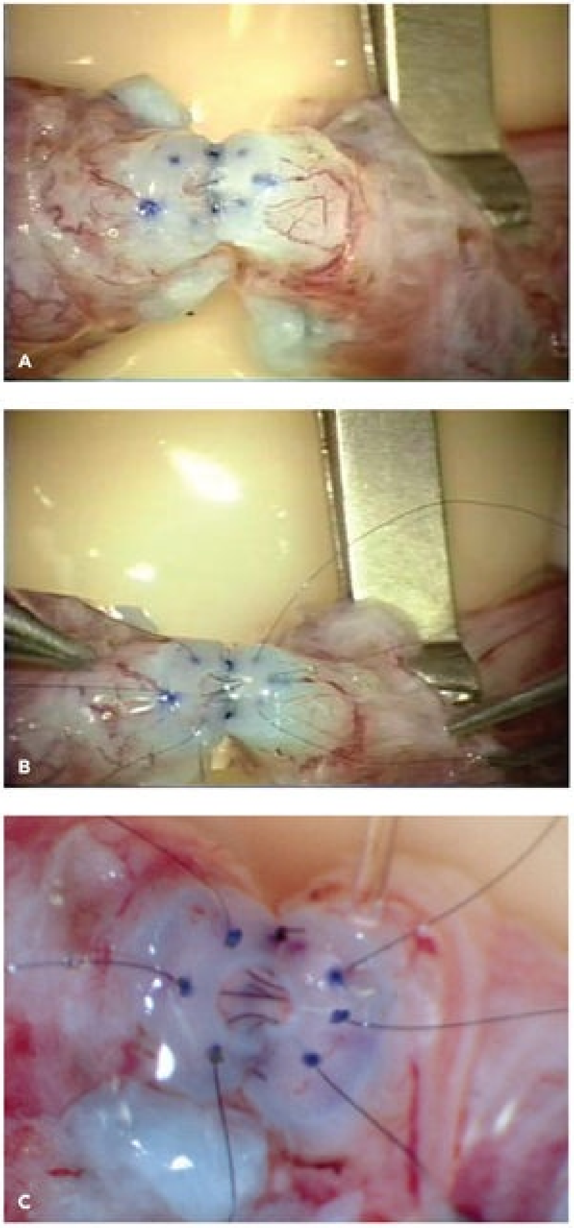

FIGURE 52.29 **A:** The vas deferens is rotated 180 degrees for placement of the remaining sutures. **B:** The sutures are placed in the same sequence as on the other side. **C:** Magnified view of placed mucosal sutures prior to tying. Mucosal sutures placed on second side prior to tying.

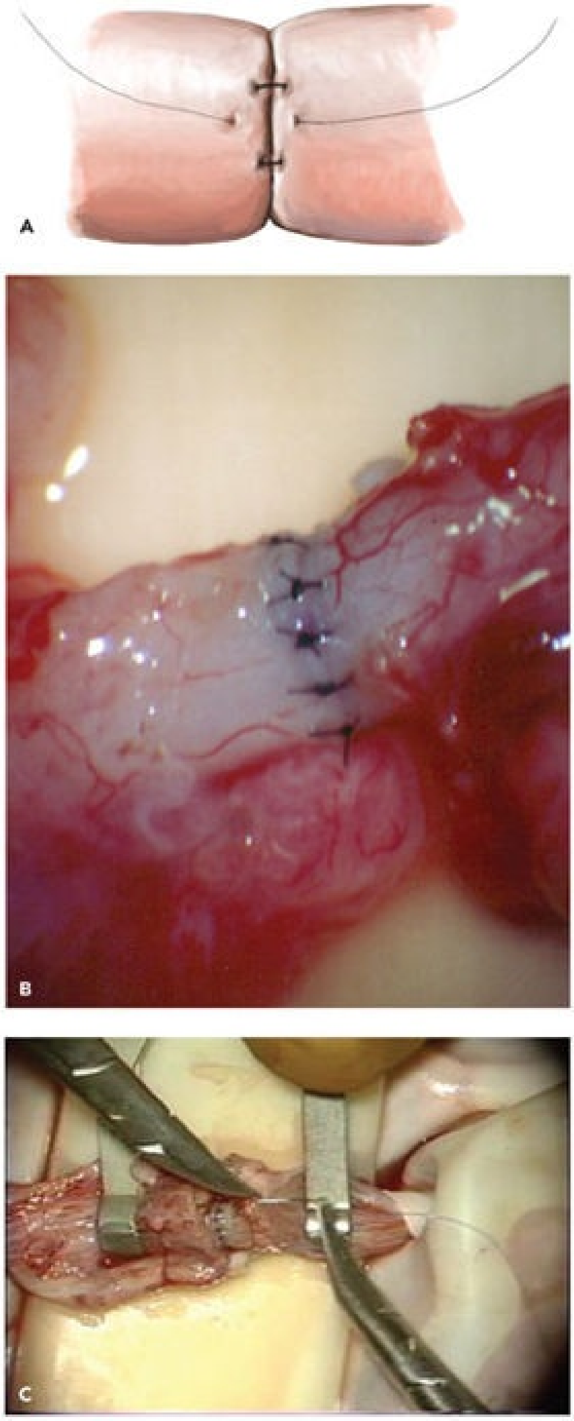

FIGURE 52.30 **A:** Following completion of muscularis layer, adventitial layer is completed (see also Fig. 52.24A3). **B:** Completed mucosal, muscularis, and adventitial sutures of anastomosis. **C:** The vasal sheath is then reapproximated with 8-0 nylon sutures, covering and protecting the anastomotic sutures.

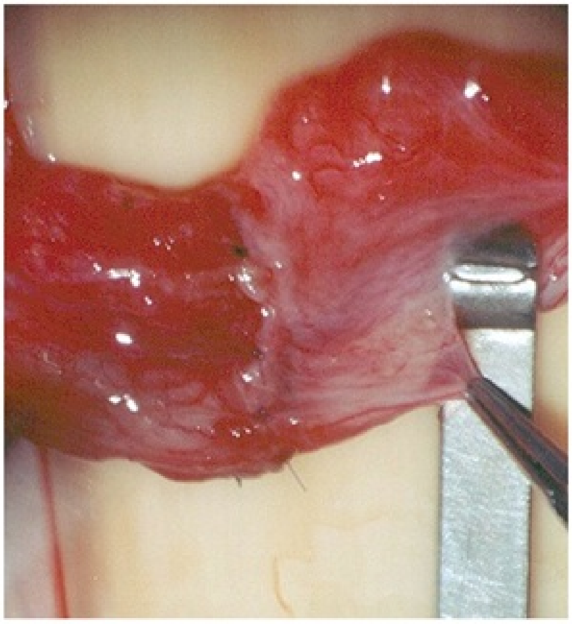

FIGURE 52.31 Completed vasovasostomy multilayer anastomosis with precise apposition of vasal ends in watertight fashion.

Vasovasostomy outcomes are optimized by mucosa-to-mucosa approximation of healthy well-vascularized tissue with minimal handling using atraumatic technique. The anastomosis should be leak-proof and tension-free. Because sperm are highly antigenic, precise anastomosis is required because sperm leakage can develop into a sperm granuloma and provoke an inflammatory reaction, potentially leading to failure of vasovasostomy (7,31). Tension on the anastomosis may result in delayed stricture and failure after an initial period of sperm in the ejaculate.

Closure

Following completion of the four-layer anastomosis, the dartos layer is reapproximated with interrupted 4-0 Monocryl followed by subcuticular skin closure with 5-0 Monocryl (Fig. 52.32). Penrose drains may be required with extensive dissection (Fig. 52.33). If drains are used, explicit instructions are provided for the patient to remove them at home the following day.

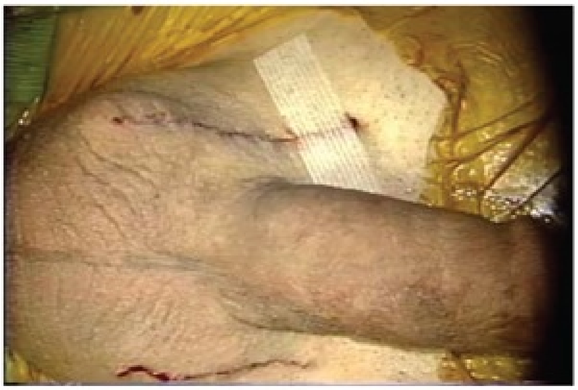

FIGURE 52.32 After closure, the nonscrotal portion of the incision is reinforced with adhesive skin-closure strips.

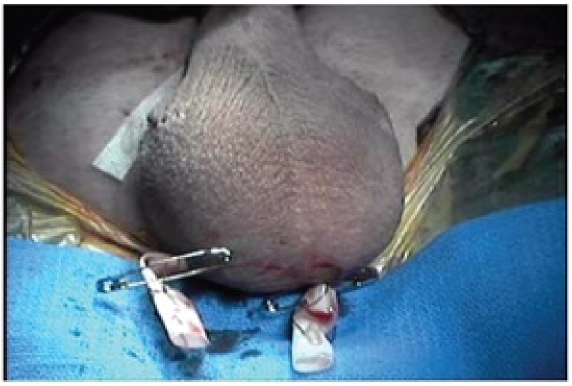

FIGURE 52.33 Penrose drains exiting the dependent portion of the scrotum provide wound drainage for cases involving extensive dissection.

Special Circumstances

If unhealthy tissue or blood supply results in cutback of the testicular portion of the vas deferens to the convoluted segment (Figs. 52.13A, 52.13B, and 52.14), anastomosis to the convoluted portion of the vas deferens uses the same principles as the standard anastomosis, with several additional considerations. A perfect 90-degree transection must be achieved; the convoluted segment is even more vulnerable to an oblique cut, resulting in insufficient mucosa and muscularis on one side. During dissection, care should be taken to preserve the blood supply without unraveling the convoluted vas. During suturing, taking too large bites of the convoluted segment increases the risk for perforation or obstruction of adjacent convolutions. Among patients undergoing vasectomy reversal involving the convoluted vas deferens, the patency and natural pregnancy rates range from 88% to 98% and 48%, respectively, comparable to outcomes with standard techniques (32,33).

The fundamental guiding principle is that one good anastomosis is superior to two tenuous connections. For example, if right epididymal obstruction and a left abdominal vas blockage are encountered, a single transeptal crossed vasovasostomy should be performed. Specifically, crossed vasovasostomy should be considered in the following circumstances: (a) unilateral inguinal obstruction of the vas deferens with an atrophic contralateral testis or (b) obstruction or aplasia of the inguinal vas or ejaculatory duct with a contralateral epididymal obstruction. Although this technique requires making a copious opening of the scrotal septum, it is greatly preferably to inguinal vasovasostomy.

In a less frequently encountered scenario, significant shortage of vasal length during a crossed vasovasostomy may warrant a testicular transposition (34). This maneuver takes advantage of the superior length of the spermatic cord to the vas deferens. Tension on the vas deferens is relieved by transferring the testes to the contralateral hemiscrotum via an opening in the septum. If multiple vasal obstructions are identified, such as concomitant ipsilateral vasectomy and inguinal hernia repair, two simultaneous vasovasostomies cannot be performed because blood supply to the intervening segment would be compromised. These situations are often solved with crossed vasovasostomy, vasoepididymostomy, and, if reconstructible bilaterally, epididymal aspiration with cryopreservation for future IVF/ICSI.

Postoperative Care and Follow-up

Vasectomy reversal is performed on an ambulatory basis. Prior to discharge, bacitracin ointment and sterile gauze dressing are applied to the closure site, followed with fluff-type gauze and snug-fitting athletic supporter. The supporter should be worn at all times, even at night, for 6 weeks. Thereafter, the supporter is worn during athletic activity until pregnancy is achieved. Light activity may be resumed in 3 days and heavy activity in 3 weeks. The patient is advised to avoid sexual activity and ejaculation for 4 weeks. Postoperative pain control includes hydrocodone with acetaminophen and a nonsteroidal anti-inflammatory drug. Semen analyses are obtained at 1, 3, and 6 months after surgery and every 6 months thereafter.

Complications

Vasovasostomy is a safe procedure with low risk for significant complications. Hematoma formation is the most common acute complication of vasectomy reversal surgery, occurring in 0.3% of patients in our series of 2,100 cases (M. Goldstein, unpublished data). All resolved in 6 to 12 weeks with conservative management. No wound infections occurred. Sperm granulomas, which often precede eventual obstruction, formed in about 5% of our patients (M. Goldstein, unpublished data). Obstruction and recurrent stricture with secondary azoospermia are other possible complications (35).

VASOEPIDIDYMOSTOMY

Vasal obstruction from prior vasectomy may promote increased intraluminal pressure, microrupture, and obstruction of delicate epididymal tubules leading to secondary epididymal obstruction in up to 60% of men 15 years postvasectomy (36). If iatrogenic postvasectomy vasal obstruction is excluded, primary obstructive azoospermia occurs most commonly due to bilateral obstruction of the epididymides. Optimal management of obstructive azoospermia resulting from epididymal obstruction includes microsurgical reconstruction with vasoepididymostomy.

Vasoepididymostomy (VE) is a safe, efficacious procedure but is considered to be the most technically challenging surgery among male reproductive microsurgical procedures. Following early reports of VE with low success rates, the application of the operating microscope in the late 1970s for microsurgical end-to-end single-tubule anastomosis (introduced by Silber) (37) and end-to-side anastomosis (described by Wagenknecht et al.) (38) initiated the modern era of VE with patency rates of up to 50% and 70%, respectively. Berger (39) popularized a triangulation technique using tubular intussusception with three double-armed microsutures placed to an epididymal tubule in a triangular manner. Marmar (40) subsequently altered this technique to include only two microsutures placed perpendicularly to the epididymal tubule for the anastomosis. Chan et al. (41) pioneered the placement of these two microsutures longitudinally in relation to the epididymal tubules, facilitating longitudinal incision of the tubules (longitudinal intussusception vasoepididymostomy [LIVE]) with increased lumen diameter for epididymal inflow at the anastomosis (42). The LIVE technique, our technique of choice, establishes precise apposition of the vasal lumen (300 to 400 μm) to the epididymal tubule lumen (150 to 250 μm) and has resulted in improved vasoepididymostomy outcomes (see “Outcomes” section). The advantages of the LIVE technique include providing 4-point fixation at the mucosal anastomosis using two double-armed microsutures. The LIVE technique’s watertight outer-layer anastomosis between the vasal sheath and epididymal tunic is crucial to avoid leakage of fluid, which can lead to formation of sperm granuloma (43).

Diagnosis

A comprehensive history and physical examination provides essential information that may confirm the diagnosis of epididymal obstruction. The most frequent cause of epididymal obstruction in the United States is prolonged vasal obstruction following vasectomy. Additional history suggesting alternate causes of obstruction includes prior epididymitis or orchitis, surgery, instrumentation, or trauma to pelvis, scrotum, prostate, or urethra. Family history of cystic fibrosis indicates that the patient could be a carrier of mutations in the cystic fibrosis transmembrane conductance regulator (CFTR) gene which is associated with congenital unilateral absence of vas deferens (CUAVD) or bilateral absence of vas deferens (CBAVD) with concomitant epididymal obstruction.

Physical examination should include comprehensive assessment of the scrotum, vas deferens, testes, and epididymides. Findings indicative of epididymal obstruction include vasectomy (performed in the proximal convoluted vas), abnormal epididymis (full, indurated, or irregular), epididymal cysts with normal testicular volume and texture, and extended duration since vasectomy (12,20,44,45). The presence of vasal sperm granuloma reduces the risk of epididymal obstruction (12). CBAVD on scrotal examination represents another finding consistent with obstruction of the excurrent ductal system. Semen analyses demonstrating azoospermia with normal ejaculation volume, pH, and fructose level are consistent with isolated bilateral epididymal obstruction which should especially be investigated with extended CFTR genetic testing panels and female partner testing for men who demonstrate abnormalities (46–48).

The diagnoses of unilateral obstruction and partial epididymal obstruction are challenging to confirm, as these patients generally do not present with azoospermia, but rather with infertility with any combination of oligospermia, asthenospermia, and teratospermia. If unilateral or partial epididymal obstruction is suspected clinically, and vasoepididymostomy or other surgical reconstruction of the excurrent ductal system is considered, cryopreservation of sperm preoperatively should be considered as the semen profile may potentially decline significantly postoperatively if the reconstructive surgery is unsuccessful.

Epididymal obstruction is confirmed intraoperatively, with the presence of active spermatogenesis within the testis and the absence of sperm in a patent vas deferens. Although additional testing including cystoscopy, scrotal and transrectal ultrasound, computerized tomography, and magnetic resonance imaging may contribute information that is consistent with epididymal obstruction, these studies are not sufficiently sensitive or specific to diagnose epididymal obstruction and are generally not required before vasoepididymostomy.

A positive serum antisperm antibody assay confirms active spermatogenesis and obviates the need for a testis biopsy (16). Active spermatogenesis must be confirmed prior to reconstruction of the excurrent ductal system. If the antisperm antibody assay is negative, which is the case in 30% of men who are obstructed, confirmation of active spermatogenesis may be completed by bilateral testicular biopsy performed either as an isolated preliminary procedure or at the time of planned reconstruction in the event that the epididymal tubules are dilated. The presence of many sperm on a touch or squash prep confirms active spermatogenesis (4). Alternatively, cytologic examination of a percutaneous testicular aspiration for spermatozoa may confirm the presence of active spermatogenesis.

Indications

Vasoepididymostomy is the indicated management for obstructive azoospermia due to epididymal obstruction. Vasoepididymostomy should be performed using an epididymal tubule containing abundant sperm (motile or immotile) or sperm parts (heads and tails). Absence of abundant sperm or sperm parts indicates that the level of epididymal obstruction is located more proximally (toward the testicle), where the anastomosis should be performed. Vasoepididymostomy should not be attempted in the absence of vasa, when the vasal gap is too large to facilitate a tension-free anastomosis regardless of appropriate surgical maneuvers for tissue mobilization, or in the case of azoospermia due to nonobstructive azoospermia (primary testicular failure).

Alternative Therapy

In addition to microsurgical vasoepididymostomy, men with azoospermia resulting from epididymal obstruction (similar to those with vasal obstruction) may have surgical sperm retrieval from the epididymides (microscopic [MESA] or percutaneous [PESA] epididymal sperm aspiration) or from the testes (testicular sperm aspiration [TESA] or testicular sperm extraction [TESE]) for IVF/ICSI to achieve pregnancy with their partners (22). With the increasing availability and use of assisted reproductive technologies, the safety and efficacy of these technologies have improved significantly, although there is a small increase in birth defects and other abnormalities in offspring of babies conceived with IVF/ICSI (49). For couples with female partners of advanced reproductive age or with significant female-factor infertility, sperm retrieval in combination with ICSI can facilitate early conception (50).

Vasoepididymostomy Surgical Technique

For vasoepididymostomy, general anesthesia is preferred because even small movements are magnified by the operating microscope and may affect the anastomosis. In the absence of any clinical evidence of complicated obstruction, regional anesthesia with sedation can be employed in cooperative and motivated patients. Intraoperative intravenous antibiotics are used.

Preparation of the Vas

A high scrotal incision (see Fig. 52.3) facilitates adequate mobilization of the inguinal portion of the vas for tension-free anastomosis with the epididymis. When isolating the vas, its periadventitial sheath should not be stripped off because this would sacrifice its blood supply (see “Vasovasostomy,” “Exposure of the Vasa Deferentia” section). Because the epididymis naturally lies laterally in the posterior aspect of the testis, the vas should be mobilized and isolated lateral to the spermatic cord to permit direct contact with the epididymis for the anastomosis. For patients with previous vasectomy, the vas should be transected at the vasectomy site to determine whether the testicular vas contains sperm and whether a vasoepididymostomy is indicated. The cut surface of the testicular end of the vas deferens is inspected with the operating microscope under 15× to 25× magnification. A healthy, white, smooth, soft mucosal ring should be observed that springs back immediately following gentle dilation with a 2- to 3-mm microvessel dilator. If the blood supply is poor, the vas should be recut until healthy tissue is found.

In patients with primary epididymal obstruction without previous vasectomy, the vas is isolated at the junction of the straight and convoluted vas, where it is hemitransected with a 15-degree ophthalmic knife (see Fig. 52.13B). Vas transection at this site allows maximal length of straight vas to be preserved for a tension-free vasoepididymostomy. Vasal fluid is sampled and then evaluated under light microscopy. Absence of sperm and sperm parts in the vasal fluid indicates epididymal obstruction. By contrast, the presence of abundant motile sperm indicates the absence of epididymal obstruction, and evaluation of vasal patency distally (abdominal end) is essential to identify the location of the obstruction (see Fig. 52.20). Patency of the abdominal end of the vas should be confirmed by saline vasogram as described (in “Vasovasostomy” section). If patency is not certain, a dye vasogram with diluted indigo carmine should be performed as described. If patency is not confirmed, formal vasography can be used to locate the obstruction. Proper technique must be followed with gentle instillation of fluid because improper technique can result in stricture, granuloma formation, or obstruction. If obstruction toward the seminal vesicle end of the vas or ejaculatory ducts is identified and found not to be amenable to surgical reconstruction (simultaneous VE with transurethral resection of the ejaculatory ducts or scrotal vasoepididymostomy with inguinal vasovasostomy is usually unsuccessful). The hemitransected vas can be reapproximated in two layers using interrupted 10-0 and 9-0 microsutures.

Identification of the Appropriate Epididymal Tubule

Selection of the correct epididymal tubule location for anastomosis is not a random event. Epididymal tubule diameter increases gradually from caput to cauda. Anastomosing to a larger tubule may result in higher patency rate and the more distal along the epididymis, the higher the pregnancy rate. Once vasoepididymostomy is selected as the optimal reconstruction technique (with patent abdominal vas and sufficient vasal length), the testis is delivered within the tunica vaginalis outside of the wound. A longitudinal incision is made on the anterior aspect of the tunica vaginalis. With long-term epididymal obstruction, a small hydrocele is commonly observed upon opening the tunica vaginalis. The epididymis is then inspected under the operating microscope at 15× to 25× magnification to select an anastomotic site (just proximal to the site of suspected obstruction). Often, a discrete line of demarcation is noted, proximal to which (closer to the testicle) there are dilated epididymal tubules, and distal to which (toward the vas) the epididymis is soft with collapsed tubules.

If the level of obstruction in the epididymis is not clearly demarcated, choose a tubule distally and puncture it with a 10-0 needle to aspirate epididymal fluid and examine it microscopically. If sperm or abundant sperm parts are not found, proceed in an identical fashion proximally in the direction of the caput. Once sperm are identified, the puncture may be sealed with bipolar cautery, and the anastomosis may be performed several millimeters proximally along the epididymal tubule.

Preparation of the Epididymal Tubule and Vas Approximation

The epididymal tunic covering the tubule is thick and tough. By contrast, the bare epididymal tubule underneath is thin and delicate, and caution should be taken to avoid accidental puncturing, resulting in leakage of epididymal fluid and collapse of the tubule. Once a potential epididymal tubule for the anastomosis is identified, a relatively avascular, straight area of the epididymal tunica is grasped with sharp jeweler’s forceps and tented upward (Fig. 52.34A). A 3- to 4-mm buttonhole is made in the tunica with microscissors to create a round opening that approximates the outer diameter of the prepared vas deferens (Figs. 52.34 and 52.35). Because microsutures are to be placed longitudinally in the tubule, a straight tubule segment is preferable to one that is curved. This allows needle bites running further along the tubule and ultimately a longer incision to be made longitudinally between the two needles.

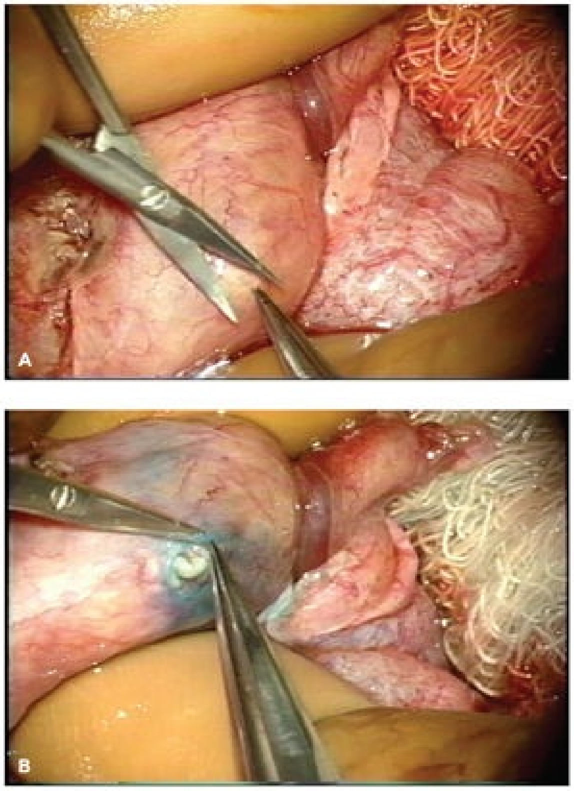

FIGURE 52.34 **A:** Once a potential epididymal tubule for the anastomosis is identified, a relatively avascular, straight area of the epididymal tunica is grasped with sharp jeweler's forceps and tented upward. **B:** A 3- to 4-mm buttonhole is made in the tunica with microscissors to form a round opening that approximates the outer diameter of the prepared vas deferens.

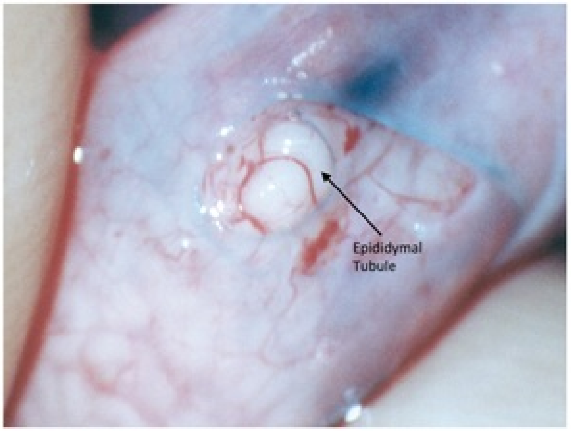

FIGURE 52.35 Epididymal tunic is precisely removed overlying selected epididymal tubule based on appearance which indicates an area below the obstruction.

After the initial cut on the epididymal tunic, there is often a thin layer of residual tunic covering the epididymal tubule. Use of indigo carmine on the tissue may enhance visualization of this overlying tunic (Fig. 52.34B). The residual tunica should be dissected off completely using sharp and blunt dissection to expose the bare epididymal tubule underneath and to facilitate its intussusception into the vasal lumen when completing the anastomosis.

The vas deferens is drawn up through an opening in the tunica vaginalis and secured in proximity to the anastomotic site with two to four interrupted 6-0 polypropylene sutures placed through the vasal adventitia and the tunica vaginalis. Care should be taken to avoid taking too deep a bite with the suture because this may result in accidental occlusion of the vasal lumen and failed surgery. The vasal lumen should reach the opening in the epididymal tunica easily, with length to spare (Fig. 52.36). To avoid tension or kinking of the vas, the surgeon should inspect the position and orientation of the vas when the testicle is delivered outside as well as when the testicle is replaced in its natural orientation into the scrotum. The posterior edge of the epididymal tunica is then approximated to the posterior edge of the vas muscularis and adventitia with two or three interrupted sutures of 9-0 nylon (see Fig. 52.36). This brings the vasal lumen in close approximation to the epididymal tubule selected for anastomosis. Adequate hemostasis of the vas and the epididymal tunic is essential, as the fluid in the epididymis cannot dissolve blood clot, which would be disastrous to the anastomosis.

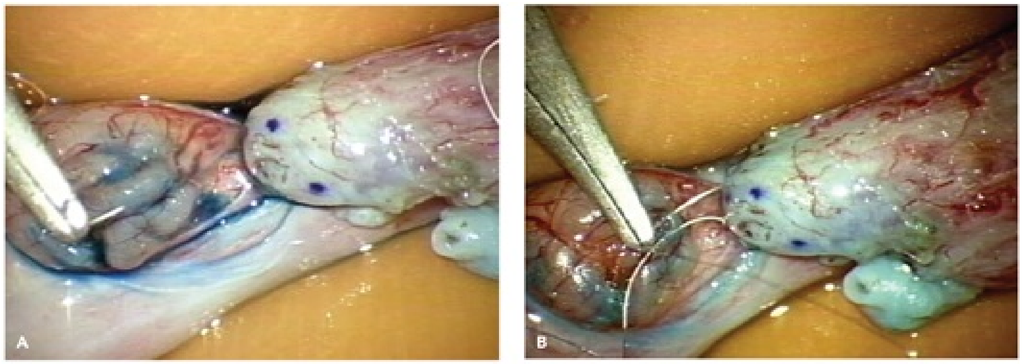

FIGURE 52.36 A: In preparation for vasoepididymostomy, the vas is secured on the edge of the tunica epididymis with two or three 9-0 sutures with its lumen opposing the midportion of the isolated epididymal tubule, prepared for placement of first of the double-armed 10-0 mucosal sutures in longitudinal fashion on the tubule. B: Placement of the second double-armed 10-0 mucosal sutures in a longitudinal fashion on the tubule.

Longitudinal Intussusception Vasoepididymostomy

The LIVE procedure is our preferred technique for microsurgical vasoepididymostomy, providing the highest patency rate among the various alternative techniques (39–41,51). To facilitate even distribution of the suture points, four microdots are placed with a microtip marking pen on the vasal ends to demarcate the exit points of the four suture needles to be placed in the vas (in a similar manner to the 6 microdot technique for vasovasostomy) (see Fig. 52.36). For the anastomosis, 1-inch monofilament 10-0 double-armed nylon sutures with 70-micron-diameter taper-point needles are used. Double-armed sutures allow inside-out placement of the needles on the mucosa, eliminating the need for manipulation of the mucosa and the possibility of back walling (see Figs. 52.39 to 52.41, see LIVE details).

As described, the vas is secured with 9-0 nylon sutures at the edge of the epididymal tunica opening, with the vasal lumen positioned at the center of the selected epididymal tubule. Under the highest magnification of the operating microscope (25× to 40×), the needles of two double-armed 10-0 microsutures are placed longitudinally on the epididymal tubule (Figs. 52.36 and 52.37). The microneedles should remain in the epididymal tubule until it is incised longitudinally. Because the diameter of the needle (70 microns) is significantly larger than the suture diameter (17 microns), pulling the needle through earlier will result in epididymal fluid leakage. Collapse of the epididymal tubule, along with impaired visibility from cloudy epididymal fluid, hinders visibility to make a precise opening in the tubule for the anastomosis or to place an additional suture if required.

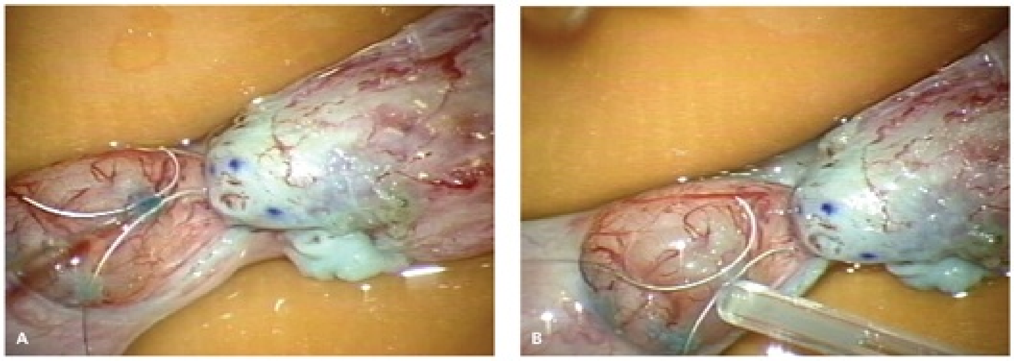

FIGURE 52.37 A: Two double-armed 10-0 mucosal sutures placed in longitudinal fashion on the tubule. B: Following initial placement, a longitudinal incision is made between the needles.

Using a 15-degree ophthalmic knife, the tubule is incised longitudinally between the two needles of the 10-0 sutures (Figs. 52.37B and 52.38). Epididymal fluid is then aspirated with a 5-microliter micropipette or with a 24-gauge angiocatheter connected to a syringe (see Fig. 52.37B). The fluid is examined for sperm under light microscopy intraoperatively.

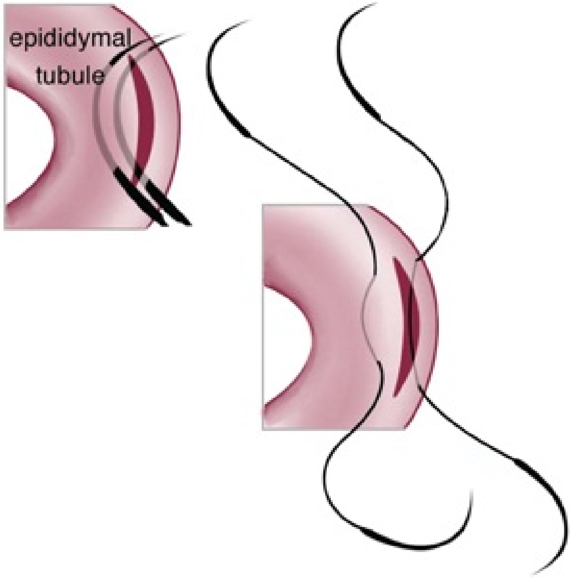

FIGURE 52.38 Following the incision made between the two needles (each from one double-armed suture), needles are subsequently pulled through.

If motile sperm are identified, cryopreservation of the sample should be considered for future use with ICSI if the anastomosis fails. Generally, if the level of the epididymal tubule is carefully selected, the fluid inside is likely to contain sperm or sperm parts. Absence of abundant sperm or sperm parts in the fluid indicates that obstruction is still proximal to the selected tubule segment. The anastomosis should be set up in the same manner as described at a more proximal site (closer to caput), and the same algorithm should be followed.

Following identification, suture placement, and incision of an optimal epididymal tubule, the needles of the two double-armed 10-0 sutures are then gently pulled through and placed to the vasal mucosa in an inside-out fashion through the four microdots (Fig. 52.39). Needle placement varies depending on whether the selected epididymal tubule for the anastomosis lies parallel (see Fig. 52.39) or perpendicular (Fig. 52.40) to the vas.

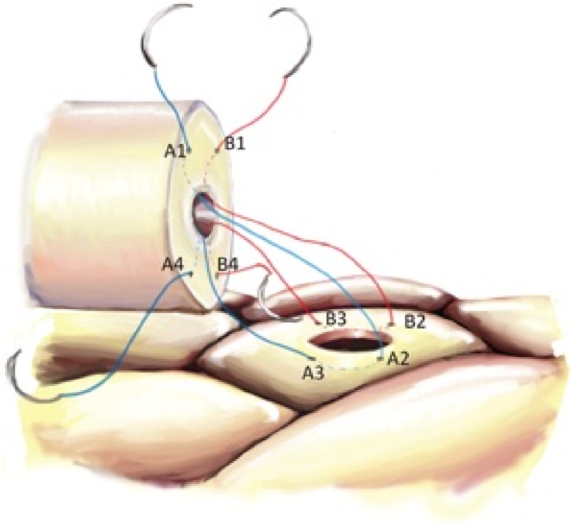

FIGURE 52.39 LIVE when the epididymal tubule lies parallel to the vasal lumen. Two-needle intussusception vasoepididymostomy. This technique allows the use of two double-armed sutures to provide a 4-point fixation on the vasal end for the anastomosis. 1: After pulling through the 10-0 mucosal sutures from the epididymal tubules, they are placed in inside-out fashion on the vasal end according to the plan for tying at the four denoted positions (*A1* and *A4* for one stitch; *B1* and *B4* for second stitch). 2: A 9-0 tension-reducing suture is placed to position the vasal lumen in direct opposition with the epididymal lumen prior to tying the mucosal sutures. Mucosal sutures are then tied to their own ends (suture end at *A1* tied to suture end at *A4*; suture end at *B1* tied to suture end at *B4*) to complete the anastomosis. 3: Ten to 12 9-0 sutures are placed on the vasal sheath and the tunica epididymis to complete the outer layer of the anastomosis.

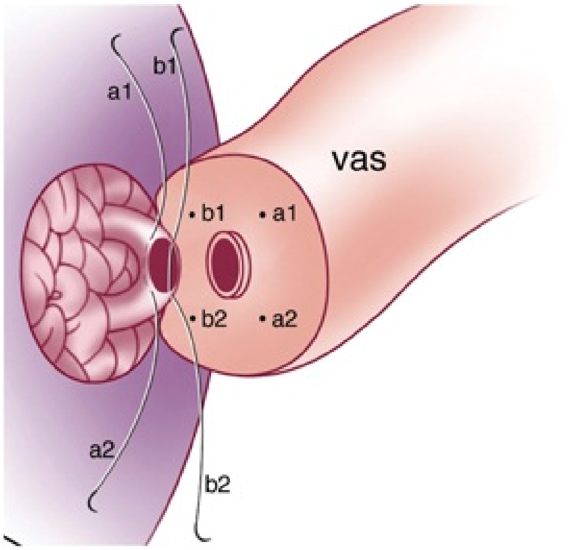

FIGURE 52.40 Placement of a double-armed microsuture for LIVE when the epididymal tubule is perpendicular to the vasal lumen. The numbers indicate suture placement. When the epididymal tubule is aligned perpendicular with the vasal lumen, each mucosal suture can be cross-tied with the end of the other mucosal suture (*a1* to *b1* and *a2* to *b2*) to complete the anastomosis.

Vasoepididymostomy: Completing the Anastomosis

To avoid tearing the 10-0 sutures out of the epididymal tubule during tying, it is essential to set up the vas to allow the vasal and epididymal lumina to be in direct apposition to each other. This is achieved by placing a 9-0 tension-reducing suture approximating the epididymal tunic to the vasal sheath prior to tying the 10-0 microsutures. This 9-0 suture is tied loosely to allow visualization of the anastomosis during tying of the 10-0 sutures. Just prior to tying, the ends of each of the 10-0 sutures should be gently pulled until the opposite end just begins to move. This prevents incorporation of a loose loop of excess suture into the anastomosis and ensures that the epididymal mucosa is plastered against the vasal mucosa prior to tying. When setting up the anastomosis, in order to achieve the lowest tension possible without kinking the vas, the vasal lumen usually may end up lying parallel (see Fig. 52.39) or perpendicular (see Fig. 52.40) to the direction of the epididymal tubule depending on anatomy. The ends of sutures for tying should be chosen carefully according to the orientation of the vas with respect to the direction of the epididymal tubule. In the setting when the vas and the epididymal tubules are parallel to each other, the two sutures are tied with their own ends on either side of the stay suture (see Fig. 52.39). By not tying until the free end moves, this assumes that the epididymal tubule is plastered against the inside of the vasal lumen. In the setting when the vas and the epididymal tubules are perpendicular to each other, it is not necessary to push the ends of the 10-0 sutures on the same side of the 9-0 tension-reducing suture to tie. Instead, the two 10-0 sutures can simply be cross-tied to each other. Modification of the LIVE technique for the use of a single-armed suture is feasible (Fig. 52.41, see "Technique" section). Finally, we recommend placing 10 to 12 interrupted sutures of 9-0 nylon for the outer layer closure approximating the vasal outer muscularis and adventitia to the cut edge of the epididymal tunica (Fig. 52.42). Care should be taken to avoid injury to the peripheral epididymal tubules during the placement of needles on the epididymal tunic.

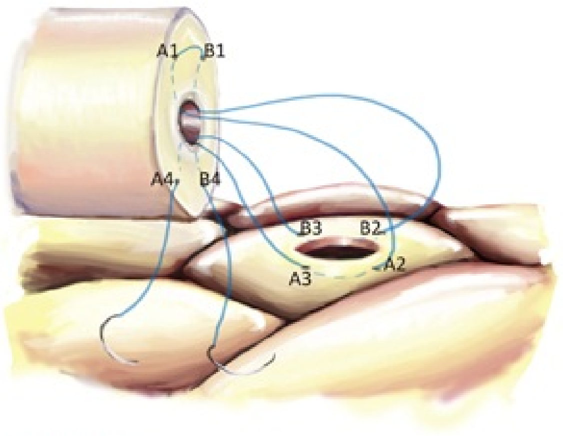

FIGURE 52.41 Placement of single long double-armed microsuture for LIVE when the epididymal tubule is parallel to the vasal lumen. The numbers indicate the placement of the first bites (1 and 2) of the two needles when the surgeon is right-handed.

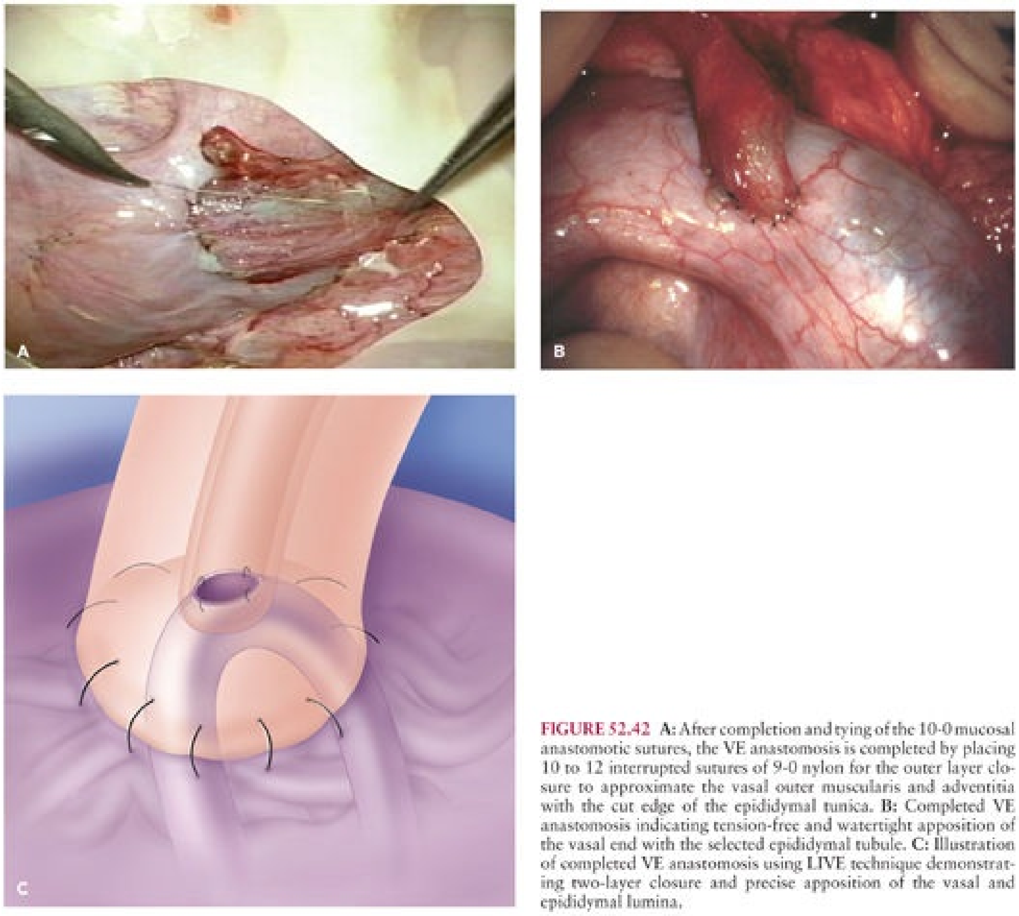

FIGURE 52.42 **A:** After completion and tying of the 10-0 mucosal anastomotic sutures, the VE anastomosis is completed by placing 10 to 12 interrupted sutures of 9-0 nylon for the outer layer closure to approximate the vasal outer muscularis and adventitia with the cut edge of the epididymal tunica. **B:** Completed VE anastomosis indicating tension-free and watertight apposition of the vasal end with the selected epididymal tubule. **C:** Illustration of completed VE anastomosis using LIVE technique demonstrating two-layer closure and precise apposition of the vasal and epididymal lumina.

Closure

After careful hemostasis and copious irrigation of the tissue, the tunica vaginalis should be closed with absorbable sutures and the testis returned intrascrotally in the correct orientation. The remaining closure is completed as for vasovasostomy. Care should be taken to avoid any tension when manipulating the testis and spermatic cord after the delicate anastomosis is completed. With careful control of hemostasis, the risk of scrotal edema or hematoma can be minimized and drainage is generally not necessary.

Maneuvers to Gain Extra Length to Bridge a Larger Gap

As mentioned in vasovasostomy technique, the simplest maneuver to gain length to bridge a larger gap for the anastomosis is mobilization of the abdominal vas superiorly toward the external inguinal ring. The skin incision may be extended toward the external inguinal ring. Care should be taken to avoid stripping the periadventitial sheath, which would compromise the vasal blood supply. When length of the vas deferens remains insufficient, the cauda and corpus epididymis can be dissected off the testis (from VE junction to the caput) and flipped up to obtain additional length without tension (see Fig. 52.14B). The full depth of the epididymis is encircled with a small Penrose drain at the level of obstruction and, under 8× to 16× magnification, it is dissected distally off the testis, yielding sufficient length to perform the anastomosis (10). Usually, a surgical plane can be developed between the epididymis and testis, and injury to the epididymal blood supply can be minimized by staying directly on the tunica albuginea of the testis. The inferior and, if necessary, the middle epididymal branches of the testicular artery are doubly ligated and divided to free an adequate length of epididymis. The superior epididymal branches entering the epididymis at the caput must always be preserved and can provide adequate blood supply to the entire epididymis. The tunica vaginalis is then closed over the testis with absorbable suture, which prevents drying of the testis and thrombosis of the surface testicular vessels during the anastomosis. The dissected epididymis can remain outside the tunica vaginalis for the anastomosis.

Use of Single-Armed Microsutures for Longitudinal Intussusception Vasoepididymostomy

LIVE can be performed using 10-0 single-armed sutures, which are less costly than the double-armed sutures (52). The disadvantage is that two of the four needle placements on the vasal end have to be done with outside-in approach. Two 10-0 sutures are initially placed on the vas in an outside-in fashion. If the selected epididymal tubule lies perpendicularly to the vasal lumen, it is recommended to place the two needles on the two dots on the same side as the dominant hand of the surgeon. If the selected tubule lies in parallel to the vas, the sutures can be first placed on the two upper microdots and then pulled through the vasal lumen. Insertion of a 2- to 3-mm microvessel dilator during the outside-in placement of the needle may further decrease the risk of back walling the vasal lumen mucosa. The LIVE procedure can then be performed in a similar fashion, with two needles placed on the epididymal tubules where a longitudinal incision is made between the needles. The sutures are then pulled through and placed to the remaining two microdots marked on the vasal end in an inside-out fashion to complete the anastomosis. Tying of the two single-armed sutures can follow the same principle as described previously (53).

Use of Long Double-Armed Microsutures for Longitudinal Intussusception Vasoepididymostomy

LIVE can be performed using a single long (6-inch) double-armed microsuture (see Fig. 52.41). Similar to the use of single-armed microsutures, the disadvantage is that two of the four needle placements on the vasal end have to be completed in outside-in fashion. The two needles at each end are first placed in the vas in outside-in fashion. If the selected epididymal tubule lies perpendicularly to the vasal lumen, it is recommended to place the two needles on the two dots on the same side as the dominant hand of the surgeon. If the selected tubule lies in parallel to the vas, the suture needles can be first placed on the two upper microdots (A1, B1) and then pulled through the vasal lumen (see Fig. 52.41). Insertion of a 2- to 3-mm microvessel dilator during the outside-in placement of the needle may decrease the risk of back walling vasal lumen mucosa. The LIVE procedure can then be performed in a similar fashion, with the two needles next placed on the epididymal tubules (in at A2 and out at A3 for one suture end, and from B2 to B3 for other suture end) where a longitudinal incision is made between the needles. The sutures are then pulled through and placed to the remaining two microdots marked on the vasal end (A4 and B4, respectively) in an inside-out fashion to complete the anastomosis (see Fig. 52.41). Because a single double-armed suture is used in this case, suture tying (A4 to B4 suture ends) needs to be done only once. Care must be taken to ensure there is no loose loop of suture before tying, so that leakage of epididymal fluid does not occur.

Surgical Caveats

Errors can occur at several crucial points of the surgery, requiring the anastomosis to be performed more proximally. Examples may include absence of sperm or sperm parts in the epididymal fluid, tearing of the epididymal tubule, or breakage of a mucosal suture. In any of these cases, a new position more proximally in the epididymis should be identified to redo the anastomosis. The surgeon should not become frustrated when it is necessary to redo the setup at a more proximal site (toward the caput epididymis). Although it is time-consuming to redo an anastomosis, the extra time is crucial. Vasoepididymostomy is a delicate operation where the outcome is highly dependent on technical perfection.

Postoperative Care and Follow-up

Postoperative care is identical to vasovasostomy. During the postoperative period, patients are advised to use an ice pack intermittently for 48 hours and to avoid strenuous activity and sexual intercourse for 3 weeks (to minimize the risks of disruption of the anastomosis due to the force of propulsion of the excurrent ductal system from orgasm). Scrotal support is recommended for 6 weeks to prevent hematoma and edema.

Postoperative semen analyses may be performed at 1, 3, and 6 months and every 6 months thereafter. Patients who have motile sperm return to the ejaculate should consider cryopreserving sperm, as initially patent anastomoses may eventually shut down. From our experience with the LIVE technique, the majority of patients who have a patent anastomosis will have sperm in the ejaculate in the first 6 months. Early patency was achieved in 73% of subjects at 4 to 6 weeks postoperatively with median best sperm count 12.9×10^6 per mL and 23% forward motility (54). Reports of sperm return to the ejaculate document that this could take up to 1 to 2 years following vasoepididymostomy including all techniques (55,56). However, it is rare for patients who have been persistently azoospermic in the first 6 months postoperatively to develop patency of anastomoses. The late “shutdown” rate, defined as the percentage of subjects who had sperm postoperatively but later became persistently azoospermic, was 4% at 1 year postoperatively in our patients. Persistently azoospermic men without cryopreserved sperm can select redo vasoepididymostomy or surgical sperm retrieval by various techniques combined with ICSI to achieve pregnancy with their partner (22).

Complications

Potential surgical complications associated with vasoepididymostomy are similar to vasovasostomy and include wound infection, scrotal edema, hematoma, orchalgia, and persistent epididymal obstruction (surgical failure). Most of these complications can be managed conservatively. More devastating complications such as ischemic epididymal fibrosis and testicular atrophy may be encountered rarely. The risk of complications increases with multiple previous unsuccessful reconstruction attempts, with significant tissue fibrosis from prior surgery (57), or in cases where additional dissection is required to mobilize the vas or the epididymis to bridge a larger gap for anastomosis.

Outcomes

Results

Preoperative and postoperative nomograms which account for age, testis volume, obstructive interval, prior reversal, reconstruction type, sperm granuloma, and intraoperative fluid quality have identified that testicular volume and obstructive interval are the factors that most significantly affect patency outcomes following vasectomy reversal (44). One of the largest published series by the Vasovasostomy Study Group demonstrated a patency rate of 86% and a pregnancy rate of 52% (20). In our published series of 194 consecutive cases, patency was achieved in 99.5% of vasovasostomy cases when sperm were found in the vasal fluid on at least one side intraoperatively (7). The pregnancy rate in the first 100 cases was 54%, which increased to 64% when female factor infertility was excluded. The LIVE technique, our preferred vasoepididymostomy approach, has resulted in improved vasoepididymostomy patency (90%, literature range 31% to 92%) and pregnancy (40%, literature range 10% to 50%) rates in both animal and human studies (see Fig. 52.39) (51,54,58,59). Numerous groups in addition to ours have subsequently demonstrated excellent LIVE technique results also for idiopathic obstructive azoospermia (60). Robotic-assisted LIVE has also been described (26,58).

It is established that type of reconstruction, duration of obstruction, type of fluid found in the vas deferens, and presence of sperm, particularly motile sperm (55), during reconstruction can affect procedure success (12,20). The requirement for vasoepididymostomy is predicted by postvasectomy obstructive interval and sperm granuloma (61). Pregnancy rates were 82% to 89% for obstructive intervals of 0 to 15 years but significantly lower, 44%, with obstructive intervals more than 15 years (12). Persistent azoospermia beyond 6 months after vasovasostomy and beyond 12 months after vasoepididymostomy is an indication of likely immediate surgical failure. Late failure approximately 14 months after initial patency was observed in 12% of men after vasovasostomy and in 21% after vasoepididymostomy (56). Late failure is usually preceded by progressive loss of motility on semen analyses, followed by decreasing sperm counts (56). Because of the possibility for late stricture formation, we recommend cryopreservation of semen specimens when motile sperm are found in the ejaculate. Failure of vasectomy reversal may be due to unrecognized epididymal obstruction and compromised anastomosis, among other causes. With patency and pregnancy rates of 67% and 30%, respectively, repeat vasectomy reversal surgery remains a viable option (57). Prognostic factors for successful initial vasectomy reversal also apply to repeat procedures.

Cost-Benefit Analyses

The decision for microsurgical reconstruction versus sperm retrieval options is complex, based on a multitude of factors including number of children desired, surgical history, prior fertility, maternal age, financial resources, microsurgeon experience, and religious beliefs. To address the comparison between microsurgical reconstruction and assisted reproductive technique (ART), several cost-benefit analyses have been conducted. Our institution has reported a cost per delivery after vasectomy reversal of $25,475 with a delivery rate of 47%, whereas the cost per delivery after sperm retrieval and ICSI was $72,521 with a delivery rate after one cycle of ART with sperm retrieval of 33% (8). Furthermore, a systematic review of four cost-benefit analyses comparing these two approaches also reported outcomes in favor of vasectomy reversal surgery for vasal and epididymal obstruction (62). Another study described the cost of MESA with ICSI/IVF to be nearly 2.5 times higher than vasectomy reversal, even in men with prior failed vasectomy reversal, in addition to the costs associated with multiple births and increased risk of birth defects (9,49,63).

Vasovasostomy and vasoepididymostomy are safe and cost-effective management options for postvasectomy infertility. Although the average interval to motile sperm in the ejaculate is 2.1 and 5.8 months, respectively, and average interval until pregnancy after successful microsurgical reconstruction is 16 months, microsurgical reconstruction has significant advantages over ART including that the normal partner avoids treatment and subsequent children are possible without the need for further intervention (56). The ASRM Guidelines recommend microsurgical reconstruction if the obstructive interval following vasectomy is less than 15 years and no female fertility risk factors are present (64). The use of ICSI with sperm retrieval is recommended with advanced female age (>37 years of age) or female fertility factors requiring IVF (i.e., tubal disease), if the chance for success is greater with this technique, or if the couple prefers this method for financial or other justification (64).

CHAPTER 53 MICROSURGICAL VARICOCELECTOMY

MARC GOLDSTEIN

Varicocele is by far the most commonly performed operation for the treatment of male infertility. Varicocele is found in approximately 15% of the general population, 35% of men with primary infertility, and in 75% to 81% of men with secondary infertility (1,2). Animal and human studies have demonstrated that varicocele is associated with a progressive and duration dependent decline in testicular function (1–9).

Repair of varicocele will halt any further damage to testicular function (5,6) and in a large percentage of men result in improved spermatogenesis (10–12) as well as enhanced Leydig cell function (13,14). The potentially important role of urologists in preventing future infertility and/or androgen deficiency underscores the importance of using a varicocelectomy technique that minimizes the risk of complications and recurrence.

DIAGNOSIS

Varicoceles are defined as dilations of the veins of the testicular pampiniform plexus, which are believed to be caused by absent or incompetent valves in the internal spermatic veins. The diagnosis of a clinically significant varicocele is generally made on physical examination of the scrotum and its contents. The patient is examined in the supine and standing position with the scrotum warmed first with a heating pad. This promotes relaxation of the scrotal dartos muscle and facilitates accurate evaluation for varicocele. The scrotum should be inspected carefully for any easily visible dilated veins. The spermatic cord should be palpated between thumb and forefinger for palpable tortuous veins. Both spermatic cords should be palpated while the patient performs a Valsalva maneuver in the upright position.

Varicoceles are graded I through III using the system outlined in Table 53.1. Grade I varicoceles are small, grade II moderate, and grade III large. Varicoceles should collapse in the supine position. If the varicocele remains prominent with the patient supine, this finding suggests a mechanical obstruction to testicular venous outflow from a retroperitoneal mass (sarcoma, lymphoma, or a renal tumor with venous thrombus). An abdominal ultrasound or computerized tomography scan should be obtained to evaluate the retroperitoneum in these men.

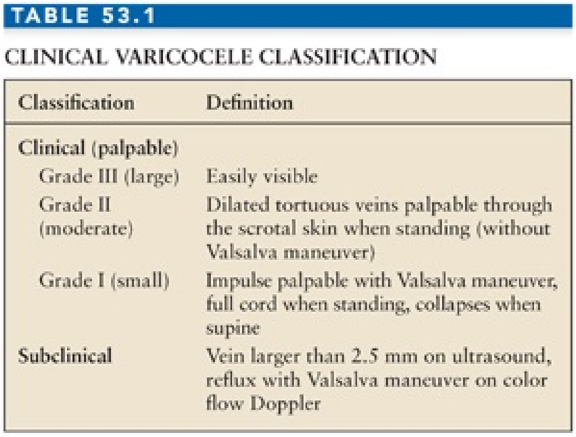

TABLE 53.1

CLINICAL VARICOCELE CLASSIFICATION

Classification	Definition
Clinical (palpable)	
Grade III (large)	Easily visible
Grade II (moderate)	Dilated tortuous veins palpable through the scrotal skin when standing (without Valsalva maneuver)
Grade I (small)	Impulse palpable with Valsalva maneuver, full cord when standing, collapses when supine
Subclinical	Vein larger than 2.5 mm on ultrasound, reflux with Valsalva maneuver on color flow Doppler

Scrotal ultrasonography with color flow Doppler imaging with the patient upright and supine may prove useful in equivocal cases or in patients with a body habitus that makes accurate physical examination of the scrotum impossible. Using ultrasonography, the diameter of the internal spermatic vein can be measured and retrograde flow through the vein during Valsalva maneuver documented. Veins that are greater than 3.5 mm can generally be detected on physical exam. Those that are 2.5 mm or less are usually not palpable and have been termed *subclinical* varicoceles (15). The need for diagnosing and treating subclinical varicoceles is controversial (16). Recent studies have indicated that repair of subclinical varicoceles is of questionable value (17). However, other reports have indicated that repair of small palpable or subclinical right varicoceles may be beneficial if present in conjunction with a larger left-sided varicocele (18–20).

A recent meta-analysis by Marmar et al. (12) clearly shows a significant increase in pregnancy rates after microsurgical varicocelectomy.

INDICATIONS

The indications for repairing varicoceles in adolescents include the following:

1. Palpable (especially grade III) left varicocele with associated ipsilateral testicular atrophy (with the volume of the left testis being at least 20% less than that of the right)
2. Palpable (especially grade III) varicocele with abnormal semen analysis results
3. Large (grade III) symptomatic (painful) varicocele
4. Bilaterally palpable varicocele with testicular atrophy

Although prophylactic treatment of adolescent varicocele for the prevention of future infertility and androgen deficiency is controversial, the author feels that it is much easier to prevent future infertility and androgen deficiency than to treat it once it has occurred. In view of the high success rate and low morbidity of microsurgical repair, the author feels that repair of grade III varicoceles is the conservative therapy since it conserves testicular function.

Based on the Best Practice Policies for Male Infertility of the American Urological Association (21), varicocele treatment should be offered to the male partner of a couple attempting to conceive when all of the following are present:

> A varicocele is palpable.
> The male partner has one or more abnormal semen parameters or sperm function test results.
> The couple has documented infertility.
> The female partner has normal fertility or potentially correctable infertility.

In addition, testicular pain associated with varicocele (in the absence of other pathology), psychological concern regarding future fertility, and cosmetic reasons are all relative indications. Varicocele repair is not indicated in men with normal semen analysis, sperm function assays, or only a subclinical (nonpalpable) varicocele.

ALTERNATIVE THERAPY

Several approaches exist for varicocelectomy, including retroperitoneal and inguinal open techniques, microsurgical inguinal and subinguinal approaches, laparoscopic repairs, and radiographic embolization. The microsurgical varicocelectomy, low inguinal (22) or subinguinal, as first described by Marmar et al. (23), is preferred because it is associated with higher success rates and lower morbidity and recurrences than nonmicrosurgical techniques (22,24).

Microsurgical Inguinal and Subinguinal Operations: The Preferred Approaches

Subinguinal varicocelectomy is currently the most popular approach. It has the advantage of allowing the spermatic cord structures to be pulled up and out of the wound so that the testicular artery, lymphatics, and small periarterial veins may be more easily identified. In addition, an inguinal or subinguinal approach allows access to the external spermatic and even gubernacular veins (25), which may bypass the spermatic cord and result in recurrence if not ligated. Lastly, an inguinal or subinguinal approach allows access to the testis for biopsy or examination of the epididymis for obstruction or repair of hydrocele (26).

Anesthesia

If the testis is delivered, as described in the following text, regional or light general anesthesia is preferred. If only the cord is delivered, local anesthesia with a 50/50 combination of 0.25% bupivacaine and 1% lidocaine is satisfactory with adjunctive intravenous heavy sedation. After infiltration of the skin and subcutaneous tissues, the cord is infiltrated prior to delivery. Blind cord block carries with it a small risk of inadvertent testicular artery injury (27). A 30-gauge needle should therefore be employed for cord block to minimize the risk of injury and hematoma.

Inguinal and Subinguinal Approaches

The introduction of the subinguinal approach, just below the external inguinal ring (23), obviates the necessity for opening any fascial layer and is associated with less pain and a rapid recovery comparable to laparoscopic procedures. At the subinguinal level, however, significantly more veins are encountered; the artery is more often surrounded by a network of tiny veins which must be ligated and the testicular artery has often divided into two or three branches, making arterial identification and preservation more difficult (28).

Subinguinally, the arterial pulsations are often dampened by compression on the edge of the external ring, making its identification somewhat more difficult than when the external oblique is opened. Table 53.2 summarizes the criteria for performing the operation inguinally (external oblique opened) versus subinguinally (fascia intact). In general, it is best to use a subinguinal approach in men with a history of any prior inguinal surgery. Under these circumstances, the cord is usually stuck to the undersurface of the external oblique and opening the fascia risks injury to the cord. A subinguinal approach is easier in obese men in whom opening and closing the fascia is difficult through a small incision. A subinguinal approach is easier in men with high, lax, capacious external rings and in men with long cords and low-lying testes. In these men, the level of the external ring is fairly proximal to the testis and opening the fascia will not result in a significant diminution in the number of veins to be ligated or in the branching of the testicular artery.

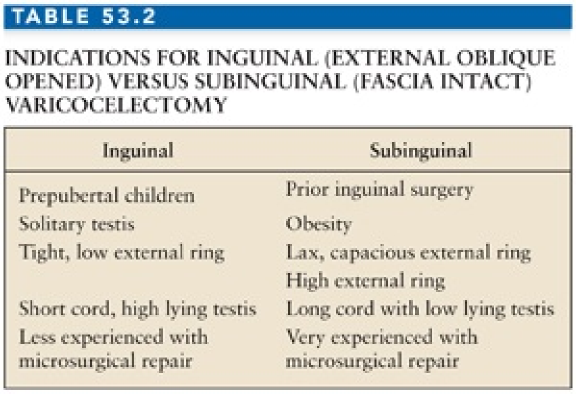

TABLE 53.2

INDICATIONS FOR INGUINAL (EXTERNAL OBLIQUE OPENED) VERSUS SUBINGUINAL (FASCIA INTACT) VARICOCELECTOMY

Inguinal	Subinguinal
Prepubertal children	Prior inguinal surgery
Solitary testis	Obesity
Tight, low external ring	Lax, capacious external ring
	High external ring
Short cord, high lying testis	Long cord with low lying testis
Less experienced with microsurgical repair	Very experienced with microsurgical repair

I recommend always opening the external oblique in prepubertal children without prior inguinal surgery. In children, the testicular artery is very small and systemic blood pressure is low, making identification of the artery very difficult in a subinguinal approach. The fascia could also be opened in men with a solitary testis in whom preservation of the artery is critical. Exposure of the cord more proximally (at the inguinal level) allows identification of the artery before it has branched, where clear pulsations are more readily observed.

Consider opening the fascia in men with prior failed subinguinal varicocelectomy in order to dissect proximal to the prior scarred ligation area. The microdissection will be quicker and easier. A subinguinal operation is significantly more difficult than a high inguinal operation and should only be used by surgeons who perform the operation frequently. Less experienced microsurgeons should start out doing inguinal operations because it is easier. An inguinal operation is employed when simultaneous ipsilateral hernia repair is performed.

Before making the incision, the location of the external inguinal ring is determined by invagination of the scrotal skin and is marked. The size of the incision is determined by the size of the testis when delivery of the testis (see in the following text) is planned. Atrophic testes can be delivered through a 2- to 2.5-cm incision. Larger testes require a 3-cm incision. The incision is made within Langer lines to minimize scarring.

If the decision is made to perform an inguinal operation and thus to open the fascia, the incision is begun at the external ring and extended laterally 2 to 3.5 cm along Langer lines (Fig. 53.1). If the operation is to be performed subinguinally, the incision is placed in the skin folds right over the external ring (Fig. 53.2).

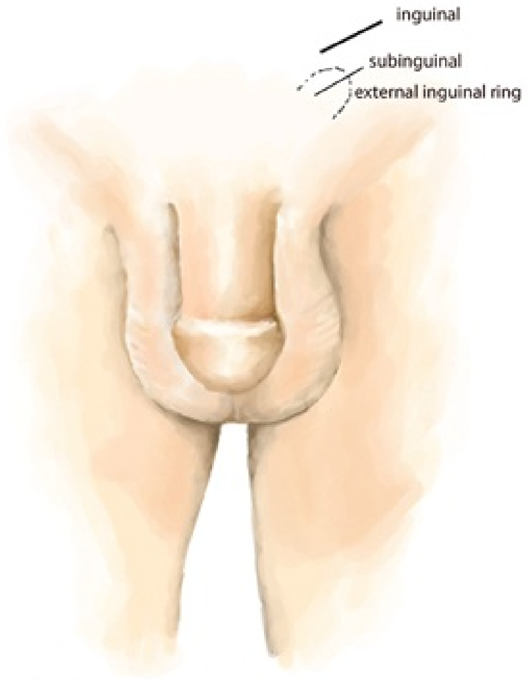

FIGURE 53.1 Subinguinally, a 2- to 3.0-cm incision is placed in the skin folds right over the external inguinal ring. Inguinally, a 3.5- to 4-cm incision is begun at the external ring and extended laterally along Langer lines.

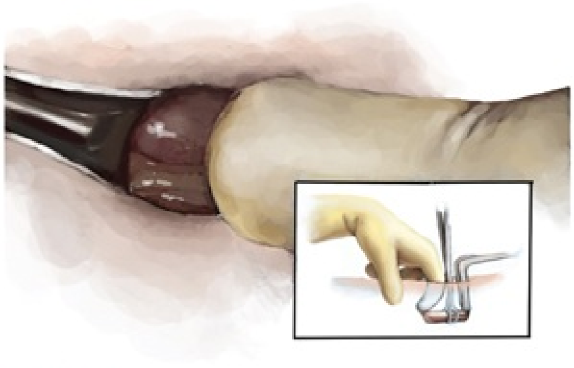

FIGURE 53.2 The index finger is then hooked under the external inguinal ring, retracting it cephalad. A small Richardson retractor is slid along the back of the index finger and retracted caudad over the cord toward the scrotum.

Camper fascia and Scarpa fascia are divided with the electrocautery between the blades of a Crile clamp. The superficial epigastric artery and vein, if encountered, are retracted or alternately, may be clamped, divided, and ligated. If an inguinal approach is selected, the external oblique aponeurosis is cleaned and opened the length of the incision to the external inguinal ring in the direction of its fibers. A 3-0 absorbable suture placed at the apex of the external oblique incision facilitates later closure.

The spermatic cord is grasped with a Babcock clamp and delivered through the wound. The ilioinguinal and genital branches of the genitofemoral nerve are excluded from the cord which is then surrounded with a large Penrose drain. If a subinguinal incision was made, Camper and Scarpa fascia are incised as described previously. An index finger is introduced into, around and along, the cord as it passes into the scrotum. The index finger is then hooked under the external inguinal ring, retracting it cephalad. A small Richardson retractor is slid along the back of the index finger and retracted caudad over the cord toward the scrotum (see Fig. 53.2). The spermatic cord will be revealed between the index finger and retractor. The assistant grasps the cord with a Babcock clamp and delivers it through the wound. The cord is surrounded with a large Penrose drain.

Dissection of the Cord

The operating microscope is then brought into the field. Under 6× to 10× power magnification, the external spermatic fascia is opened with a Bovie electrocautery in the direction of the cremasteric fibers in order to avoid injury to the cremasteric arteries. A 5-0 Vicryl suture is placed at the apex of the opening to facilitate later closure. The relatively avascular internal spermatic fascia is opened with scissors as high as possible and held open with the straight mosquito forceps (Fig. 53.3). The magnification is increased from 10× to 25× power, and after irrigation with 1% papaverine solution, the cord is inspected for the presence of pulsations revealing the location of the testicular artery. A micro-Doppler is extremely useful in identifying arteries (Fig. 53.4). Once the testicular artery is identified, it is dissected free of all surrounding tissue, tiny veins, and lymphatics using a fine-tipped nonlocking microneedle holder and microforceps. The artery is encircled with a vessel loop for positive identification and gentle retraction (Fig. 53.5). The suspected artery is tested by elevating the artery with the tips of the microneedle holder until it is completely occluded and then slowly lowering it until a pulsating blush of blood appears just over the needle holder. If the artery is not immediately identified, the cord is carefully dissected beginning with the largest veins. The veins are stripped clean of adherent lymphatics (Fig. 53.6) and the underside of the largest veins inspected for an adherent artery. In approximately 50% of cases, the testicular artery is adherent to the undersurface of a large vein (29). All veins within the cord, with the exception of the vasal veins, are doubly ligated with either hemoclips (Fig. 53.7A) or by passing two 4-0 silk ligatures, one black and one white, beneath the vein (Fig. 53.7B). These are then tied and the vein divided. Medium hemoclips are used for veins 5 mm or larger, small auto-hemoclips for veins 1 to 5 mm and 4-0 silk for veins smaller than 2 mm. The use of an automatic clip applier (LigaClip, small size, Ethicon, Somerville, New Jersey) significantly reduces operating time. The bipolar cautery can be used for veins smaller than 0.5 mm. The vasal veins are preserved, providing venous return. If the vas deferens is accompanied by dilated veins greater than 2.5 mm in diameter, they are dissected free of the vasal artery and ligated. The vas deferens is always accompanied by two sets of vessels. As long as at least one set of deferential veins remains intact, venous return will be adequate. At the completion of the dissection, the cord is run over the index finger and inspected to verify that all veins have been identified and ligated. Small veins adherent to the testicular artery are dissected free and ligated, or, if smaller than 1 mm, cauterized using a bipolar unit with a jewelers' forceps tip and divided. Cremasteric arteries are found (usually between and adherent of two cremasteric veins) and preserved in at least 90% of cases. Recent studies employing power Doppler in men with nonobstructive azoospermia undergoing testicular sperm extraction have found that tubules containing sperm are most likely to be found in areas of the testis with the greatest blood supply. Therefore, logic would dictate that preservation of maximum testicular blood supply, including both testicular and cremasteric arteries, would be beneficial to testicular function. At the completion of the dissection, only the testicular arteries, cremasteric arteries, lymphatics, and vas deferens with its vessels remain (Fig. 53.8). Dissection is not deemed complete until a run through the cord reveals no additional internal or external spermatic veins. Each time a vein is found and ligated, any remaining veins will dilate up.

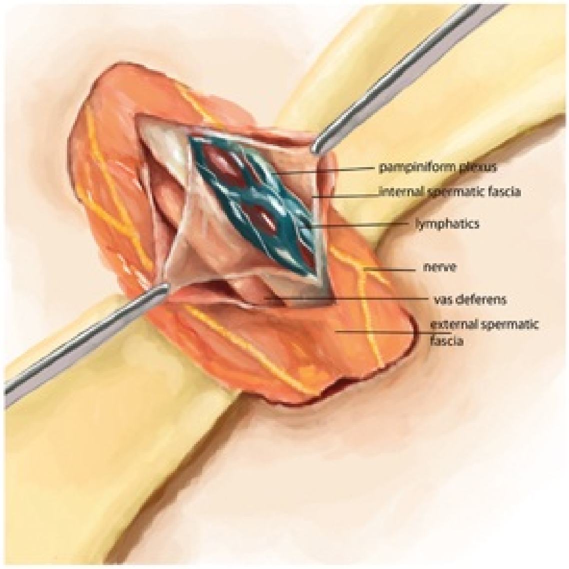

FIGURE 53.3 The relatively avascular internal spermatic fascia is opened with scissors as high as possible and held open with the straight mosquito forceps.

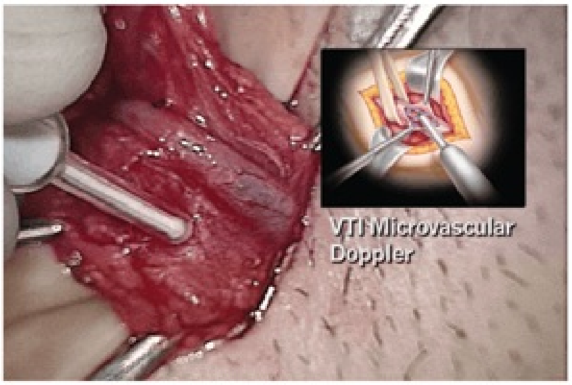

FIGURE 53.4 A micro-Doppler is extremely useful in identifying arteries.

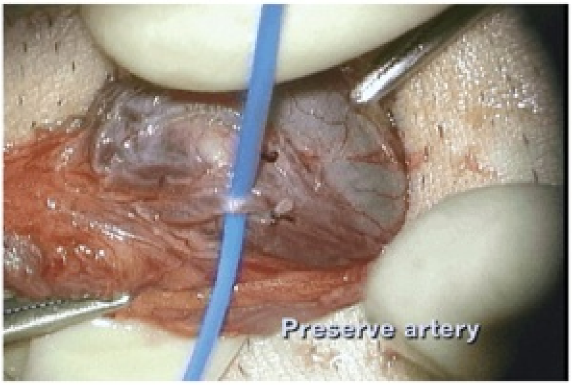

FIGURE 53.5 The artery is encircled with a vessel loop for positive identification and gentle retraction.

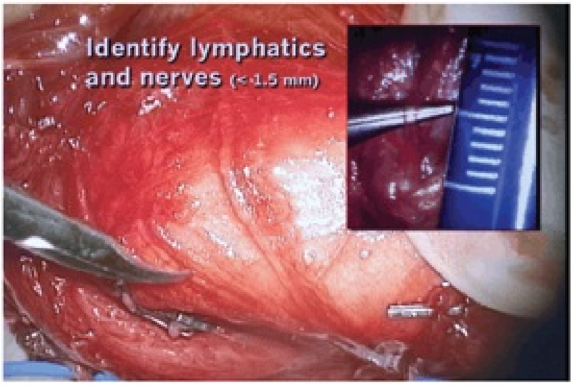

FIGURE 53.6 The veins are stripped clean of adherent lymphatics.

FIGURE 53.7 All veins within the cord, with the exception of the vasal veins, are doubly ligated with either hemoclips (**A**) or by passing two 4-0 silk ligatures, one black and one white beneath the vein (**B**).

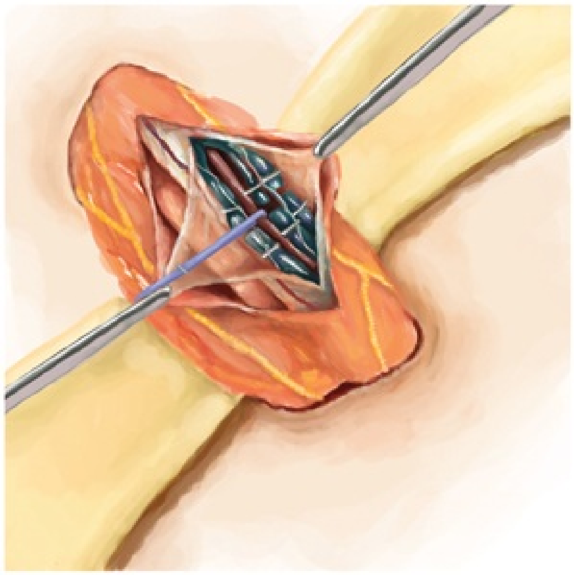

FIGURE 53.8 Only the testicular arteries, cremasteric arteries, lymphatics, and vas deferens within its vessels remain.

Delivery of the Testis

Delivery of the testis through a small inguinal or subinguinal incision guarantees direct visual access to all possible avenues of testicular venous drainage. Delivery of only the cord allows access to most external spermatic collaterals but may miss those close to the testis and will not allow access to scrotal or gubernacular collaterals which have been demonstrated radiographically to be the cause of 10% of recurrent varicoceles (25). With gentle upward traction on the cord and upward pressure on the testis through the invaginated scrotum, the testis is easily delivered through the wound. All external spermatic veins are identified and double ligated with hemoclips and divided (Fig. 53.9). The gubernaculum is inspected for the presence of veins exiting from the tunica vaginalis. These are either cauterized or doubly clipped and divided. When this step is completed, all testicular venous return must be within the Penrose surrounded cord.

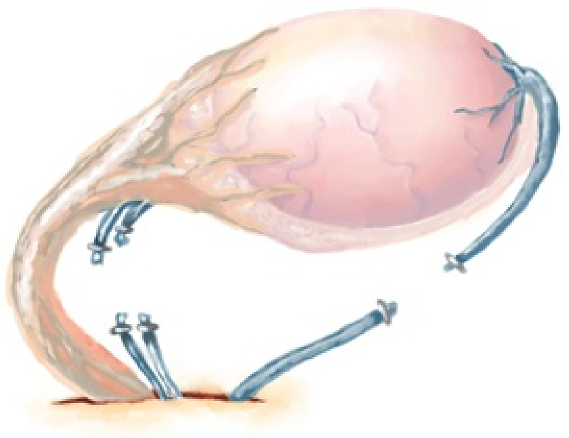

FIGURE 53.9 All external spermatic and gubernacular veins not within the Penrose are identified and doubly ligated or clipped and divided.

Hydroceles are found in 15% of testes associated with varicoceles. As little as 3 mL of hydrocele fluid can significantly alter testicular temperature regulation (30). If a hydrocele is noted when the testis is delivered, it is repaired. Small ones may be treated with excision of a segment of the hydrocele sac and cauterization of the edges. Larger hydroceles are treated with either a bottleneck or microsurgical excision technique (26,31). The temporary high venous pressure immediately after varicocelectomy can make good hemostasis difficult to achieve after excisional hydrocelectomy. Therefore, there should be no hesitation to employ a scrotal Penrose drain placed in the dependent portion of the scrotum for 24 hours after combined varicocelectomy and excisional hydrocelectomy. The testis is then returned to the scrotum and the Penrose drain is left beneath the cord structures. Grabbing the previously placed 5-0 Vicryl left at the apex of the opening, the spermatic fascia is closed with 2 to 3 interrupted sutures of 5-0 Vicryl (Fig. 53.10). This covers the testicular artery ligation area.

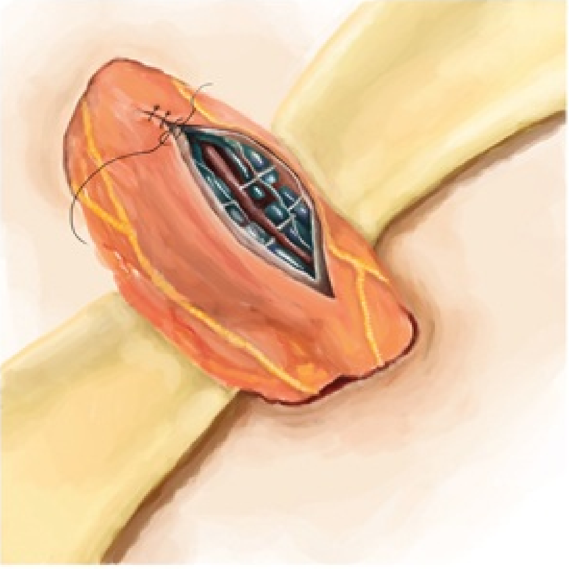

FIGURE 53.10 The spermatic fascia is closed with interrupted sutures of 5-0 Vicryl.

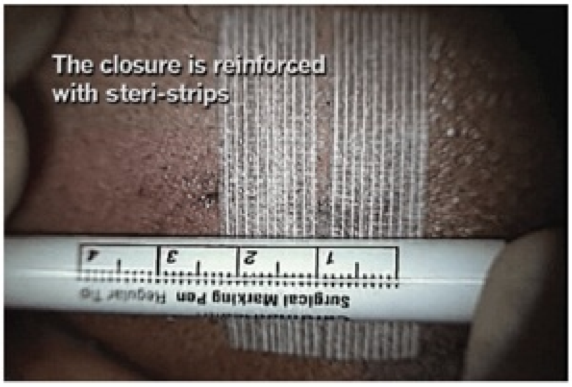
The external oblique aponeurosis, if opened, is reapproximated with continuous suturing using the previously placed 3-0 suture. Scarpa fascia and Camper fascia are reapproximated with a 5-0 monofilament absorbable subcuticular suture reinforced by two to three Steri-Strips (Fig. 53.11). A scrotal supporter is applied and stuffed with fluff-type dressings. The patient is discharged on the day of surgery with a prescription for Tylenol with codeine. Light work may be resumed in 2 or 3 days.



The closure is reinforced with steri-strips

FIGURE 53.11 Scarpa fascia and Camper fascia are reapproximated with a 5-0 monofilament absorbable subcuticular suture and reinforced by two to three Steri-Strips.

If any large external or gubernacular veins are ligated after delivery of the testis, the cord is again run over the index finger to search for veins that may dilate after gubernacular or external veins are ligated. The external spermatic fascia is closed with interrupted 5-0 Vicryl, facilitated by the previously placed suture at the apex of the external spermatic fascia.

Radiographic Occlusion Techniques

Radiographic coil occlusion of the internal spermatic veins has been successfully employed for varicoceles (32–34). These techniques are performed under a local anesthetic through a small cutdown incision over the femoral vein. The recurrence rate after balloon occlusion was originally 11% and more recently is reported as low as 4% (25,35–37). Failure to successfully cannulate small collaterals and external spermatic veins and scrotal collaterals results in recurrence. Venographic placement of a balloon or coil in the internal spermatic vein is successfully accomplished in 75% to 90% of attempts (38–41); therefore, a significant number of men undergoing attempted radiographic occlusion will ultimately require a surgical approach. In addition, the radiographic techniques take between 1 and 3 hours to perform compared to 25 to 45 minutes required for surgical repair. Although rare, serious complications of radiographic balloon or coil occlusion have included migration of the balloon or coil into the renal vein, resulting in loss of a kidney, pulmonary embolization of the coil or balloon (36), femoral vein perforation or thrombosis, and anaphylactic reaction to radiographic contrast medium. Antegrade scrotal sclerotherapy via cannulation of a scrotal vein has been employed in Europe (42–44). The recurrence rate is similar to balloon or coil techniques. Long-term follow-up is not available, and the consequence of escape of the sclerosing agent into the renal vein and vena cava is unknown. In addition, the larger the varicocele, the higher the failure and recurrence rate with this technique. We have seen many men referred with late (2 to 5 years) recurrence after radiographic occlusion. They typically present as slow-filling veins that become prominent at the end of the day. Initial cursory physical examination can miss these recurrences. We believe these recurrences are likely due to recanalization through the coils because, unlike surgical repair, the veins are not ligated and divided. Although often initially successful, I believe that radiographic occlusion is less durable than microsurgical ligation.

COMPLICATIONS OF VARICOCELECTOMY

Hydrocele

Hydrocele formation is the most common complication reported after non-microscopic varicocelectomy. The incidence of this complication varies from 3% to 33%, with an average incidence of about 7%. Analysis of the protein concentration of hydrocele fluid indicates that hydrocele formation after varicocelectomy is due to lymphatic obstruction (45). At least half of post-varicocelectomy hydroceles grow to a size large enough to warrant surgical excision due to the discomfort and growth of the hydrocele to a large size. The effect of hydrocele formation on sperm function and fertility is uncertain. It is known that men with varicocele have significantly elevated intratesticular temperatures (46,47), and this appears to be an important pathophysiology phenomenon mediating the adverse effects of varicocele on fertility (48). The development of a large hydrocele creates an abnormal insulating layer that surrounds the testis. This may impair the efficiency of the countercurrent heat exchange mechanism and therefore obviate some of the benefits of varicocelectomy (30).

Use of magnification to identify and preserve lymphatics can virtually eliminate the risk of hydrocele formation after varicocelectomy (22,49,50). The management of post-varicocelectomy hydrocele is identical to that for other hydroceles (see Chapter 54).

Testicular Artery Injury

The diameter of the testicular artery in humans is 1.0 to 1.5 mm. The testicular artery supplies two-thirds of the testicular blood supply and the vasal and cremasteric arteries the remaining one-third (51). Microdissections of the human spermatic cord have revealed that the testicular artery is closely adherent to a large internal spermatic vein in 40% of men. In another 20% of men, the testicular artery is surrounded by a network of tiny veins (29). During the course of cord dissection for varicocelectomy, the artery may go into spasm and even in its unconstructed state is often difficult to positively identify and preserve. Injury or ligation of the testicular artery carries with it the risk of testicular atrophy and/or impaired spermatogenesis. Starzl’s transplant group (52) reported a 14%

incidence of frank testicular atrophy when the testicular artery was purposely ligated. The actual incidence of testicular artery ligation during varicocelectomy is unknown, but some studies suggest it is common (53). Animal studies indicate that the risk of testicular atrophy after testicular artery ligation varies from 20% to 100% (27,54). In humans, atrophy after artery ligation is probably less likely due to the contribution of the cremasteric as well as vasal arterial supply (51). In children, the potential for neovascularization and compensatory hypertrophy of the vasal and cremasteric vessels is probably greater than in adults, making atrophy after testicular artery ligation less likely. Use of magnifying loupes, or preferably an operating microscope and/or a fine-tipped Doppler probe, facilitates identification and preservation of the testicular artery and therefore minimizes the risk of testicular injury. Radiographic balloon or coil occlusion techniques also eliminate this risk.

Varicocele Recurrence

The incidence of varicocele recurrence following surgical repair varies from 0.6% to 45% (24,55–57). Recurrence is more common after repair of pediatric varicoceles. Radiographic studies of recurrent varicoceles visualize periarterial, parallel inguinal, or midretroperitoneal collaterals or, more rarely, transscrotal collaterals (25). Retroperitoneal operations miss parallel inguinal and scrotal collaterals. Nonmagnified inguinal operations have a lower incidence of varicocele recurrence but fail to address the issue of scrotal collaterals or small veins surrounding the testicular artery. The microsurgical approach with delivery of the testis lowers the incidence of varicocele recurrence to less than 1% compared to 9% using conventional inguinal techniques (22,50).

RESULTS

Varicocelectomy results in significant improvement in semen analysis in 60% to 80% of men. Reported pregnancy rates after varicocelectomy vary from 20% to 60% (12). A randomized controlled trial of surgery versus no surgery in infertile men with varicoceles revealed a pregnancy rate of 44% at 1 year in the surgery group versus 10% in the control group (58). In our series of 1,500 microsurgical operations, 43% of couples were pregnant at 1 year (59) and 69% at 2 years when couples with female factors were excluded. Microsurgical varicocelectomy results in return of sperm to the ejaculate in up to 50% of azoospermic men with palpable varicoceles (60–64).

The results of varicocelectomy are also related to the size of the varicocele. Repair of large varicoceles results in a significantly greater improvement in semen quality than repair of small varicoceles (17,65). In addition, large varicoceles are associated with greater preoperative impairment of semen quality than small varicoceles, and consequently, overall pregnancy rates are similar regardless of varicocele size. Some evidence suggests that the younger the patient is at the time of varicocele repair, the greater the improvement after repair and the more likely the testis is to recover from varicocele-induced injury (66). Varicocele recurrence, testicular artery ligation, or post-varicocelectomy hydrocele formation are often associated with poor postoperative results. In infertile men with low serum testosterone levels, microsurgical varicocelectomy alone results in substantial improvement in serum testosterone levels (13,14,66–68).

SUMMARY

Varicocele is an extremely common entity present in 15% of the male population. Varicoceles are found in approximately 35% of men with primary infertility but 75% to 81% of men with secondary infertility. Mounting evidence clearly demonstrates that varicocele causes progressive duration-dependent injury to the testis. Larger varicoceles appear to cause more damage than small varicoceles and, conversely, repair of large varicoceles results in greater improvement of semen quality. Varicocelectomy can halt the progressive duration-dependent decline in semen quality found in men with varicoceles. The earlier the age at which varicocele is repaired, the more likely is recovery of spermatogenic function. Varicocelectomy can also improve Leydig cell function resulting in increased testosterone levels (59,66,67).

The most common complications after varicocelectomy are hydrocele formation, testicular artery injury, and varicocele persistence or recurrence. The incidence of these complications can be reduced by employing microsurgical techniques, inguinal or subinguinal operations, and exposure of the external spermatic and scrotal veins. Employment of these advanced techniques of varicocelectomy provide a safe, effective approach to elimination of varicocele, preservation of testicular function, and, in a substantial number of men, an increase in semen quality and likelihood of pregnancy as well as increase in serum testosterone in men with androgen deficiency.

CHAPTER 54 EPIDIDYMECTOMY

KHALID ALRABEEAH AND PETER CHAN

With the advances in medical imaging to evaluate the nature of most scrotal masses along with the availability of broad-spectrum antimicrobials to control infection of scrotal organs, surgical removal of all or part of the epididymis is done infrequently. Nonetheless, when conservative management fails, epididymectomy, although invasive with potential risks of ultimately requiring an orchiectomy and compromising fertility, can be effective in managing defined epididymal pathologies or chronic scrotal pain in carefully selected patients. Because complete and partial epididymectomy is infrequently performed, most urologists have variable levels of experience in these procedures. This further highlights the importance of having a thorough understanding of the various issues related to epididymectomy ranging from preoperative counseling to anatomic details to the variation of surgical techniques so that in the rare event that calls for such a procedure, one can aim not only to minimize any potential complications and risks of compromising the fertility status of the patients but also to maximize long-term satisfaction of the patients particularly in relation to chronic scrotal pain control.

INDICATIONS

The indications of epididymectomy include scrotal pain localized to the epididymis (e.g., postvasectomy), chronic epididymitis, painful large/complex epididymal cystic disease, trauma, tuberculous epididymitis, and schistosomal epididymitis. Epididymectomy for other less common epididymal pathologies such as benign epididymal adenoma, sarcoidosis, and epididymal malignancies (primary and metastatic) have also been described in the literature. Postvasectomy scrotal pain, chronic epididymitis, and painful epididymal cysts or spermatoceles are the most common indications for epididymectomy (Table 54.1), as shown by a series of recent studies on epididymectomy (1–13).

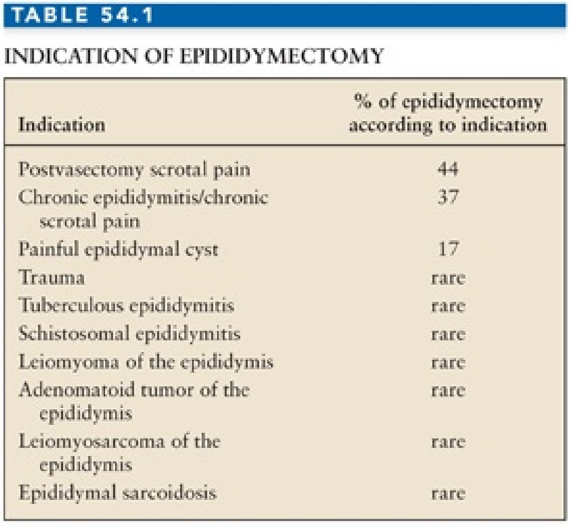

TABLE 54.1

INDICATION OF EPIDIDYMECTOMY

Indication	% of epididymectomy according to indication
Postvasectomy scrotal pain	44
Chronic epididymitis/chronic scrotal pain	37
Painful epididymal cyst	17
Trauma	rare
Tuberculous epididymitis	rare
Schistosomal epididymitis	rare
Leiomyoma of the epididymis	rare
Adenomatoid tumor of the epididymis	rare
Leiomyosarcoma of the epididymis	rare
Epididymal sarcoidosis	rare

COUNSELING ISSUES

Patients with chronic scrotal pain syndrome are challenging to manage. No single treatment modality can guarantee effective alleviation of the pain; hence, the logic is to begin with conservative treatment such as reassurance, warm, local compresses, sitz baths, scrotal supports, massotherapy, exercise, and relaxation followed by medical treatments ranging from analgesic, anti-inflammatory, antibiotics, antioxidants, anxiolytic, alpha-blockers, anticholinergics to narcotics, and neuroleptic drugs. Additional adjunctive treatments with physiotherapy, biofeedback, psychotherapy, regional anesthesia, and acupuncture may also be considered. Invasive and irreversible treatment such as surgery should only be considered as the last resort and the patients should always be informed, in addition to any potential complications, that the pain may not be fully relieved and may even worsen. Thus, just like any patients suffering from chronic pain such as chronic pelvic pain syndrome, men with chronic scrotal pain syndrome are best managed with a multidisciplinary approach involving, in addition to urologists, general surgeons, pain specialists/anesthetists, psychologists, sexologists, physiotherapists, infectious disease specialists, radiologists, reproductive medicine specialists, and acupuncturists.

Proper preoperative counseling for invasive surgery such as epididymectomy in the absence of clear epididymal pathologies such as solid or cystic mass, chronic inflammation, or infection is particularly important. Although epididymectomy is usually performed unilaterally, the surgeon must disclose its potential negative impact on fertility, particularly if there is any indication on history and physical examination that suggests impaired testicular function or the integrity of the excurrent ductal system on the contralateral testis. In the case of partial epididymectomy for resection of localized epididymal lesion, simultaneous microsurgical vasoepididymostomy should be offered in an attempt to maximize the quantity of sperm in semen for preservation of fertility. Likewise, sperm banking by cryopreservation prior to surgery, the potential needs of simultaneous surgical sperm extraction for use with in vitro fertilization/intracytoplasmic sperm injection in the future should also be part of the discussion and preoperative counseling in addition to surgical risks and complications.

Chronic pain is a common presentation in men undergoing epididymectomy and can have a significant psychosocial impact on the individual’s quality of life. At the same time, chronic scrotal pain can also be caused by psychosocial factors, making surgical management or medications such as anti-inflammatory and analgesics ineffective in relieving the pain. As in patient with chronic orchialgia undergoing surgical denervation procedure, we advocate for all patients requiring epididymectomy specifically for chronic pain to undergo multiple sessions of nerve block with local anesthesia or “sham nerve block” with a small amount (<1 mL) of saline to the spermatic cord (with the patient blinded). If pain persists despite properly performed nerve block, surgery with denervation or epididymectomy may not adequately resolve the pain postoperatively. On the other hand, if the pain resolves with a sham nerve block, then psychosomatic factor may play a significant role in the etiology of the chronic pain in the subject. We feel that this information can help surgeon inform patients to have a realistic expectation of the outcomes of surgery. Men with pain and tenderness clearly and specifically localized to the epididymis are the best candidates for epididymectomy.

SURGICAL TECHNIQUES

Anatomic Consideration

Detailed knowledge of epididymal anatomy is essential before undertaking surgery of this delicate structure. The epididymis is blessed with a rich blood supply derived from the testicular vessels superiorly and the deferential vessels inferiorly. With this extensive interconnections between these branches, either the testicular or the deferential branches (but not both) to the epididymis may be divided without compromising epididymal viability. This is particularly important when performing partial epididymectomy (see the following text). Another important piece of anatomic details of the blood supply of the epididymis is that because the epididymal branches of the testicular artery are medial to and separate from the main testicular artery and veins, epididymectomy may be performed on the epididymis without compromising testicular blood supply.

Interestingly, anatomic studies using immunohistochemistry indicated that innervation of the epididymis is denser than that of testis (14). Indeed, there is an extensive sympathetic nerve network innervating the cauda epididymis and vas deferens (15) controlled by the abdominal and pelvic sympathetic nervous system to generate transport of spermatozoa from the epididymis through the vas deferens. Human epididymis is densely innervated by nerve fibers immunoreactive to a wide range of neuropeptides including tyrosine hydroxylase, neuropeptide Y, vasoactive intestinal polypeptide, calcitonin gene-related peptide, galanin, peptide histidine isoleucine, and substance P (14). Besides regulation of smooth musculature function, some of these neuropeptides (most notably substance P and calcitonin gene-related peptide) have been shown to take part in the processing of pain (16,17).

A recent histologic study reported a reproducible, distinct anatomic distribution of nerves in the spermatic cord that is commonly found to have pathologic condition such as wallerian degeneration in men with chronic orchialgia. In decreasing order of nerve density, the three primary sites of this trifecta nerve complex are localized in (a) cremasteric muscle fibers, (b) perivasal tissues and vasal sheath, and (c) posterior cord lipomatous/perivessel tissues (18). Targeting these specific abnormal nerves may enhance the efficacy of pain control during surgical denervation or epididymectomy in patients with chronic orchialgia.

In human, distal caput, corpus, and cauda epididymis is a single, tightly coiled, 5- to 7-m long tubule. When refractory chronic pain due to obstruction of the outflow of the excurrent ductal system (such as postvasectomy) can be localized to a specific area such as cauda epididymis, partial epididymectomy may alleviate the pain. However, one must keep in mind that effectively, the surgery allows the point of obstruction to be migrated more proximally along the epididymis and there is a potential risk that similar pain may recur proximally. Even with complete epididymectomy for chronic pain due to obstruction, there is a risk that obstruction and pressure may build up postoperatively at the level of the testis leading to chronic orchialgia. Thus, prior to undertaking epididymectomy for pain control, the patient must receive proper counseling of the potential risks of recurrence of ipsilateral chronic pain.

Anesthesia

Simple epididymectomy can be completed within 1 hour, thus the choices of anesthesia including general, regional, and, in motivated patient, local anesthesia are all reasonable options. However, in complicated cases such as those with extensive inflammation that may require complicated dissection or if additional procedures such as microsurgical reconstruction with vasoepididymostomy and/or epididymal or testicular sperm retrieval are planned with a partial epididymectomy, general or long-acting regional anesthesia is preferred.

After induction of appropriate anesthesia, intravenous administration of antimicrobial drugs should be considered in cases when infectious causes of epididymitis are suspected.

Incision

For unilateral epididymectomy due to chronic pain secondary to inflammatory/infectious or obstructive causes, an ipsilateral transverse or midline scrotal incision can be used. A high scrotal incision should be considered if there is extensive inflammation that may require dissection and resection of the vas deferens in the subinguinal region or if a simultaneous vasoepididymostomy is planned during a partial epididymectomy. These incisions can also be used in most cases when the indication of epididymectomy is epididymal mass, as the great majority of these masses are benign adenomatoid tumors. However, when there is a history of rapid growth of an epididymal mass that is solid and hypervascular on sonography, the lesion may represent malignant epididymal tumor. In these extremely rare cases, an inguinal incision, as in radical orchiectomy for testicular tumor, should be used to allow early control of the spermatic cord and associated vasculature and lymphatics.

When scrotal incision is used, it should be large enough to allow delivery of the testis and epididymis. The tunica vaginalis can be exposed by developing the plane between it and the dartos muscle layers with a combination of sharp and blunt dissection. The use of electrocautery can provide excellent hemostasis. Alternatively, after the skin incision, some surgeons advocate to gather the successive layers with a suture placed at either end or in an Allis clamps to facilitate wound closure at the end of the procedure. In either approaches, one should attempt to deliver the intravaginal contents with the tunica vaginalis intact to allow for closure separate from the more superficial scrotal layers.

Handling of the Vas Deferens

Prior to opening the tunica vaginalis, in cases of inflammatory or infectious epididymitis, one should dissect superiorly along the spermatic cord toward the external inguinal ring to allow inspection for any sinus openings. If infectious epididymitis is suspected, appropriate culture of a swab of the operative field or any suspicious fluid should be performed followed by copious irrigation of the field. If the extent of inflammation involves more proximally along vas deferens and the spermatic cord, the incision may need to be extended or new incision made subinguinally to allow for adequate exposure for complete removal of inflammatory tissues. When epididymectomy is performed for postvasectomy pain, dissection along the spermatic cord should be performed to expose the vasectomy site to allow the testicular end of the vas deferens and any associated sperm granuloma to be resected.

In epididymectomy for other indications, the vas deferens may be divided and ligated at the junction of the convoluted and straight vas. This is particularly important if a partial epididymectomy for a benign focal lesion is planned and a simultaneous vasoepididymostomy is to be performed as it will allow the straight vas to be used for the vasoepididymostomy. Ligation of the vas can be done using absorbable sutures. Titanium clips should be avoided in patients with pain as the primary presentation.

In patient with pain as the chief complaint, microsurgical denervation can be considered simultaneously during epididymectomy. A formal denervation (see Chapter 54 on denervation) can achieve satisfactory results for pain alleviation but may inadvertently lead to decreased scrotal and penile skin sensation. Relief of chronic severe pain localized to the epididymis may be better achieved, in addition to epididymectomy, by denervating the perivasal nerve fibers (18) using a microbipolar forceps. Care should be taken during the procedure, as it may inadvertently damage the vas deferens.

The tunica vaginalis is opened to expose the epididymis. If extensive scarring from inflammation or infection has occurred, testis and epididymis may need to be dissected free from the visceral or inner side of the tunica vaginalis.

Partial Epididymectomy

When performing partial epididymectomy for localized benign lesions or cystic mass originated from the epididymis, opening of the tough overlying tunica epididymis may allow a surgical plane to be developed to allow clean isolation of the lesions from the vessels in the tunica and the rest of the epididymis. This maneuver is often overlooked even during simple spermatocelectomy and epididymal cyst removal. When the plane between the lesion and the epididymal tunica is properly developed, there should be minimal blood vessels on the surface of the lesion and the lesion can often be removed en bloc. Use of an operating microscope providing 6× to 25× magnification facilitates the dissection to allow preservation of the vasculature to minimize the risks of ischemic injury to the testis and the remaining epididymis and minimizes the risk of hematoma.

If fertility is desired and the contralateral testis is not functioning or absent, simultaneous vasoepididymostomy can be performed (see chapter for vasoepididymostomy) with the straight vas to an epididymal tubule proximal to the lesion. Microsurgical epididymal sperm aspiration (MESA) can be performed in conjunction particularly if preoperative semen cryopreservation failed to reveal adequate motile sperm. Extraction of testicular tissue for sperm cryopreservation (see chapter for micro TESE) may be needed if MESA fails to yield adequate motile sperm for cryopreservation.

When performing partial epididymectomy without concomitant vasoepididymostomy, attempt should be made to identify the outflow epididymal tubule for closure, which can be achieved with cauterization with microbipolar forceps with closure of the overlying epididymal tunica. This can minimize the formation of a sperm granuloma that may cause inflammatory pain in the future.

Complete Epididymectomy

After opening the tunica vaginalis, the divided testicular vas can be dissected back toward the cauda epididymis and removed with the epididymis en bloc. The convoluted vas is usually closely attached to the cauda epididymis. Separation of the convoluted vas and cauda epididymis is only necessary if one is attempting to preserve the convoluted vas. The epididymis can be divided from the testis with dissection beginning from the cauda portion (globus minor), reflected cephalically, and continued toward the caput epididymis (globus major). Alternatively, complete epididymectomy can begin at the caput and continue toward the cauda epididymis. The overlying tunica epididymis can be opened to allow separation of the epididymal tubules from the testis tunica albuginea. Dissection should begin in the lateral aspect of the epididymis, as the vasculature to the testis and epididymis generally lies in the medial aspect. Again, if infectious epididymitis is suspected, appropriate culture of a swab of the operative field or any purulent or suppurative exudate should be performed followed by copious irrigation and suction of the field.

Microsurgical technique with appropriate optical magnification is essential to preserve testicular blood supply. Dissection can be performed with a combination of sharp dissection using fine microscissors and blunt dissection and use of a microbipolar cautery forceps for hemostasis. Larger vessels should be ligated with sutures. One will encounter a variable anastomotic network of vasculatures from the vasal and testicular vessels. Although the vasculature associated with the cauda epididymis (from the vasal vasculature) will be sacrificed when removing the testicular end of the vas along with the epididymis, vessels encountered midway up during the dissection should be preserved as much as possible, as they originate from the main testicular vasculature entering cephalically. Although sometimes variable anatomically, the epididymal branches of the main testicular artery are usually encountered on the medial aspect on the plane of dissection in the corpus and caput epididymal regions and can be divided without compromising the testicular blood supply. The use of microsurgical technique, including use of a microbipolar cautery for hemostasis, is the key to allow maximal preservation of vasculature associated with the testis to avoid postoperative atrophy.

The attachment between caput epididymis and testis consists of a parallel bundle of efferent ductules, which can be ligated with absorbable suture and cauterized with a microbipolar to minimize the risks of sperm granuloma formation. Upon removal of the epididymis and the associated vas deferens, the epididymal bed should be irrigated. Appropriate antimicrobial drug may be used in cases suspicious of infectious epididymitis.

The epididymal bed should be carefully inspected under optical magnification to identify any significant bleeding to obtain hemostasis without compromising blood supply to the testis. In cases with extensive inflammation and suspicion of significant damage to the testicular blood supply, intraoperative sonogram with Doppler evaluation of the blood flow of the testicular parenchyma may help to confirm a healthy testicular vascular status.

Closure

If the tunica epididymis can be preserved, it should be reapproximated with running absorbable sutures to close the raw epididymal bed to minimize postoperative hematoma and leakage of testicular fluid from the efferent ductules. The tunica epididymis can also be approximated to the tunica albuginea of the testis but care should be taken to avoid suturing the testicular vessels subjacent to the tunica albuginea. Microsurgical technique and use of the microbipolar forceps will minimize the risk of such injury.

The tunica vaginalis is closed with absorbable sutures. In addition to copious irrigation, thorough inspection of the dartos and scrotal skin, preferably achieved with careful invagination, for any bleeding vessels for fulguration are the keys to minimize postoperative wound infection, scrotal abscess, and hematoma. The dartos layer and skin are closed with absorbable sutures. In infectious epididymitis, one may choose to use interrupted stitches to allow partial opening of the incision for drainage to prevent hematoma and postoperative scrotal abscess formation.

Although usually unnecessary, scrotal drainage is recommended in cases at risk for hematoma or scrotal abscess. Scrotal drainage can be accomplished by using a Penrose drain tunnelled through the dartos layer and the tunica vaginalis sac prior to completing their closure (with at least 10 cm in length intrascrotally to avoid slipping out). The drain should exit the scrotum through a new stab wound in a dependent area where it is secured to the scrotal skin with a 2-0 silk suture and safety pin. Side holes of the drain are unnecessary, as the tract occupied by the drain will allow fluid to exit to the dressing instead of accumulating intrascrotally. The drainage can be removed if no significant drainage is noted in the dressing after 24 to 48 hours.

Compression dressings to scrotum rarely holds effectively for more than an hour even when the patient is in bedrest. Surrounding the scrotum with fluff-type gauze held in place by a scrotal supporter with a hole cut out for the penis allows urination without removal of the supporter.

Special Considerations for Epididymal Malignancy

Although extremely rare, epididymectomy for malignancy requires a different approach. As mentioned previously, typical clues of an epididymal mass being malignant include finding of solid lesions on sonogram with hypervascularity and history of rapid growing in size. Besides adenocarcinoma, primary epididymal malignancies may include sarcoma, germ cell tumors, lymphoma, and plasmacytoma (19–23). In men with a known history of advanced malignancies such as prostate, kidney, and gastrointestinal tract, newly found solid, hypervascular growing mass in the epididymis may represent metastatic carcinoma (24–26).

In addition to the use of inguinal incision to deliver the testis and epididymis with the tunica vaginalis intact, the use of a modified Chevassu maneuver (27) to first isolate and cool with slush ice the operating field followed by temporary occlusion of the vasculature of the spermatic cord and gubernaculums can allow biopsy of the epididymal mass with intraoperative histologic evaluation of its frozen section for confirmation of malignancy. If malignancy is confirmed, radical epididymo-orchiectomy should be performed. Otherwise, epididymectomy may proceed as previously describe while sparing the testis.

OUTCOMES AND POSTOPERATIVE EVALUATIONS

Complications of epididymectomy include hematoma formation, orchitis, testicular injury, abscess formation, wound infection, persistent and recurrent chronic scrotal pain, and infertility. Inadvertent injury to testicular vasculature may lead to testicular hypotrophy or atrophy, which may contribute to hypogonadism if the contralateral testis is absent or atrophic.

Postoperatively, patients should be reevaluated at 2 to 6 months for improvement in pain. Physical examination to reevaluate the testicular size should be performed. If hypotrophy is suspected, scrotal sonography with vascular Doppler study may help to confirm any ischemic testicular injury. Serum testosterone and semen analyses are optional evaluations of testicular function that are indicated if there are signs or symptoms of new-onset hypogonadism or infertility.

RESULTS

Pain refractory to medical therapy remains the most common symptoms requiring epididymectomy. The results of postepididymectomy satisfaction in symptomatic relieve vary depending on the indications of surgery. In cases with postvasectomy scrotal pain and painful epididymal cysts, the overall reported satisfaction rate is around 85%. However, the overall satisfaction rate in patients with chronic epididymitis is lower (62%) (Tables 54.2 to 54.4) (1–13). In our unsystematic review of the current literature on epididymectomy, there appear to be some clinical factors that correlate or predict the success of pain relief postepididymectomy. For example, the presence of mechanical obstruction or localized tenderness to the epididymis seems to be a good predictor of long-term success in pain relief. On the contrary, a significantly lower percentage of patients with findings of chronic inflammatory changes in the epididymis, failure in relief of pain following spermatic cord block preoperatively, or pain radiating to the groin are less satisfied with postepididymectomy pain relief.

CONCLUSIONS

Complete or partial epididymectomy remains a valuable resort for the management of chronic epididymal pain refractory to conservative and medical therapies. Various epididymal pathologies such as chronic infection/inflammation, complex epididymal cysts, and benign and malignant epididymal masses are additional indications for epididymectomy. It is our hope that the information provided in this chapter on preoperative counseling, intraoperative surgical techniques, and postoperative outcomes can help clinicians to be better prepared to deliver the best care to patients who require epididymectomy.

CHAPTER 55 EJACULATION INDUCTION PROCEDURES

Anejaculation is defined as failure of ejaculation (retrograde or antegrade) and needs to be distinguished from **anorgasmia (lack of pleasurable sensation)** (1). Anejaculation can be a result of damage to the spinal ejaculatory center (spinal cord injury), peripheral and autonomic nervous system neuropathy (diabetes mellitus, retroperitoneal dissection), transverse myelitis, multiple sclerosis, or iatrogenic secondary to psychotropic medications (2,3). Psychogenic (idiopathic) anejaculation is a diagnosis of exclusion when no obvious pathology can be identified. Psychogenic anejaculation occurs in 30% of men who are unable to ejaculate. Considering time factor, anejaculation can be divided into two categories: primary (lifelong) failure to ejaculate voluntarily by either masturbation or through intravaginal intercourse and secondary anejaculation occurring in patients who report an ability to ejaculate in the past (4,5).

Since the time of the father of evidence-based medicine, Dr. Cochran, who himself suffered from anejaculation, little agreement exists about pathophysiology and optimal evaluation and treatment of men with anejaculation (6).

Most men undergo psychological evaluation first despite lack of prospective randomized trials that psychoanalysis is able to overcome primary anejaculation (6,7).

It is critical to determine if the patient has ever ejaculated voluntarily either by self-stimulation or intravaginally. Presence of **nocturnal emissions** excludes major neurologic deficits. Ability to achieve orgasm verifies that the patient is able to achieve adequate level of arousal and can reach the threshold level (arousal) necessary to activate the ejaculatory generator.

DELAYED EJACULATION

Definition

Delayed ejaculation (DE) is a condition in which it takes an extended period of normal sexual arousal and stimulation to achieve ejaculation and orgasm. In cases of DE, the intravaginal ejaculation latency time (IELT) is persistently lengthened, which may cause the individual to cease sexual activity prior to achieving orgasm due to exhaustion. This condition causes significant distress or interpersonal difficulties such that the patient seeks medical attention (8,9). DE can be either a lifelong condition, in which the patient has never experienced normal IELT (categorized as primary DE), or an acquired condition, in which the patient has previously experienced normal latency but now suffers from extended IELT (secondary DE). Some patients, particularly those suffering from secondary DE, are often able to masturbate themselves to orgasm despite difficulty achieving orgasm through sexual intercourse (8,10).

Rowland et al. (8) provided more specific criteria for the diagnosis of DE. As most sexually healthy males reach orgasm 4 to 10 minutes after vaginal penetration, men with a consistent IELT approximately two standard deviations above the mean (21 to 23 minutes) may be diagnosed with DE. In practice, Rowland et al. (8) suggest that men exhibiting latencies lasting longer than 25 to 30 minutes, in conjunction with the psychological distress described earlier, demonstrate sufficient symptoms for a diagnosis of DE.

Evaluation

In addition to detailed developmental and sexual history, full physical exam with neurologic exam should be performed. In patients who are not sure about the ability to achieve orgasm, we perform an ultrasonographic (US) orgasmic/ejaculatory study using **transperineal ultrasound**. The patient is allowed to self-stimulate using audiovisual adult materials after adequate erection is achieved via intracavernosal injection if needed. During ultrasound, the change in cross section of bulbous urethra (BU) (measure of arousal) is assessed and the patient is allowed to stimulate for up to 30 minutes. If the patient achieves progressive distention of BU and reaches central nervous system (CNS) threshold level for ejaculation, the rhythmic contractions of bulbocavernosal muscle (BCM) (regulated by spinal cord motor generator) are measured and indicate that subject achieved necessary arousal to initiate cascade of ejaculatory events. For those patients who suffer from retrograde ejaculation (RE), postorgasmic urine analysis will show sperm in men who have normal sperm production. Lack of sperm in urine does not exclude RE, as men with nonobstructive azoospermia (NOA) will not have sperm in ejaculate despite RE. If NOA is anticipated, then transrectal ejaculatory study with power Doppler allows one to clearly visualize flow of semen through the ejaculatory ducts and confirms RE or verifies a disorder of emission (Fig. 55.1).

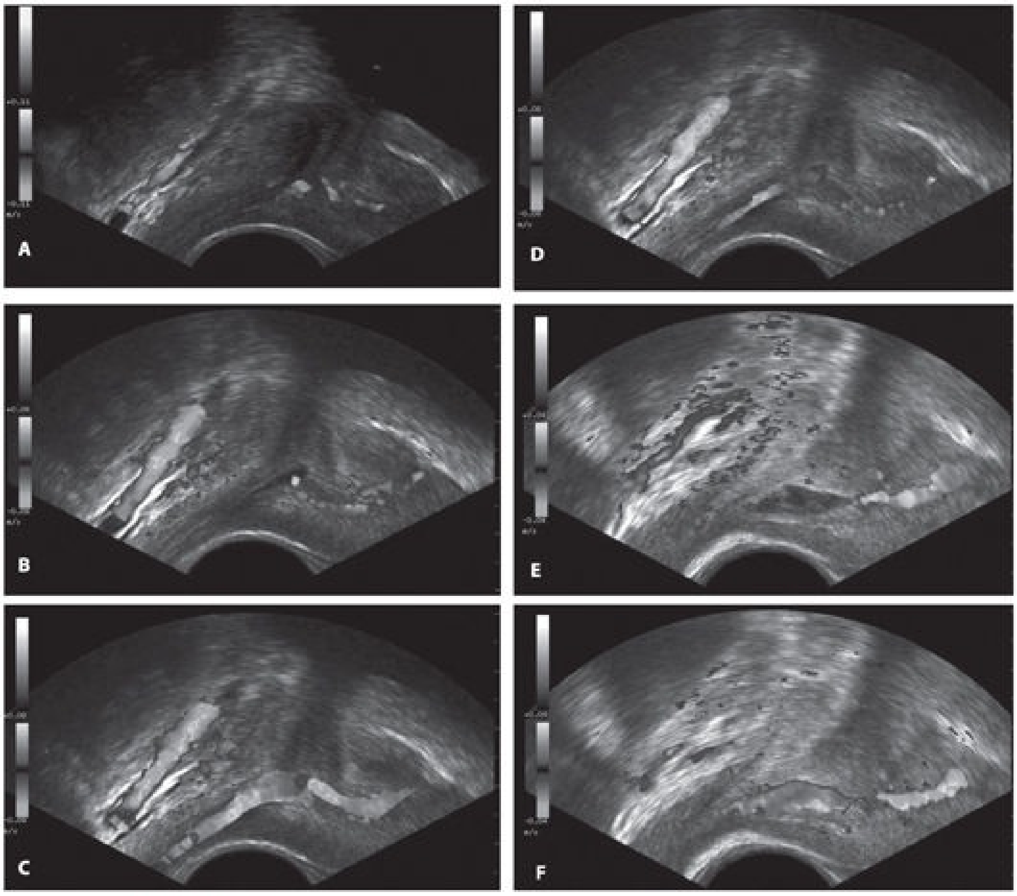

FIGURE 55.1 Flow of semen during ejaculation can be assessed using TRUS ejaculatory study. **A–F:** Progressive images taken at 10 ms intervals of one ejaculatory bolus indicates normal emission of semen from seminal vesicles through ejaculatory ducts into prostatic urethra and outside resulting in antegrade ejaculation.

Biothesiometry may help to identify men with decreased penile sensitivity (**age-related penile hyposensitivity**), which can be often treated with penile vibratory stimulation (11) (Fig. 55.2).

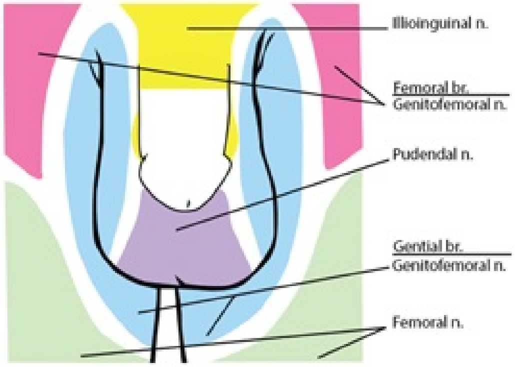

FIGURE 55.2 Innervation of the perineum and scrotum important in evaluation of ejaculatory dysfunction.

Medical Treatment

Corona et al. (12) and study of our own patients have shown that **hypogonadism is associated with anejaculation and DE**. Thus, correcting hypogonadism and improving erectile function is a first step in treatment of men with anejaculation or DE (arbitrary defined as >30 minutes of intravaginal stimulation). Erectile dysfunction is clearly associated with ejaculatory delay and anejaculation (13). Treatment with tadalafil has been shown to improve ejaculatory function (14). Review of our own experience indicates that testosterone level >650ng per dL may be needed to improve ejaculatory function but more research is needed in this area. Men with elevated prolactin (PRL) should have magnetic resonance imaging (MRI) of pituitary to exclude prolactinoma. Anecdotal reports indicate that empiric treatment with low-dose 0.25 to 0.5 mg of Dostinex has been associated with ability to ejaculate.

Medical therapy has been used for over three decades in men with anejaculation. Sympathomimetic agents have been a mainstay of medical therapy. They may work better in men who have RE, as they increase bladder neck resistance and direct flow of semen toward meatus. **Pseudoephedrine in doses of 30 to 120 mg** taken 1 to 2 hours prior to sexual intercourse can be used together with 5PDE inhibitor to improve erectile function. Imipramine has also been successfully used in RE (15). Midodrine has been successful in 50% of patients with anejaculation and RE but midodrine can result in very high blood pressure and is only approved for treatment of severe orthostatic hypotension (16,17).

Oxytocin analogs have been proposed as treatment of anejaculation, but clinical experience is at best limited. Recently, **trazodone** has been successfully used in men with disorders of orgasm and ejaculation secondary to selective serotonin reuptake inhibitors (SSRIs) (18). Trazodone may be considered in men who have nonorganic sexual dysfunction (19). SSRI weekend “vacation” buspirone, amantadine, and pramipexole (Mirapex) have all been proposed as potential treatment of anejaculation but no prospective trials exist to assess their efficacy (20).

Penile Vibratory Stimulation

Penile vibratory stimulation (PVS) has been used for therapeutic treatment of anorgasmia and to achieve ejaculation and help with erections (21,22) (Fig. 55.3).

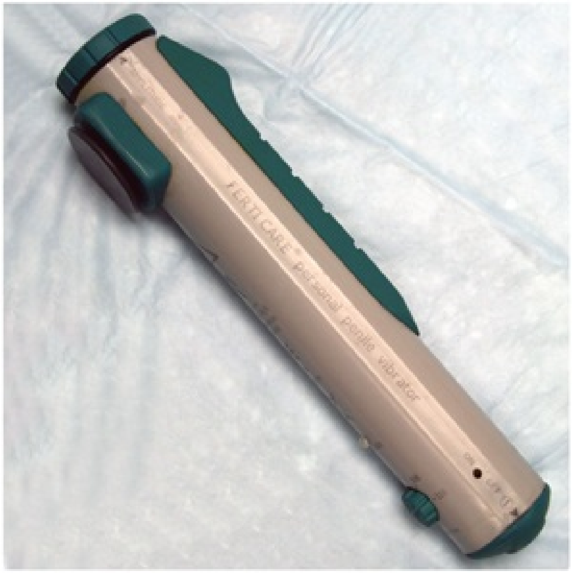

FIGURE 55.3 Penile vibrator has (a) amplitude adjustment, (b) frequency adjustment, (c) vibrating head, and (d) amplitude warning light.

Success of PVS depends on residual neuromotor control of ejaculatory centers. In complete upper motor neuron lesions, reflex erections can be achieved in 93% of men but antegrade ejaculation only in 5% of men (23). PVS has been successfully used as initial form of therapy in diabetic men with anejaculation and resulted in 50% of pregnancy rate. There seems to be a decrease in quality of semen parameters with nocturnal emission yielding highest concentration, followed by PVS and electroejaculation (EEJ) yielding lowest sperm concentration (24). PVS combined with at home vaginal self-insemination has resulted in 43% of pregnancies in men with spinal cord injury (SCI) (25).

Although testicular sperm extraction and epididymal aspiration of sperm in men with SCI and anejaculation combined with intracytoplasmic sperm injection is a feasible procedure, nonsurgical approaches should be initially tried (26).

PVS has been shown to result in higher density of sperm than EEJs (27,28). On average, men respond to **100-Hz vibration and 2.5-mm amplitude** in our practice using Ferticare vibrator (Fig. 55.4). In diabetic men, amplitude has to be increased up to 3.5 mm, but patient has to be instructed about possibility of skin erosion with vigorous use and limit pressure. We do not prescribe a Ferticare vibrator unless the patient demonstrates (in the office) that he can operate the vibrator safely. Skin erosion can occur in men with decreased genital sensitivity. Once the patient is able to ejaculate by self-stimulation with his partner present, he is encouraged to attempt intravaginal intercourse after achieving level of arousal close to ejaculation. This therapy was successful in 43/46 of men (93.4%) who were able to ejaculate by masturbation after mean follow-up of 14 months. Thirty out of 43 men who were able to ejaculate by self-stimulation were able to ejaculate intravaginally (own data). This combination therapy aimed at improving underlying pathology and focusing on increase of arousal has been recommended by ad hoc expert consultation on disorders of ejaculation and orgasm (8,29).

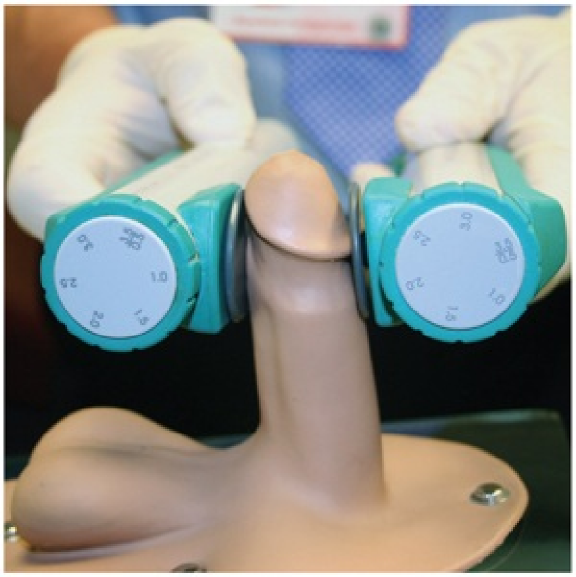

FIGURE 55.4 Two Ferticare penile vibrators can be used in men refractory to penile vibratory stimulation using maximum amplitude and frequency of single vibrator.

PVS has been successfully used in paraplegic men and in men with idiopathic anejaculation. In our practice, we always induce erection with either intracavernosal (IC) injection of 5 to 7 units of Trimix or 5PDE inhibitor given a couple of hours prior to vibratory stimulation (VST). VST is first performed under the supervision of a physician or trained registered nurse (RN), as skin erosion and abrasions are not uncommon in inexperienced patients or patients with decreased sensation in genital area. By progressive increase of amplitude and frequency of stimulation, ejaculation can be achieved within 10 to 20 minutes in most of patients with an intact nervous system and much quicker in patients with SCI (30). Once optimal settings are achieved in a sexual medicine laboratory, a prescription is given for the patient to use a vibrator at home. If the bulbocavernosus reflex (BCR) and the hip flexor response (HR) are both intact, the patient is much more likely to be successful with PVS as they, essentially, demonstrate a wholly active reflex arc and integrity of all of the neural pathways involved. Bird and colleagues reported that if both BCR and HR are positive, PVS is successful in inducing an ejaculatory reflex in 94% of men with an injury level between T1 and T6 and 67% of men with an injury level between T7 and T12. No patient was successful if neither reflex was positive. PVS allows for the retrieval of a semen specimen in a very simple fashion that can be used for home self-insemination, intrauterine insemination (IUI), or in vitro technologies. In the appropriate SCI male, PVS is the first-line option for treatment. The first-line option is *not* surgical sperm retrieval coupled with intracytoplasmic sperm injection.

Vigorous prostatic massage and in vitro fertilization (IVF) using sperm obtained during nocturnal emission has been reported, but the IVF success rate using those techniques is lower than expected (31).

Electroejaculation

EEJ should be considered when vibratory stimulation fails to induce ejaculation (30). Risk of autonomic dysreflexia in men with SCI below T5 is low (30). EEJ requires general anesthesia in patients with intact spinal cord and may lead to rectal mucosal injury (thermal injury). However, it is a rather rare complication if the rectal temperature is monitored (Fig. 55.5).

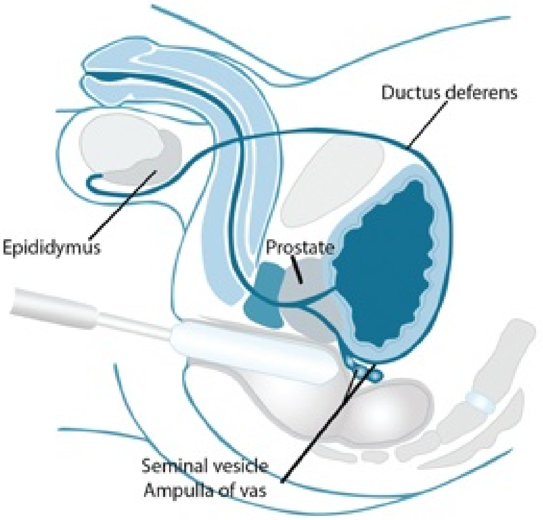

FIGURE 55.5 Position of the probe during electroejaculation. Longitudinal electrodes are pressed against the prostate seminal vesicles. Rapid increase in voltage and amperage leads to antegrade and retrograde ejaculation.

EEJ is a painful procedure in men with intact sensation in the lumbar or sacral region; thus, general anesthesia is required in men who have pinprick sensation in L–S dermatomes. Neuromuscular block (paralysis) is typically employed (32).

Indications include anejaculation due to SCI, retroperitoneal lymph node dissection (RPLND), idiopathic anejaculation, diabetes autonomic dysfunction, spina bifida, and multiple sclerosis.

Contraindications for EEJ include Crohn disease, ulcerative colitis, rectal cancer, large rectal fissure, extensive inflammatory changes in rectum, preexisting erosions of rectal mucosa, and patients with pacemakers.

Preparation: Alkalinization of urine is performed starting a day before by using 10 to 30 mL of Bicitra diluted in 4 to 8 oz of water with meals and the night before the procedure. A morning dose on the day of the procedure depends on the need for general anesthesia. Patients with SCI are advised to perform bowel evacuation the night before the procedure. Non-SCI patients perform an enema to clear the rectum. SCI patients prone to autonomic dysreflexia may be pretreated with subinguinal nifedipine 10 to 30 mg. The patient should report sudden headache or palpitations.

Position: left lateral position with adequate padding of the right forearm and placement of pillow in between the knees which should be slightly bent. The person collecting the specimen should stand in front of the penis and the person performing the EEJ stands behind.

The bladder should be emptied by catheterization using a plastic catheter in all EEJ cases and 5 to 20 mL of medium instilled in bladder. Anoscopy is performed to exclude any lesions of the anus and mucosa (Fig. 55.6).

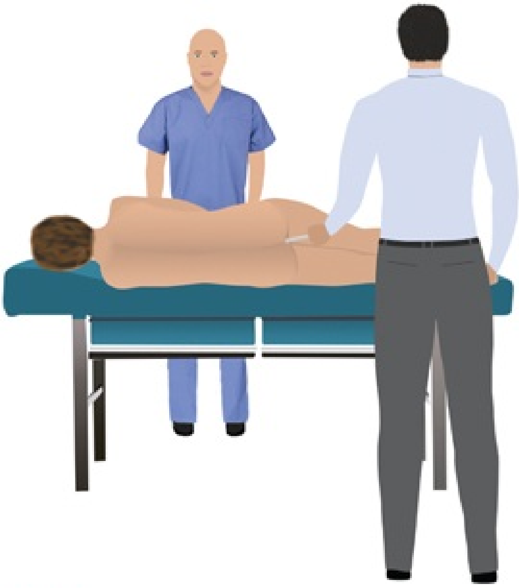

FIGURE 55.6 During EEJ, patient is placed in the lateral decubitus position with adequate padding of extremities. The EEJ operators insert the probe in the rectum and applies progressively increasing voltage to the prostate and seminal vesicles. The assistant stand in front of patient to collect semen through antegrade ejaculation in the sterile container. Retrograde ejaculate also has to be obtained by catheterization of the bladder. Assistant or anesthesiologist monitors patient's blood pressure to avoid life-threatening autonomic dysreflexia.

Equipment: Seager Electrostimulation Power Unit and Probes (Dalzell USA Medical Systems) is the most commonly used system approved for use in humans in the United States.

Probes: The probe has three attached linear electrodes embedded in medical grade PVC. Probes are placed in the rectum applying mild pressure to direct electrodes toward prostate and seminal vesicles. It is important that probe electrode surface temperature is monitored throughout the electrostimulation procedure. Temperature sensors are connected to a digital display on the power unit via the probe cord. The digital meter has both a warning light and an audible indicator showing when a set temperature has been reached. If the preset temperature should be reached, the warning audible will be activated and the machine will shut down. It cannot be used again until a different probe is selected. Standard-sized probes have diameters ranging from 1 inch (2.5 cm) to 1 516 inch (3.30 cm): 1 inch, 1 18 inch, 114 inch, and 1 516 inch (2.5 cm, 2.8 cm, 3.1 cm, and 3.3 cm). EEJ probes deliver an output of 0 to 40 V AC, the same frequency as the input power source (60 Hz), with current up to 1 Amp max.

Current is delivered by a rapid increase in voltage then held for 5 seconds and returned to 0 V. Starting voltage is typically 2.5 to 5 V and increased by 2.5 V intervals until antegrade ejaculation, peak voltage of 35 V, or temperature increase above 39.5°C. Gentle milking of the urethra may aid in collecting all the antegrade specimen into a collection cup. Subsequently, the bladder is catheterized and retrograde fluid collected. Anoscopy is performed again to document intact anal mucosa.

Monitoring: Blood pressure and heart rate are monitored and stimulation discontinued if systolic blood pressure exceeds 200 mm Hg or diastolic 130 mm Hg.

EEJ success depends on the underlying etiology, level and completeness of SCI, and time from SCI to EEJ (Table 55.1).

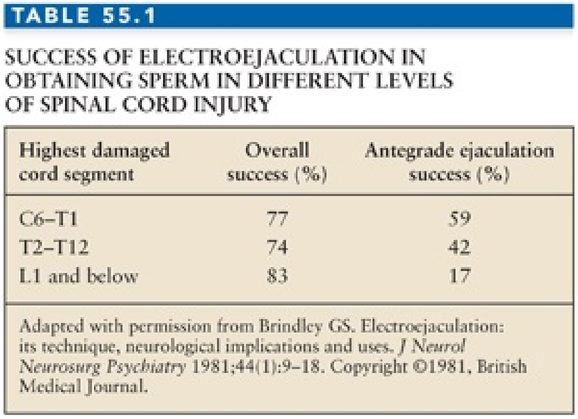

TABLE 55.1

SUCCESS OF ELECTROEJACULATION IN OBTAINING SPERM IN DIFFERENT LEVELS OF SPINAL CORD INJURY

Highest damaged cord segment	Overall success (%)	Antegrade ejaculation success (%)
C6–T1	77	59
T2–T12	74	42
L1 and below	83	17

Adapted with permission from Brindley GS. Electroejaculation: its technique, neurological implications and uses. *J Neurol Neurosurg Psychiatry* 1981;44(1):9–18. Copyright ©1981, British Medical Journal.

Failure of emission occurs with complete damage to the anterior horn of the L5–S2 regions. Depending on the nature of neurologic injury, patients can ejaculate antegrade, retrograde, or partially antegrade with RE. Thus, examination of the urine is always indicated. The antegrade specimen should be collected separately from retrograde specimen. Both antegrade and retrograde specimens should be delivered to the laboratory for further processing and either immediate use or cryopreservation.

Complications: Minor like abdominal discomfort or severe muscle spasm and UTI can occasionally happen. Autonomic dysreflexia and thermal injury to the rectum have to be discussed with patient. Colonization with methicillin-resistant *Staphylococcus aureus* (MRSA) and *Clostridium difficile* bowel infection has been reported.

Autonomic dysreflexia (AD) is a clinical medical emergency in individuals with SCI above the T6 level. An episode of AD is characterized by elevated arterial blood pressure (BP) and most commonly bradycardia but tachycardia can also be encountered. Elevation of systolic blood pressure (SBP) by 20 to 30 mm Hg in SCI patient during the procedure may be considered a dysreflexia episode. AD varies in intensity from asymptomatic minor BP elevation to severe headaches and life-threatening emergency with SBP climbing as high as 300 mm Hg. AD is typically triggered by irritation of the bladder or rectum (33). In patients with SCI who experience recurrent episodes of AD from self-catheterization or bowel emptying, preventive procedures like botulinum toxin injection into the detrusor or intravesical capsaicin may be considered first to decrease the risk of AD during EEJ. Use of lidocaine gel anally has decreased the incidence of AD in SCI (34). Management of the acute episode of AD consists of stopping the procedure which triggered AD and tilting patient upright (induces pooling of blood in the abdominal and lower extremity vessels). Use of antihypertensive drugs should be considered if SBP exceeds 150 mm Hg. Nifedipine 10 to 30 mg sublingually is an effective treatment of AD and if given 15 minutes prior to procedure can prevent a significant increase in BP in a patient prone to frequent AD. Captopril 25 mg has also been used successfully in acute episodes of AD (35). Prazosin 3 mg twice a day for 2 weeks prior to the procedure has decreased the number of episodes of AD.

Epididymal sperm aspiration or testicular biopsy is a next logical step to obtain sperm for IVF in failed EEJ. VST, EEJ, and epididymal aspiration or testicular biopsy remain important tools to obtain sperm for reproductive purposes in men with neurogenic anejaculation secondary to SCI and peripheral neuropathy (36). EEJ can also be considered in men with psychogenic anejaculation who fail medical treatment and behavioral modifications (37).

Retrograde Ejaculation

Evaluation of RE is straightforward as postorgasmic semen analysis revealing sperm confirms the diagnosis. Adequate amounts of sperm can be obtained from the retrograde ejaculate by catheterization. Urine alkalinization prior to retrieval of retrograde specimen is advised (38). If no sperm is identified, then color Doppler transrectal ultrasonographic ejaculatory study (TRUS-Ej) should reveal either failure of emission (lack of visible semen transfer from seminal vesicles) or azoospermia with RE if semen is seen flowing through the prostatic urethra and into the bladder (Figs. 55.7 and 55.8).

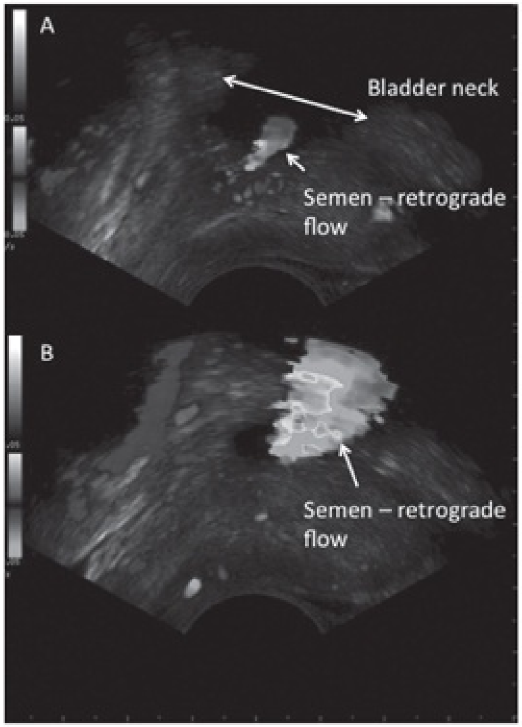

FIGURE 55.7 Retrograde ejaculation revealed by ejaculatory TRUS study in men with anejaculation and open bladder neck with no sperm identified in urine after ejaculation. Patient had bilateral obstruction of vas deferens from vasectomy. Notice open bladder neck and increase amount of semen flowing into the bladder.

B
Semen flow through ejaculatory duct
Prostatic cyst
PROST LGHT during ejaculation - above the cyst

FIGURE 55.8 Transrectal ejaculatory study is helpful in evaluation of anejaculation and obstructions of the ejaculatory ducts. In example above, the patient with azoospermia and low seminal volume was found to have a prostatic cyst overlaying left ejaculatory duct. Ejaculatory study showed that the semen flows freely above the cyst; thus, cyst is nonobstructive.

Treatment

Urinary sperm retrieval remedies a patient's infertility caused by RE by collecting viable sperm from postejaculatory urine to achieve pregnancy through artificial insemination. Jefferys et al. (39) reviewed three retrieval methods. The first method is centrifugation and resuspension of postejaculatory urine specimens, in which a urine specimen is obtained through voiding or catheterization, then suspended in medium, centrifuged, and resuspended before being used for artificial insemination. This method has by far the largest sample size, achieving a 15% pregnancy rate (35 pregnancies achieved out of 229 cycles). The second method, the Hotchkiss technique, involves emptying the bladder through voiding or catheterization, then rinsing the bladder with Ringer lactate. Some of the Ringer lactate is then injected into the bladder, after which the patient was asked to ejaculate. The ejaculate is then collected through voiding or catheterization and used for artificial insemination. The Hotchkiss technique or modified Hotchkiss technique, although less frequently studied than centrifugation, has achieved a higher pregnancy rate of 24% (7 pregnancies out of 29 cycles). The final method of urinary sperm retrieval, ejaculation on a full bladder, was described by only two papers studied in the Jeffreys et al.'s (39) review. In each case, the patient ejaculated with a full bladder and the ejaculate was then suspended in Baker buffer. This method, although also suffering from a small sample size, has achieved a 60% pregnancy rate (3 pregnancies out of 5 cycles) (39).

A review by Jefferys et al. (39) identified three key treatment methods for RE, including the retrieval of sperm from postejaculatory urine, medical treatment, and surgical treatment. Here, we will summarize the efficacy of each method as identified in the Jefferys et al. (39) review.

Studies examining the medical management of RE used the achievement of antegrade ejaculation as the metric for successful treatment. Although the sample sizes for these studies are again too small to make definitive statistical conclusions, the findings suggest that a combined treatment of sympathomimetics and anticholinergics is most effective, achieving antegrade ejaculation in 39% of patients. Treatment with sympathomimetics (synephrine, ephedrine sulphate, phenylpropanolamine, or midodrine) or anticholinergics (brompheniramine maleate or imipramine hydrochloride) alone, in contrast, achieved antegrade ejaculation in 28% and 22% of patients, respectively (39).

Only two papers reviewed by Jefferys et al. (39) describe surgical procedures for the treatment of RE. The injection of collagen into the bladder neck, as described by Reynolds et al. in 1998, resulted in two pregnancies and one live birth. The surgical removal of sperm, as described by Rosalund et al. in 1998 also resulted in a pregnancy through intracytoplasmic sperm injection. However, investigators acknowledge that surgical treatment of RE risks testicular scarring and damage that may cause further exacerbate ejaculatory dysfunctions, and therefore, surgical options should be considered carefully before execution (39).

In our practice, we have used Deflux 3 to 4 mL per each treatment to progressively bulb up the bladder neck in men with RE caused by resection of the bladder neck. Each procedure is performed every 3 months. Fifty percent of men achieve some antegrade ejaculation.

SUMMARY

In the future, anejaculatory treatment will most likely include specific medications to enhance arousal and lower the threshold for spinal cord ejaculatory centers in men with an intact spinal cord. Activation of 5-HT1A and 5-HT2C receptors activates the spinal cord motor generator and decreases ejaculatory latency and increases the effectiveness of copulation in rats (40). Gulliano et al. has recently reported success with induction of ejaculation by microstimulation of lumbar spinothalamic neurons, thus giving hope for future microstimulation of ejaculatory centers in men with SCI (41).

In summary, recent advances in neurobiology and new imaging modalities have dramatically expanded our understanding of ejaculatory function in animals and humans and should lead to the development of specific medications to treat DE and anejaculation in patients without complete SCI.

CHAPTER 56 ANATOMY OF THE TESTIS

MARK SIGMAN

An understanding of normal testicular anatomy is important for all urologists involved in male reproductive surgery. Proper knowledge of normal allows recognition of those instances of abnormal anatomy. Inadvertent injury to testicular arteries may result in testicular atrophy and potentially infertility and hypogonadism. Many of the testicular structures are extremely small, which has led to the adoption of magnification provided by an operating microscope by male reproductive surgeons. There is often a close coloration between physical exam findings and findings on surgical exploration. Small soft testes usually indicated impaired or absent spermatogenesis. Small firm testes are often associated with sclerosis and scarring of the testicular parenchyma, which may make testicular microdissection more difficult. Therefore, the surgeon should be familiar not just with normal anatomy but the particular physical exam findings on the patient to be operated on which will help preparation for the actual surgical procedure.

GROSS ANATOMY

Testicular Position

The testes are ovoid organs that lie within the scrotum with the long access of the oval, usually, but not always, in a vertical direction. The epididymis is most commonly aligned in a vertical posterior direction attached to the posterior surface of the testes. Normal testicular size is commonly reported to be 15 to 25 mL in volume (1) when measured with bead-like orchidometers; however, the recorded size depends on the measuring device used and often larger sizes obtained with devices such as punched out elliptical rings with which normal adult sizes commonly exceed 30 mL (2). The right testis is often slightly larger than the left. The testis and epididymis reside within the parietal layer of the tunica vaginalis (Fig. 56.1). Often attached to the caput epididymis is the appendix epididymis, whereas just in front of this is another embryologic remnant, the appendix testis. Either of these structures may torse resulting in pain. The capsule of the testis is actually composed of three layers. The most superficial layer is the visceral layer of the tunica vaginalis followed by the thickest component, the tunica albuginea, which consists of bundles of collagen fibers. From a surgical point of view, these two layers act as one, and surgical incisions into the capsule are closed in one layer. Underneath the tunica albuginea is the tunica vasculosa, which is a thin delicate layer that contains a plexus of small blood vessels. These vessels are easily injured during incisions into the testicular capsule. Delicate septations arise from the tunica albuginea separating groups of seminiferous tubules into lobules. The tunica albuginea is thickest along the posterior portion of the testes where it forms the mediastinum testis which extends into the posterior portion of the testis. Within the mediastinum is the rete testis that connects the seminiferous tubules to the efferent ductules (Fig. 56.2).

BLOOD SUPPLY

The testis has three arterial supplies. Two-thirds of testicular blood supply derives from the testicular artery with the remaining one-third divided between the deferential and cremasteric arteries (3). The testicular artery, also referred to as the internal spermatic artery (Fig. 56.3), arises directly from the aorta at level L3 below the renal arteries. It crosses anterior to the ureter and lies on the anterior surface of the psoas major muscle. The right testicular artery also crosses anteriorly to the vena cava; however, it is posterior to the bowel including the duodenum, root of the mesentery, terminal ileum, as well as the arteries associated with those portions of the bowel (right colic artery and the ileocolic artery). The left testicular artery is similarly posterior to the distal portion to the descending colon as well as the left colic artery and the inferior mesenteric vein. Both the right and left testicular arteries begin as single arterial structures. Once they enter the spermatic cord, the arteries may branch and thus one to three or more testicular arteries may be found within the spermatic cord (4,5). The numbers of testicular arteries and veins within the spermatic cord increase as the cord travels from the pelvis through the internal ring toward the scrotum. Although there is considerable variation in the pelvis, there is usually one artery and two veins. The mean number of vessels at the level of the inguinal canal is 2 arteries and 8 veins, whereas at the level of a subinguinal incision it is 3 arteries and 11 veins. A single testicular artery is present in 69% of cords within the inguinal canal, whereas this is the case only 25% of the time in the subinguinal region (6). In addition, the arteries in the subinguinal region are much more likely to be surrounded by a complex of veins than in the inguinal region. Thus, varicocele repair in the subinguinal region is technically more demanding than if performed in the inguinal canal (7).

FIGURE 56.3 Testicular blood supply (cremasteric vessels not pictured).

As with the arterial blood supply within the spermatic cord, there is considerable variation in the course of the arteries within the testis. The arteries enter the testis beneath the epididymis, usually in the corpus region. These capsular arteries travel in the tunica vasculosa in an inferior direction toward the lower pole, sending out other capsular branches interiorly. The arteries also then ascend from the lower pole superiorly along the anterior surface of the tunica vasculosa. Branches extend from the anterior surface over the testicular parenchyma (Fig. 56.4). Centripetal arteries descend within the septa between lobules. Before reaching the rete testis, they leave the septa as recurrent arteries, enter the lobule and travel vertically back towards the tunica—the opposite direction of the centripetal arteries. Segmental arterioles branch off the recurrent arteries in the interstitium which branch further as as interstitial arterioles. These arterioles form branching capillaries among Leydig cell clusters. Some of these leave the Leydig cells as inter-Leydig cell capillaries and penetrate into the lamina propria of the seminiferous tubules, and after some distance, these intramural capillaries leave the seminiferous tubule wall and are again surrounded by Leydig cells. They then continue as postcapillary interstitial venules which enter intralobular small veins (Fig. 56.5) (8).

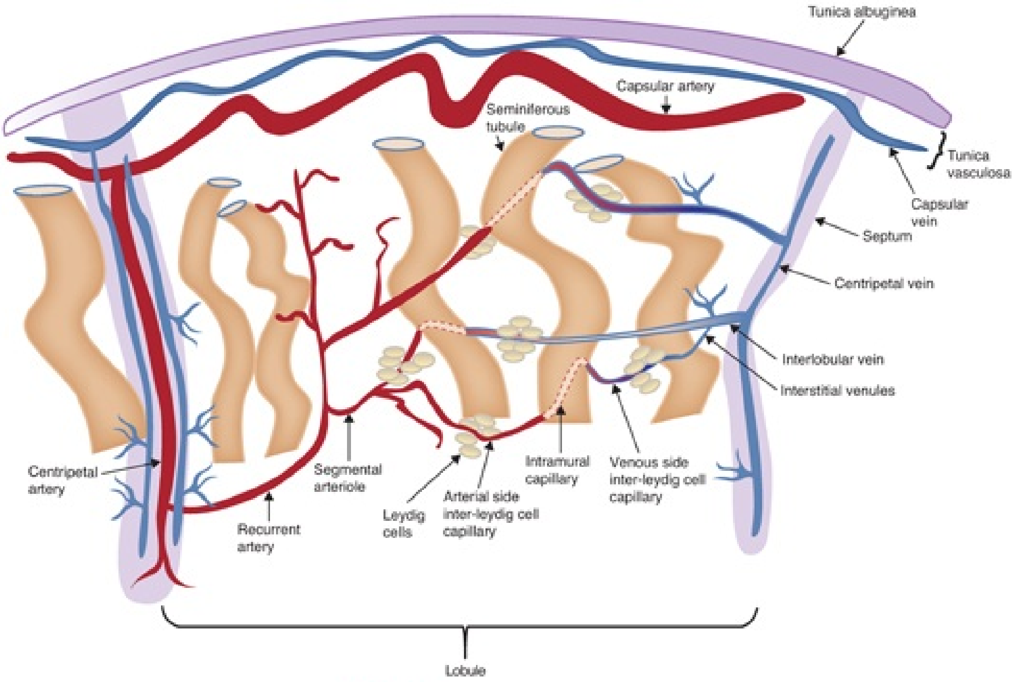

FIGURE 56.5 Microvasculature of the testis.

Often, but not always, the least vascular regions of the testis are the medial and lateral surfaces of the superior pole (6). However, incisions in the upper pole, if under the caput epididymis, may injure the rete testis and interfere with the entry of sperm into the efferent ductules and therefore should be avoided. Often, the midsection of the testis has fewer vessels, and a horizontal incision in this region is commonly used for testicular sperm retrieval. However, because of the variability of arterial blood flow, optical magnification should be used and allows for the identification of less vascular regions of the anterior surface of each individual testis. The deferential artery travels with the vas deferens after branching from the superior or inferior vesicular artery. It travels inferiorly toward the cauda of the epididymis. In general, this remains a single artery throughout the course of the vas deferens. The cremasteric artery branches off from the inferior epigastric artery. It travels on the cremasteric fascia to the surface of the tunica vaginalis.

There are extensive communicating channels between the various arterial supplies to the testis. The communicating channels between deferential and testicular arteries have been reported in 87% of humans, whereas communications between the cremasteric artery and the testicular artery have been found in 50% of specimens (9). The testicular artery anastomoses may occur at any point from the internal inguinal ring to the tunica albuginea. In contrast, the deferential artery tends not to demonstrate anastomoses until the level of cauda epididymis. In general, the testicular arteries tend to be larger than either the cremasteric or deferential arteries. Considerable variation in size may exist between branches of the testicular artery, with some branches being quite small and therefore easily injured during surgery. Optical magnification is very helpful in identifying these small branches.

There are four potential venous outflow systems from the tests: testicular (spermatic), vasal (deferential), external cremasteric, and gubernacular veins. Intratesticular veins travel between the lobules of the seminiferous tubules interconnecting in the tunica vasculosa, but they do not follow the course of the intratesticular arteries. They exit posteriorly either near the mediastinum following the course of the rete testis or exit through the tunica to superficial veins on the testicular capsule (10). These veins merge with deferential veins forming the pampiniform plexus in the spermatic cord. Within the spermatic cord, there are more testicular veins than arteries. The testicular arteries are typically closely adherent to veins that have multiple interconnecting anastomoses (11). This is thought to be important for countercurrent heat exchange. As a result, intratesticular temperatures are 3° to 4° lower than rectal temperature (12). The deferential veins follow the vas deferens proximally. External cremasteric veins lie within the cremasteric muscle fibers and may exit the cord through the floor of the inguinal canal or in the subinguinal region, draining into the inferior epigastric vein (13). Finally, gubernacular veins exiting the tunica vaginalis through the gubernaculum have been identified in 79% of varicocelectomy patients (4). The significance of the gubernacular veins is unclear—some have suggested they are a potential source of varicocele recurrence if they are not ligated (4); however, others have demonstrated no benefit in clinical outcomes to ligation of these veins (14).

Proper knowledge of the testes arterial, venous, and lymphatic anatomy is important for male reproductive surgery. Because there is considerable variation in the number of testicular arteries, it is not surprising that some studies have demonstrated testicular atrophy from testicular artery ligation, whereas others studies have not (15,16,17,18,19,20,21). In addition, high ligation of the artery is less likely to result in atrophy than low ligation because of the interconnections between the vasal and testicular arteries. This characteristic is used with the Fowler-Stephens orchiopexy (22). During microsurgical varicocele repair, the testicular arteries are spared but occasionally may be injured. However, because of the anastomotic channels or the presence of multiple arteries, testicular atrophy only occurred in 5% of the cases of testicular artery ligation (23). Of note, during vasectomy, the deferential artery may be injured; therefore, performance of a simultaneous varicocele repair and vasectomy has an increased chance of testicular atrophy. The use of optical magnification allows the surgeon to identify and preserve testicular deferential and cremasteric arteries to lessen the chance of atrophy. Similarly, with varicocele repair, all the testicular veins within the cord are ligated, leaving only the deferential (and possibly gubernacular) veins to provide venous drainage. Ligation of deferential, testicular, and cremasteric veins, as may be intentionally done for testicular denervation for orchialgia, risks testicular atrophy. During testicular biopsy or testicular sperm retrieval, incisions into the testicular capsule should follow a direction less likely to cross blood vessels—typically in a medial to lateral direction. Within the testicular parenchyma, performing dissection between lobules lessens injury to the intratesticular vasculature (24). These subcapsular vessels can be seen and avoided using an operating microscope (25).

LYMPHATIC DRAINAGE

Lymphatic channels leave the testis and tunica vaginalis, forming trunks within the spermatic cord. Commonly, four to eight lymphatic channels may be identified. With traditional nonmagnified varicocele repair, these channels were inadvertently ligated resulting in a high incidence of postoperative hydroceles (approximately 15% to 25%). Lymphatic sparing microsurgical varicocele repair has reduced the postoperative hydrocele incidence to 1% or less (26).

INNERVATION

Testicular pain is mediated by both sympathetic nerve fibers, which travel next to the testicular arteries as well as branches from the ilioinguinal and genital femoral nerves. Autonomic nerves derived from the 10th to 11th thoracic spinal segments form ganglions in the regions of the vena cava and aorta near the takeoff of the gonadal arteries (27). The nerve fibers then descend along the path of the testicular arteries, forming a superior and inferior spermatic nerve (28). Parasympathetic fibers originating from the vagus nerve and the inferior spermatic nerve innervate the lower pole of the testis as well as the vas deferens and epididymis (28). Beyond carrying pain fibers, the exact role of these nerves in testicular function remains unknown. For the reproductive surgeon, the important points of testicular innervation are that within the spermatic cord the nerves are microscopic and multiple. In a recent study, approximately 25 microscopic nerves were identified within the spermatic cords (29). Because these nerves are small, it is, therefore, easy to temporarily denervate the testis with a spermatic cord block with local anesthetic infiltration into the cord. Although this only temporary elevates pain, this accurately identifies patients that have significant pain relief of orchialgia from spermatic cord denervation procedures (30). Because the nerves tend to be microscopic, they are not individually ligated rather the testicular arteries, lymphatics, and some venous drainage is preserved, whereas the remaining cord structures are ligated and divided. This approach assures division of the multiple microscopic testicular nerves. Depending on the patient’s fertility concerns, the vas deference may or may not be spared (31).

TESTICULAR PARENCHYMA

The testicular parenchyma consists of seminiferous tubules and interstitial tissue. Within the seminiferous tubules are Sertoli cells, germ cells, and tubular fluid. The interstitium contains Leydig cells, blood vessels, lymphatics, fibroblasts, macrophages, and mast cells. Seventy percent to 80% of the testis is composed of seminiferous tubules with the remainder consisting of interstitial tissue (10). There are approximately 600 to 1,200 seminiferous tubules within the human testis (32). The seminiferous tubules are coiled looped structures with the ends of the tubules in the rete testis and the tubules extending radially from that point toward the periphery. The rete testis leads to 6 to 12 efferent ducts which pass through the tunica albuginea and enter and form the caput epididymis. From a surgical prospective, with microsurgical technique, it is possible to separate the lobules of seminiferous tubules and to dissect between individual seminiferous tubules in a radial fashion without extensive injury to the testis. With optical magnification, the surgeon often finds Leydig cell nodules in testes of infertile men. Lymphatic structures are typically not visualized within the interstitium during testicular surgery but are visualized within the spermatic cord. All spermatogenesis takes place within the seminiferous tubules; therefore, the tubule diameter and color depends on the status of spermatogenesis. Tubules containing normal spermatogenesis tend to have a pale yellow-orange color and are opaque when examined under the operating microscope (Fig. 56.6A). In contrast, tubules with Sertoli-only patterns have a smaller diameter, appear white and semitranslucent (see Fig. 56.6B).

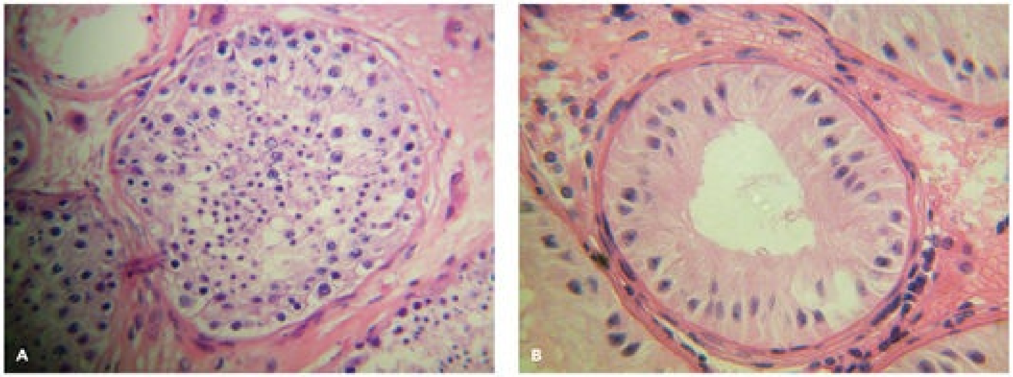

FIGURE 56.6 A: Normal testicular histology, 400×. B: Sertoli-only histology, 400×.

SUMMARY

The last decade has seen significant advances in testicular surgery. It has become clear that optical magnification and a proper knowledge of the testicular anatomy is imperative for the success of surgery and the avoidance of testicular artery injury, causing impaired testicular function, and lymphatic ligation, causing hydrocele formation.

CHAPTER 57 SPERM RETRIEVAL TECHNIQUES

KELLY A. CHILES AND PETER N. SCHLEGEL

Azoospermia is defined as the complete absence of sperm in the ejaculate after analysis of two ejaculated specimens. Up to 15% of infertile men are azoospermic, and the etiology can be either obstructive azoospermia (OA) or nonobstructive azoospermia (NOA). OA is estimated to be responsible for 40% of cases of azoospermia and can result from such varied causes as congenital absence of the vas deferens or ejaculatory duct obstruction and iatrogenic etiologies such as vasectomy, injury to the vasa during inguinal surgery, or injury to the epididymis from scrotal surgeries such as hydrocelectomy. NOA comprises the remaining cases and results from failure of the testis to produce sperm. It is imperative that the clinician determine through careful history and exam if the cause is lack of sperm production or obstruction because this will dictate the optimal approach for sperm retrieval. For NOA, only the testis can be targeted for retrieval purposes; however, with OA, the vas deferens, epididymis, and/or testis can likely be used.

OA can be suspected based on history (prior vasectomy or bilateral inguinal surgeries), physical exam (normal testicular volume [>20 mL], absent vasa, or congested epididymides), and laboratory values (normal follicle-stimulating hormone [FSH] [<8 mIU/mL], positive serum antisperm antibody assay, or decreased ejaculate volume [<1.5 mL]) (1). NOA can similarly be suspected based on history (known hypogonadism), physical exam (atrophic testis), and laboratory values (FSH elevated 2 to 3 times upper limit of normal, negative antisperm antibody assay, karyotype anomalies, or Y chromosome microdeletions). In addition, men with ejaculatory dysfunction such as anejaculation or retrograde ejaculation are also candidates for epididymal sperm retrieval, although some of these men may also use less invasive sperm retrieval techniques such as penile vibratory stimulation, electroejaculation, or postejaculatory urine sperm retrieval depending on the etiology of their aspermia. Furthermore, men with obstruction may benefit from reconstruction, particularly if more than one biologic child is desired, because primary reconstruction is more cost-effective than sperm retrieval and repeated in vitro fertilization (IVF) cycles. If the female partner, however, has fertility issues that necessitate IVF and intracytoplasmic sperm injection (ICSI), surgical sperm retrieval may be more appropriate than reconstruction.

There are expected differences in the quality and quantity of spermatozoa retrieved based on the etiology of azoospermia, method of recovery, and tissue of origin. Epididymal sperm is often more mature and motile, whereas testicular sperm is usually immotile except in the case of obstruction. Notably, the virtually limitless supply that is recovered with microsurgical epididymal sperm aspiration (MESA) allows multiple samples that can be frozen for future IVF cycles and has a distinct advantage over the more limited numbers harvested from testicular tissue. The sperm retrieval can be done any time prior to the IVF cycle with multiple vials cryopreserved. Percutaneous epididymal sperm aspiration (PESA) generally has a relatively low yield of sperm, most of which are severely damaged with low motility. Percutaneously retrieved sperm with very poor motility may reduce IVF success rates, and low sperm motility may adversely affect the ability to freeze sperm for future use. Patients should be counseled accordingly regarding this possibility.

Sperm retrieval from men with impaired sperm production (NOA) for use with assisted reproductive technology (ART) is preferentially performed the day before oocyte retrieval, although it can be performed the same day if necessary. Timing is important because all methods of sperm retrieval commit the female partner to ART, and the female can be spared an unnecessary procedure if no sperm are found and the couple defers the use of donor sperm. It is recommended that surplus sperm be frozen for potential use in the future so as to spare the male partner additional procedures. Although it is understood that there is an expected loss of up to half of the frozen spermatozoa during the freeze-thaw process, there is no data to suggest that the sperm which survive the freeze-thaw process are inferior to fresh sperm. In fact, there seems to be no difference in either the fertilization or pregnancy rate from fresh or frozen-thawed sperm when men have normal sperm production and are obstructed (2). For men with normal production and obstruction, elective sperm retrieval for freezing prior to the IVF/ICSI cycle may be preferred. For men with NOA, best results are obtained fresh sperm.

Contraindications to sperm retrieval efforts include anyone who cannot undergo scrotal surgery such as men with active groin or urinary infections or men who are not physically able to withstand the stress of surgery. Retrieval is not recommended for men with complete deletions of the AZFa or AZFb regions of the Y chromosome because no patients have had sperm found with these conditions. Relative contraindications include men who have already undergone a failed, thorough bilateral microscopic-assisted testicular sperm extraction (microTESE) by a trained microsurgeon because the chance of successful sperm retrieval in these men is virtually zero.

INTRAOPERATIVE SPECIMEN EVALUATION

All methods of sperm retrieval warrant evaluation under phase-contrast microscopy during the procedure in order to document if sperm have been retrieved and degree of motility. Additional pathologic evaluation of a permanent specimen or analysis by an andrology laboratory does not replace the real-time information which can be obtained from a properly performed intraoperative wet prep. In the case of testis biopsy, a touch prep is prepared by gently touching a slide to the cut surface of the testis, adding a drop of human tubal fluid (HTF) media. For epididymal aspirations, a tiny drop of aspirated specimen is placed on a slide, mixed with HTF, and for TESE specimens, after complete tissue dispersion of the retrieved sample by the urologist, a small fraction of tissue is placed on a slide. After a drop of HTF is added, a cover slip is carefully placed. Analysis under a microscope at 400× magnification will not only reveal the presence or absence of sperm but motility can be assessed as well. The presence of many motile or immotile sperm in the testis or in the epididymal fluid confirms the diagnosis of OA in men who are candidates for reconstruction (3). The identification of adequate (enough to fertilize all retrieved oocytes), viable (at least twitching) sperm during a TESE procedure signifies success, and the procedure can be terminated.

A permanent, fixed touch prep is a second kind of specimen evaluation that is most useful in men with NOA. After touching a slide to the cut surface of the testis, it is fixed with 95% ethyl alcohol and stained with the Papanicolaou technique. This technique is specifically used to differentiate between late maturation arrest and complete spermatogenesis. It allows the pathologist to scan through multiple depths of the specimen to identify if the spermatozoa have developed tails or not. Traditional permanent section of biopsy specimens uses such thin-cut paraffin embedded specimens that pathologists are unable to identify if the spermatozoa have tails, and thus, they cannot differentiate between late maturation arrest and complete spermatogenesis without the aid of touch preps.

TESTIS BIOPSY

Indications

Testicular biopsy for fertility purposes has both diagnostic (documenting the degree of spermatogenesis in order to predict the chance of successful sperm retrieval) and therapeutic (providing sperm for use in conjunction with ART) benefits, and the decision to biopsy is tightly linked to the serum FSH levels and physical exam of the patient. Biopsy is indicated in azoospermic men with normal FSH levels and testicular size/consistency, at least one palpable vas deferens, and a negative antisperm antibody assay to differentiate OA from NOA. Biopsy can be performed prior to a more invasive procedure such as vasal or epididymal reconstruction in order to verify spermatogenesis, or it can be performed concomitantly with TESE in order to provide diagnostic information regarding degree of spermatogenesis or associated histology. Testis biopsy is not indicated prior to sperm retrieval efforts for azoospermic men who clinically have primary testicular failure. Furthermore, men with congenital bilateral absence of the vas deferens and normal FSH and testicular size always have sperm production, and biopsy is therefore not indicated prior to undergoing sperm retrieval.

It is imperative that biopsy results be interpreted with caution in cases where no spermatogenesis is seen. The testicular parenchyma is not homogenous, and a biopsy will only sample a very small fraction of the 600 to 800 seminiferous tubules. The four histologic subtypes which can be found include normal spermatogenesis, hypospermatogenesis, maturation arrest, and Sertoli cell–only; on occasion, a biopsy will demonstrate more than one histologic subtype. Because there can be small foci of spermatogenesis randomly scattered throughout the testis, a random biopsy that does not demonstrate any spermatogenesis does not preclude sperm production elsewhere. When determining the chance of successful sperm retrieval, the most advanced stage of spermatogenesis is always used instead of the most prevalent stage. Men who have no germ cells (Sertoli cell–only histology) appreciated on testis biopsy are still candidates for TESE because these men have approximately a 35% to 40% chance of finding sperm during formal microTESE. The chance of successful sperm retrieval for maturation arrest and hypospermatogenesis are, respectively, about 71% and 96% when microTESE is undertaken (4).

Intratubular Germ Cell Neoplasia

One admittedly controversial indication for testicular biopsy is in men at increased risk of testicular cancer or intratubular germ cell neoplasia (ITGCN). These include men who have a history of male factor infertility, cryptorchidism, contralateral testicular cancer, and atrophic testis (<12 mL) and patients with disorders of sex development (5). Men who are undergoing orchiectomy for testicular cancer can consider concomitant contralateral testicular biopsy because up to 9% of these men will have ITGCN in the contralateral testicle (6). Prepubescent boys undergoing orchidopexy do not warrant biopsy because of the rarity with which ITGCN is found, although adult males undergoing orchidopexy for undescended testis should consider it because 1.7% of men with a history of cryptorchidism are found to have ITGCN. The pathologic finding of ITGCN lends itself to additional controversy because there is no gold standard for management. Although 70% of men with ITGCN will develop a germ cell tumor within 7 years, immediate treatment is not always required. Radical orchiectomy is typically done for men with ITGCN and a contralateral normal testicle. Radiation therapy is considered for men with a solitary testicle to preserve androgen production.

Technique: Testicular Sperm Aspiration, Percutaneous Testicular Biopsy, and Open Biopsy

Testicular biopsy can be performed in either the office or the operating room. When testis biopsy is performed with a fine needle, it is known as testicular sperm aspiration (TESA); when performed with a biopsy gun, it is often called a percutaneous testicular biopsy (PercBiopsy); and when performed open, it is simply referred to as a biopsy. Proper positioning of the testis within the scrotum is paramount regardless of approach. With the epididymis secured posteriorly, the testicle is held by the surgeon’s nondominant hand with the skin stretched tightly over the anterior surface. For percutaneous approaches, we routinely use 1% lidocaine diluted 9:1 with 8.4% sodium bicarbonate for local anesthesia; injection is into the skin initially and then deeper into the tunica. When performing TESA, an 18- to 25-gauge syringe is introduced along the long axis of the testis (Fig. 57.1). Tubule architecture is intentionally disrupted with repeated passes of the needle in multiple directions while continuously aspirating. For more ample tissue retrieval, PercBiopsy is used. A small 2- to 3-mm nick in the skin is made to facilitate passage of a 14-gauge × 10-cm core biopsy gun (Fig. 57.2). Introduction of a needle or biopsy gun should preferentially be in the anteromedial or anterolateral superior pole of the testis because this is the area least likely to contain larger arterial branches running deep to the tunica albuginea.

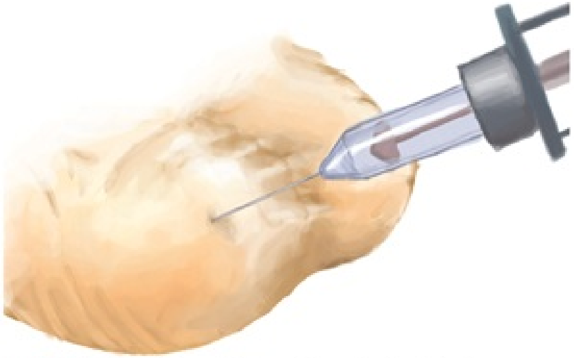

FIGURE 57.1 Technique of fine needle aspiration of testis.

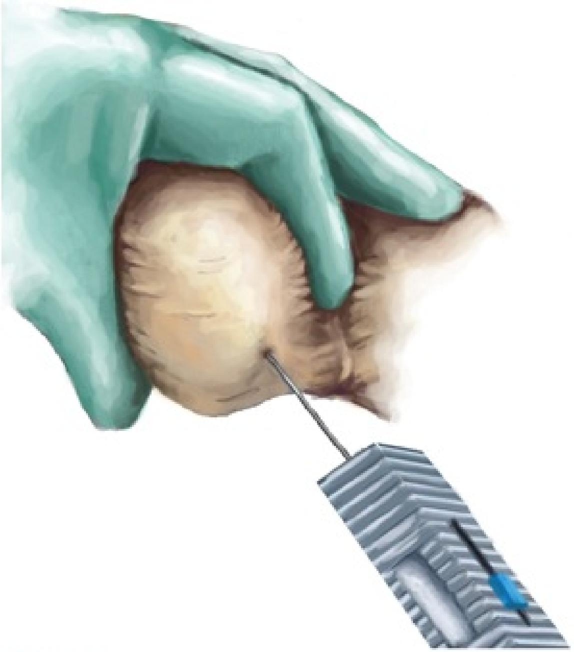

FIGURE 57.2 Technique of PercBiopsy.

For an open biopsy, a 1-cm incision is carried down to the level of the tunica albuginea. Optical loupes or preferably an operating microscope provides sufficient visualization of the subtunical blood supply (7). A stay suture (preferably polypropylene or nylon) is placed through a nonvascular region of the tunica albuginea. Using a 15-degree microknife, a 0.5-cm transverse incision is made in an avascular spot. Seminiferous tubules should easily extrude without applying significant pressure; if not, the tunica incision should be deepened or lengthened to facilitate easy delivery of tubules (Fig. 57.3). Excess pressure and manipulation of the tissue should be minimized in order to preserve the architecture as much as possible. The specimen can be sharply excised and placed in either Bouin, Zenker, or collidine–buffered glutaraldehyde solution; formalin should be avoided because it distorts seminiferous tubular architecture. Hemostasis is achieved with a microbipolar cautery. The tunica albuginea is closed with 5-0 polypropylene or Vicryl, tunica vaginalis with 4-0 Biosyn, and the dartos layer closed hemostatically with 4-0 Biosyn; skin closure is effected with subcuticular 5-0 Caprosyn. A 0.25% bupivacaine with epinephrine is injected in the subcutaneous tissue.

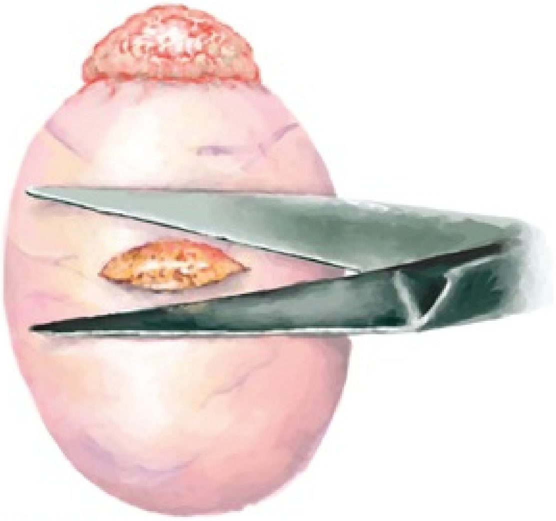

FIGURE 57.3 Technique for open testicular biopsy.

Importantly, there are a few distinctions in biopsy technique regarding whether it is being performed for oncologic purposes or fertility preservation. In cases of high suspicion for malignancy or ITGCN, an inguinal approach should be used. Furthermore, specimen preservation should take into account the likely need to perform immunohistochemistry, and as such, formalin can be used so as to allow appropriate tissue manipulation. If Bouin fixative is used, the pathologist should be alerted because this may change his or her choice of tests. In addition, fine needle aspiration and percutaneous biopsy do not sample enough tissue to provide a diagnosis, and thus, open biopsy is more likely to yield the needed volume.

Technique: Conventional Testicular Sperm Extraction and Microscopic-Assisted Testicular Sperm Extraction

Conventional and microTESE differ only in the use of an operating microscope to allow approximately 15× magnification; although the operative steps are analogous, the greater magnification allows the direct evaluation of individual seminiferous tubules which significantly increases the duration of the microTESE procedure compared to conventional TESE but improves the chance that the tiny biopsy samples taken will contain sperm. Under general or spinal anesthesia, a median raphe incision just large enough to deliver the testis is made. At this point in microTESE, an operating microscope is used to provide the 6× to 8× optical magnification which allows subtunical blood vessels to be easily visualized. The tunica albuginea is incised with a 15-degree ultrasharp knife in an avascular plane along the midpole of testis (Fig. 57.4). Bipolar cautery is used to maintain hemostasis and minimize injury to tubules adjacent to blood vessels. The testis is gently bivalved along its equatorial plane to widely expose the parenchyma. Strict attention is paid to minimizing tissue injury with gentle handling, and the authors recommend liberal use of “Saturday night hands” (8). Examination of the tubules occurs under 10× to 15× magnification, and every plane of the testis is systematically investigated in order to identify relative differences in tubule diameter and color. Larger, opaque or whiter tubules are more likely to contain germ cells and have some degree of spermatogenesis. A homogenous appearance of tubules can portend a poor retrieval prognosis. If no promising tubules are appreciated, additional dissection in the upper and lower poles are performed to thoroughly visualize all aspects of the testis. Unlike testicular biopsy where only a fraction of the superficial seminiferous tubules are sampled, all aspects of the testicular parenchyma are extensively surveyed. Centrifugal vessels that course along the septae separating tubules are avoided.

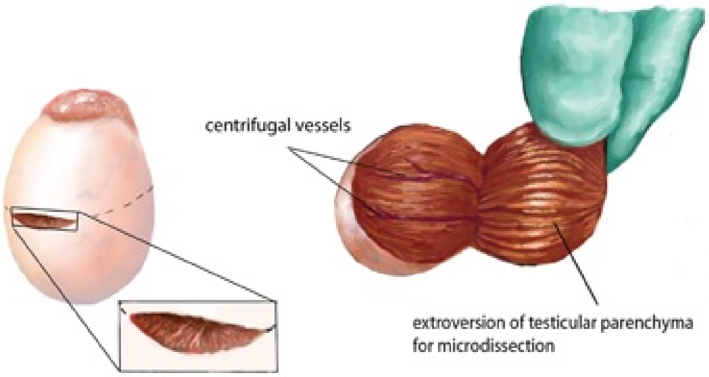

FIGURE 57.4 Technique of microTESE. *Inset* shows dilated epididymal tubules of varied appearances. The most dilated, yellow tubules should be avoided as they predominantly contain macrophages and degenerating sperm.

Only tubules judged to have the most likely chance of containing sperm are retrieved and set aside for processing prior to delivery to the andrology laboratory. Tubule processing is one of the most critical steps in successful retrieval efforts, and this is routinely managed by the urologist at our institution in order to guarantee meticulous preparation prior to microscopic examination. The microTESE technique allows for relatively small amounts of testicular tissue to be excised (up to 5 mg). In addition to preserving testicular function through minimal tissue removal and minimizing bleeding/cautery, this small volume lends itself to complete tissue disruption, optimizing sperm release from inside the tubules with mechanical disruption. The excised tubules are first placed in a small amount of buffered human tubule fluid or similar media supplemented with 6% Plasmanate. Iris scissors are used to initially separate the tightly coiled tubules until no individual clumps of tubules can be appreciated. This homogenate is next repeatedly aspirated and passed through a 24-gauge angiocatheter to assure complete dispersion of the testicular tissue. Embryologists routinely examine a small fraction of every surgical specimen in the operating room during the microTESE procedure. If no sperm are found initially, we continue our search until all planes of the testis have been surveyed, with each surgical specimen being processed and examined in real time, dictating the degree of our search. If no sperm are found after an exhaustive search of one testis, we will deliver the contralateral testis through the same scrotal incision and begin the search anew. Retrieval efforts are complete when either sperm are identified in the operating room or all areas of both testes have been completely examined. Prior to closure of the tunica, meticulous hemostasis is obtained because any subsequent scar which develops in the testis after sperm retrieval efforts is secondary to postoperative bleeding. Closure of the tunical layers, dartos, and skin is effected as described earlier. In addition, injection of 0.25% bupivacaine under the tunica vaginalis, along the spermatic cord, and into the scrotal sac is used. A total of 40 mL of bupivacaine is typically used to provide effective block of the multiple sources of innervation to the testis/scrotum. The subcutaneous tissue is injected with 0.25% bupivacaine and epinephrine.

Outcomes: Testicular Sperm Retrieval

As with any surgical procedure, infection and bleeding are known risks that can be minimized with meticulous hemostasis and attention to detail. Unique to testicular sperm retrieval efforts, testicular function decline is also a risk. We have found that limiting postoperative bleeding through meticulous hemostasis will minimize scarring and thus reduce subsequent androgen decline. Because men with NOA often have a baseline deficit of testicular function, it is not surprising that there is a measurable decrease in testosterone production that may not fully return to baseline after sperm retrieval efforts (9). The ultimate serum testosterone level is determined, in part, by both baseline hormone production as well as the extent of surgery. Notably, open techniques such as MESA and TESE involve longer operating times, and microTESE, although providing the greatest chance of sperm retrieval in the context of the least testicular damage, often necessitates the longest duration under general anesthesia.

The gold standard of sperm retrieval for NOA is microTESE when taking into account the higher success rates as well as ability to limit damage to the testicle (10). We have routinely demonstrated success in over 50% of men with NOA, including men with multiple prior failed attempts using conventional open methods, and scarred and atrophic testis. Our results have shown that microTESE results are independent of serum FSH levels and testicular volume. Even men with very atrophic testes and markedly elevated FSH have similar chances of sperm retrieval to men with borderline FSH levels because the microTESE procedure is able to identify even limited areas of sperm production in these grossly abnormal testes. The most recent data at Weill Cornell revealed a sperm retrieval success rate of 794 of 1,414 (56%) that translated into a fertilization rate of 4,423 of 8,705 injected oocytes (51%), and ultimately, a live delivery rate of 41% (11) of couples in whom viable sperm were successfully retrieved on microTESE.

EPIDIDYMAL SPERM RETRIEVAL

Technique: Percutaneous Epididymal Sperm Aspiration

After subcutaneous and spermatic cord block, the epididymis is firmly positioned against the scrotal skin and a 21- to 25-gauge needle and tuberculin syringe are used to aspirate fluid. The small volume of aspirate is often on the order of microliters and can be expanded with about 0.1 mL of human tubule fluid in the syringe. Additional samples can be taken traveling along the epididymis from cauda to caput until adequate healthy, motile sperm are found via intraoperative evaluation of small aliquots of specimen. Blind punctures of the caput should be limited to avoid the inherent risk of injury to the major vessels which insert into the testis immediately adjacent and inferior to the caput.

Technique: Microsurgical Epididymal Sperm Aspiration (Preferred Technique)

Under local or general anesthesia, a single median raphe incision or two transverse scrotal incisions within the scrotal skin folds is made, the hemiscrotum entered, and the tunica vaginalis opened widely. Using an operating microscope, the epididymis is exposed and carefully surveyed. Grossly dilated yellow/brown tubules are predominantly identified throughout the length of the epididymis and color noted. These yellow tubules are likely to contain nonviable, damaged sperm with blunt tails and many macrophages. The tubules containing clear golden fluid are more promising in providing sperm with optimal motility than tubules containing thick yellow fluid. Iris scissors are used to remove a 2- to 3-mm buttonhole of overlying epididymal tunic before the dilated tubule is punctured with a micropipet to aspirate this very sperm-rich fluid (Fig. 57.5). Alternatively, and not requiring specially prepared sharp, pointed pipettes, an opening is made in the tubule with a 15-degree microknife. Fluid is then aspirated into readily available standard 5-μL laboratory pipettes (12). Only minute amounts of fluid may be aspirated; however, this fluid is incredibly concentrated; typically a million sperm are found in each microliter of epididymal fluid. Because these men often have long durations of obstruction, it is not uncommon to find healthier appearing, motile sperm closer to the caput than the cauda. As with TESE, samples are evaluated intraoperatively to confirm the aspiration of adequate, viable sperm. The site of puncture is sealed with bipolar cautery prior to returning the testis to the scrotum, and the scrotum is closed as previously described with the liberal use of local anesthetic.

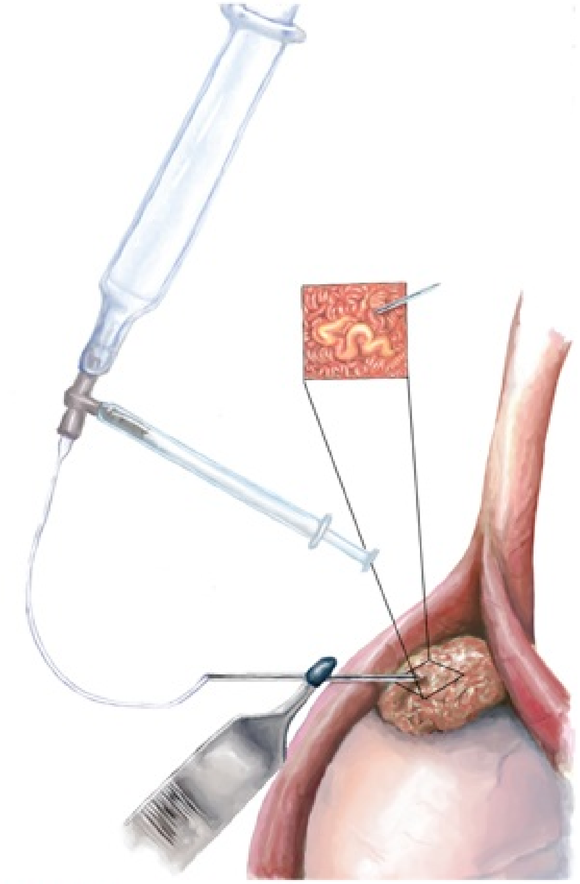

FIGURE 57.5 Technique of MESA. *Inset* shows dilated epididymal tubules of varied appearances. The most dilated, yellow tubules should be avoided as they predominantly contain macrophages and degenerating sperm.

Outcomes: Epididymal Sperm Retrieval

The risk of injury to blood vessels secondary to blind puncture of the epididymis with PESA precludes its use at our institution. Hematoma and pain are the immediate complications of such bleeding; however, it is the subsequent testicular atrophy secondary to injury to the testicular vessels that poses the greatest long-term risk to the patient.

MESA in the context of OA is over 99% successful regardless of etiology of obstruction. PESA has a relatively decreased chance, in the range of 80% to 90% successful. MESA, notably, also yields millions of sperm which can be easily cryopreserved into multiple vials, obviating the need for any future sperm retrieval procedures (13,14). Notably, partners of men with congenital bilateral absence of the vas, a defect associated with cystic fibrosis, should also be tested for mutations of the cystic fibrosis transmembrane conductance regulator gene given the frequency of cystic fibrosis mutations in the general population.

CHAPTER 58 SIMPLE ORCHIECTOMY

JONATHAN L. SILBERSTEIN

Simple orchiectomy involves the removal of one or both testes at the distal spermatic cord, usually through a transscrotal approach. Importantly, this is in direct contrast to a radical orchiectomy performed through an inguinal incision performed for a testicular mass with suspicion of malignancy. Radical orchiectomy is intended to remove the entire testis, epididymis, and distal spermatic cord up to the inguinal ring without violating the scrotum and disrupting the normal testicular lymphatic drainage. In contrast, a simple orchiectomy is used for the treatment of benign intrascrotal processes, such as epididymoorchitis unresponsive to antibiotics, or a devitalized testicle secondary to torsion or trauma. If the etiology of a testicular lesion is unclear and there is any possibility of malignancy, we favor an inguinal approach as it will not violate the scrotum and the added morbidity is minimal.

The testis account for 95% of circulating testosterone, and bilateral simple orchiectomy may be used as a method of surgical castration to rapidly deplete circulating androgens (1). Surgical castration may be used for palliation in men with metastatic prostate cancer and will result in normalization of prostate-specific antigen and objective tumor response in the vast majority of patients albeit at the cost of profound metabolic changes resulting in increased rates of cardiovascular disease, metabolic syndrome, fatigue, osteopenia/osteoporosis, depression, and loss of libido (2). Rarely, surgical castration via bilateral simple orchiectomy may be performed to reduce sexual recidivism among sexual predators (3). Importantly, regardless the intended rationale for surgical castration, medical castration may achieve the same desired effects without the burden of surgery and is the preferred option in many nations.

DIAGNOSIS

Diagnoses requiring simple orchiectomy depend on the condition being treated and vary greatly between benign intrascrotal processes and metastatic prostate cancer. For benign intrascrotal processes requiring simple orchiectomy, such as epididymoorchitis unresponsive to antibiotics, or devitalized tissues secondary to torsion or trauma, diagnosis is most commonly made through careful history and physical exam. Patients should be asked about the chronicity of the onset of their symptoms (acute, chronic), location (laterality, isolated to the scrotum), history of trauma or surgical intervention, lower urinary tract symptoms (urgency, frequency), or systemic symptoms (fever, rigors). The clinician should perform a thorough physical examination of the abdomen, inguinal region, spermatic cord, scrotal skin, testes, tunica vaginalis, epididymis, and rectal exam when indicated. Additionally, the cremasteric reflex should be assessed by stroking or gently pinching the skin of the upper thigh while observing the ipsilateral testis, absence of this reflex suggests testicular torsion, which may be a surgical emergency. If the etiology of a scrotal process is equivocal after history and physical examination, color Doppler ultrasonography is the diagnostic test of choice because it is inexpensive, noninvasive, and will provide information on vascularity as well as anatomic details (4). Radionuclide scintigraphy is an alternative imaging option and will provide information on testicular vascularity but without anatomic details of ultrasound. Importantly, acute processes potentially requiring simple orchiectomy may be emergent, and if radiology is not available, suspicion is high, or the viability of the testis is in question, immediate exploration of the scrotum with intraoperative inspection and Doppler should be performed in lieu of delayed intervention following radiographic evaluation. For patients with chronic testicular pain, laboratory evaluation with urinalysis, urine culture, urine microscopy, semen culture, and urethral swab for sexually transmitted disease evaluation may be helpful in determining the diagnosis of a bacterial orchitis.

The diagnosis of metastatic prostate cancer requiring castration may be made via digital rectal exam and prostate-specific antigen screening prompting transrectal ultrasound-guided biopsy and ultimately radiographic imaging demonstrating systemic disease. Alternatively, patients with previously treated local disease may be diagnosed with biochemical recurrence or progression prompting radiographic evaluation.

INDICATIONS FOR SURGERY

Indications for simple orchiectomy depend largely on the diagnosis; in cases of penetrating scrotal trauma or blunt scrotal trauma with suspicion rupture of the testis, immediate scrotal exploration and intraoperative assessment is required (5). Even with rupture of the testis, salvage is often still possible with debridement of necrotic and extruded seminiferous tubules followed by closure of the tunica albuginea, although complete rupture may require orchiectomy (6). For suspected orchitis or epididymitis resulting from probable urinary tract infection, treatment with antibiotics and supportive care will almost always obviate the need for scrotal exploration and orchiectomy. Even for patients with Fournier gangrene, necrotizing fasciitis around the male genitalia, requiring emergent surgical debridement, the need for orchiectomy is rare due to the independent blood supply to the testis. Simple orchiectomy may be performed for chronic orchalgia after exhaustive efforts have been made to resolve issue with nonsurgical intervention, although the preferred intervention is microsurgical denervation with transection of the branches of the genitofemoral nerve and preservation of the testis, vas, and testicular artery (7). In cases of testicular torsion at the time of scrotal exploration, the testis is detorsed and observed; if viable orchiopexy is performed and if not viable, then simple orchiectomy to remove ischemic tissue is necessary.

Malignant diseases of the testes, such as suspected germ cell tumor, should never be managed with simple orchiectomy through a transscrotal approach. Suboptimal approaches to testicular neoplasms, including scrotal orchiectomy and transscrotal biopsy, can alter the normal lymphatic drainage of the testis and increase the burden of therapy for the patient (8). A meta-analysis of 206 cases of scrotal violation reported a local recurrence rate of 2.9%, compared to 0.4% for patients treated with inguinal orchiectomy, but no difference in systemic relapse or survival were appreciated (8). Therefore, if there is any suspicion of testicular cancer, a radical orchiectomy through an inguinal incision should be performed.

The indications for surgical or chemical castration in the treatment of advanced prostate cancer are not altogether clear. Although it is clear that castration is beneficial for patients with symptomatic metastatic disease (9) and should be avoided in those with localized disease because it may result in decreased overall survival (10), for patients who do not fit into either of these categories, the timing of initiation of castration is controversial. Medical castration is an alternative to bilateral simple orchiectomy. Although surgical castration rapidly results in a decrease in circulating androgen (1), medical therapies can achieve a similar result either through inhibition of androgen synthesis, blockade of the androgen receptor, or inhibition of gonadotropin-releasing hormone (GnRH). The most commonly used modality of medical castration are GnRH agonist; analogues of GnRH that inhibit the pituitary gonadal axis, resulting in the downregulation of luteinizing hormone–releasing hormone receptors and subsequent decrease in gonadotropin secretion. Importantly, these cause a temporary increase, or flare, in the available androgen and may result in exacerbation of life-threatening symptoms and coadministration to block the flare with an antiandrogen is standard practice. For patients with impending spinal cord compression, surgical castration or medical castration with ketoconazole provides the most rapid declines in circulating androgen to prevent impending impingement. Although the psychological effects of surgical castration can be daunting for the patient, from an economic viewpoint, surgical castration is much more cost-effective than medical castration. One last consideration is that surgical castration is irreversible, whereas medical castration may be given intermittently, although to date, there is an ongoing debate whether intermittent androgen blockade has equivalent outcomes.

SURGICAL TECHNIQUE FOR SIMPLE ORCHIECTOMY

Orchiectomy when performed electively is a straightforward outpatient procedure that may be performed with local, regional, or general anesthesia. Local anesthetic sensory blockade is obtained by infiltrating the spermatic cord in the region of the vas deferens in the high scrotum just below the pubic tubercle with a 0.5% bupivacaine solution. Care must be taken to ensure that the block is not injected intravascularly by drawing back on the syringe prior to injecting the medication. The same solution is then injected subcutaneously at the site of the scrotal incisions. Sensory blockade should then be tested with pickups before the beginning of the procedure. For scrotal exploration in cases of blunt or penetrating trauma, general anesthesia may be preferable because the extent of the exploration may not be fully realized at the start of the procedure. If simple orchiectomy is performed for castration and no prosthesis is to be placed, antibiotic prophylaxis is not absolutely indicated; however, it is our preference that a first-generation cephalosporin should be given intravenously within 30 minutes of scrotal incision. Antibiotic prophylaxis is mandatory for trauma, possible infectious etiologies, or when placing a testicular prosthesis.

Scrotal Approach

Scrotal approach to the simple orchiectomy may be through a single midline incision or two separate lateral incisions over the upper portion of the scrotal cord. Two incisions may decrease the need for mobilization and potentially reduce the risk for postoperative hematoma but may increase morbidity. Regardless of how many incisions are made, the first step is to shave the anterior scrotal wall to remove existing hair; the scrotum and genitalia are then prepared in a sterile manner. A 2.5- to 3.0-cm midline incision is made just through the skin within the median raphe in the anterior scrotal wall using a no. 15 blade scalpel while the assistant pushes a testicle toward the incision between his or her thumb and index finger so that the testicle lies directly under the incision (Fig. 58.1). By electrocautery, the incision is then carried down through the dartos and cremasteric layers until the parietal portion of the tunica vaginalis is incised directly over the testis. This is usually evidence by a gush of fluid from the peritesticular space. The incision in the tunica vaginalis is lengthened in both directions, enough to allow exposure of the entire testicle through the wound. The surrounding tunics are freed from the spermatic cord by a combination of blunt and sharp dissection. Meticulous hemostasis may be obtained in each layer as it is entered with electrocautery. Once the spermatic cord is isolated, the vas deferens is separated, doubly clamped, divided, and ligated with 2-0 Vicryl or 2-0 silk ties (Fig. 58.2). The remainder of the cord structures may be divided into one or more bundles and are doubly clamped on the proximal side and singly clamped on the distal side. Once divided, the proximal portion of the cord is ligated with a 0 Vicryl or silk free tie behind the most proximal clamp, which is then removed, and a 0 Vicryl suture ligature is placed just distal to the free tie (see Fig. 58.2). Before the cord is released to retract proximally, the tunics, dartos, and subcutaneous areas are again inspected for hemostasis. Once this is felt to be adequate, the cord is allowed to retract and attention is turned to the opposite testicle. It is then removed through the same midline or a separate transverse scrotal skin fold incision in the same manner. This leaves two openings in the tunica vaginalis and dartos layers, which are separated by a median septum. These deep layers are then closed in one layer using a 3-0 Vicryl running suture. Allis clamps are placed at either end of the median septum to facilitate the exposure (Fig. 58.3). The skin is then closed with interrupted 3-0 chromic sutures or a continuous subcuticular absorbable closure and a gauze dressing is applied. Drains are not required but can be considered if there is doubt about hemostasis. Compression or turban dressings may also be used if there is concern over postoperative hemostasis or edema.

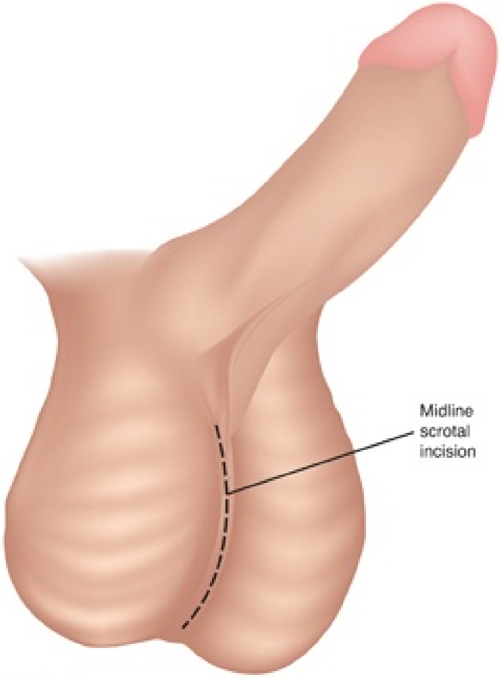

FIGURE 58.1 A midline scrotal incision over the median raphe allows access to both testes or bilateral scrotal incisions over the upper lateral scrotum is an alternative approach.

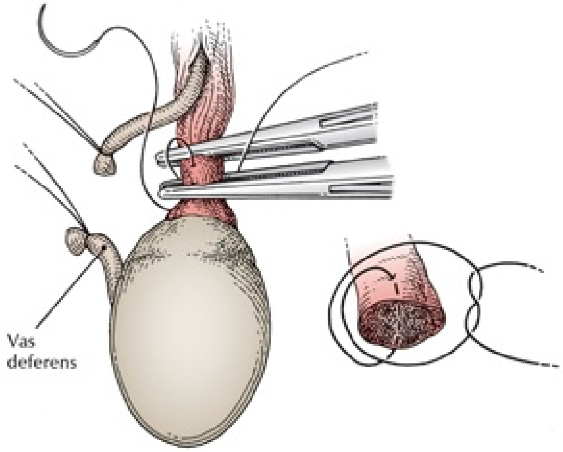

FIGURE 58.2 The vas deferens is ligated separately from the vascular structures of the cord. The vascular structures are double ligated with both a free tie proximally and a suture ligature distally using 0 Vicryl to ensure hemostasis.

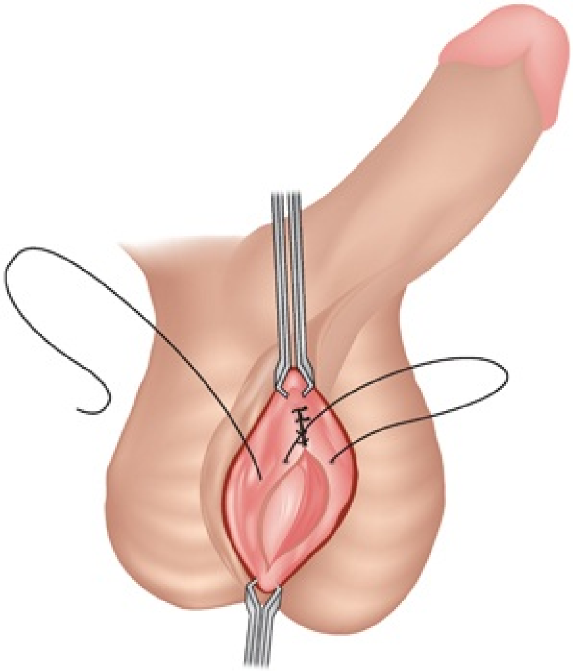

FIGURE 58.3 Closure of the deep layers of the scrotum, including the dartos musculature and testicular tunics laterally and the midline septum in one running layer.

The bilateral scrotal approach is similar except that two separate transverse scrotal incisions are made within a scrotal skin fold and between the scrotal vessels, which typically run transversely, over the upper portion of the scrotal spermatic cord (see Fig. 58.1). Manual manipulation to bring the testicle just beneath the scrotal skin in the location of the incision can help decrease the size of the incision. The incision is carried down through the tunica vaginalis and the testicle and distal cord are mobilized through the incision. The vas is separated from the surrounding cord structures, and all are clamped and divided similar to the midline approach (see Fig. 58.2). Following meticulous hemostasis, interrupted two-layer closure is performed.

Testicular prostheses are available for use in patients who desire a better cosmetic result, and these may be placed in the scrotal pouch where the testicle had been (11). Following orchiectomy, the empty scrotum is copiously irrigated with antibiotic solution and the prosthesis is inserted in the empty fossa (Fig. 58.4). Care should be taken to place the prosthesis away from the scrotal incision, which is easily avoided with either the single incision in the raphe or the lateral scrotal incisions in the upper portion of the scrotum. The prosthesis may be tacked to the skin with a suture or be allowed to be mobile; we prefer the latter because it more realistically recapitulates the normal testis.

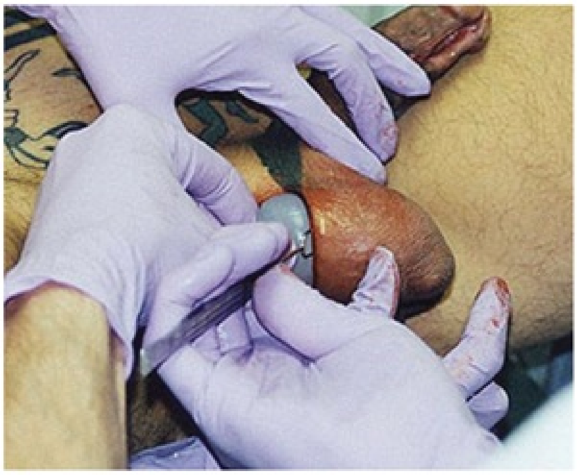

FIGURE 58.4 A placement of a testicular prosthesis into the scrotal fossa.

Suprapubic Approach

This approach is more invasive than the scrotal approach but is advantageous in patients in whom one wants to avoid a scrotal incision and/or place testicular prostheses at the time of the orchiectomy (12). The patient again is placed in the supine position and the suprapubic area is shaved. A 4- to 5-cm transverse incision is made in the midline approximately 2 to 3 cm above the pubic symphysis (Fig. 58.5). This is extended down through the subcutaneous tissues to the level of the rectus fascia using electrocautery. The subcutaneous tissue is then swept bluntly toward the external inguinal ring, exposing the distal spermatic cord, which is then isolated just distal to the ring in the upper scrotum (Fig. 58.6). Right-angle retractors are helpful to obtain exposure during this dissection by moving the incision toward the side being worked on. The spermatic cord is looped with a Penrose drain and the testicle is delivered into the wound by placing upward pressure on the scrotum and testicle, with simultaneous upward traction on the cord with the Penrose drain. The gubernaculum is then divided, which mobilizes the testicle (Fig. 58.7). The vas deferens and spermatic cord are then divided as previously described. If testicular prostheses are desired, they are then placed into the empty scrotum after adequate hemostasis is ensured, and a purse-string suture of 3-0 silk is used to close the neck of each hemiscrotum to prevent migration of the prosthesis (see Fig. 58.7). The Scarpa fascia is closed with 3-0 Vicryl suture, and the skin is closed with a 4-0 Vicryl subcuticular suture reinforced with benzoin and Steri-Strips.

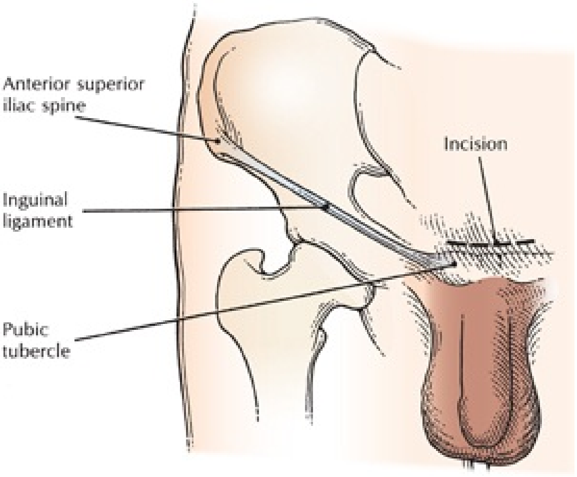

FIGURE 58.5 A midline suprapubic incision 2 to 3 cm above the pubis allows access to both testes at a level just below the external ring.

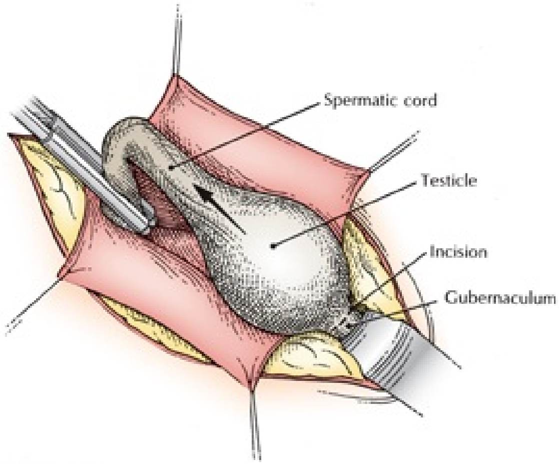

FIGURE 58.6 Isolation of the cord with a Penrose drain. Division of the gubernaculum allows complete mobilization of the testis from the scrotum.

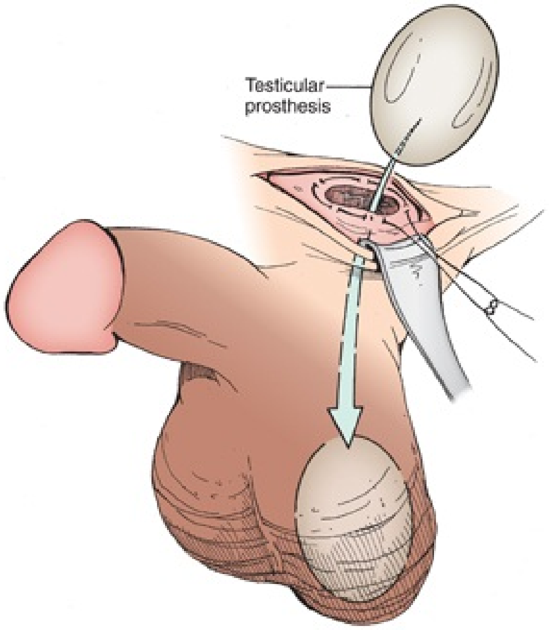

FIGURE 58.7 If a prosthesis is desired, it is placed into the empty hemiscrotum. To prevent migration, a purse-string suture is used to close the neck of the hemiscrotum, eliminating the need for an anchoring suture.

Subcapsular Orchiectomy

For patients electing orchiectomy for androgen ablation, alternatives to the total removal of the testis and epididymis have been explored and include subcapsular orchiectomy and subepididymal orchiectomy (1,13–15). These not only give the cosmetic effect of a testis being present but also achieve the therapeutic goal. There has been some controversy (16) over the efficacy of subcapsular orchiectomy since it was first described in 1942 by Riba (15); however, multiple modern studies have demonstrated its efficacy and suggest that any residual testosterone production is most likely a result of incomplete removal of the intratesticular contents (1).

The operation may be approached either through the anterior scrotum or upper lateral scrotum with two separate incisions as previously described (see Fig. 58.1). Once the testicle is delivered to the wound, the tunica albuginea is opened in midline in a cephalad-to-caudad fashion. Hemostats are placed on the edges of the capsule to provide traction, and an index finger is placed behind the capsule to invert it (Fig. 58.8). This maneuver facilitates the removal of the parenchymal contents, which are swept to the midline using a gauze sponge. The midline attachment of the parenchyma is divided using electrocautery, and the remainder of the interior capsule is cauterized to ensure hemostasis and complete destruction of all testicular parenchyma (Fig. 58.9). The tunica albuginea is then closed using a running 3-0 Vicryl suture (Fig. 58.10) and the residual testicular tunics, adnexa, and cord are returned to the scrotum. The deep layers of the scrotum are closed followed by the skin in an interrupted fashion as previously (see Fig. 58.3).

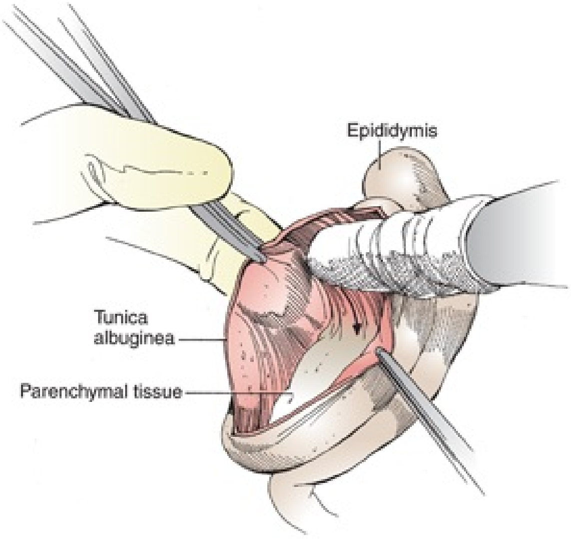

FIGURE 58.8 The tunica albuginea is opened in midline opposite the epididymis and the contents are swept bluntly to the midline attachment.

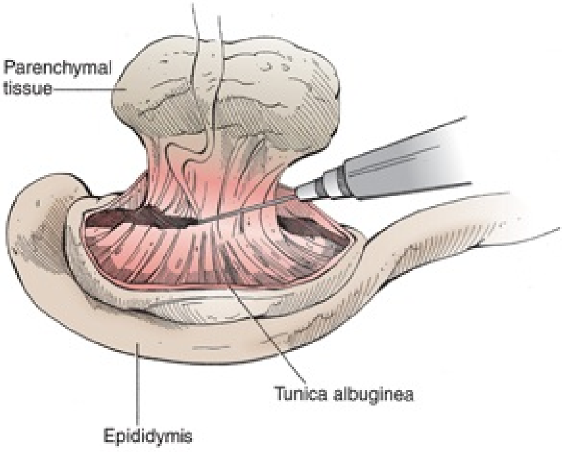

FIGURE 58.9 The parenchymal tissue is then removed at its midline attachment with electrocautery and the internal surface of the capsule is cauterized.

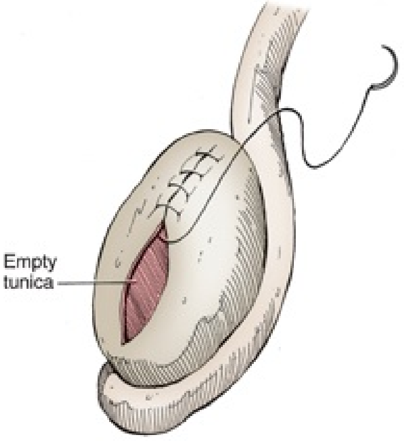

FIGURE 58.10 The tunica albuginea is reapproximated with a running 3-0 Vicryl suture.

Subepididymal Orchiectomy

Kihara and Oshima (14) have also described an epididymal-sparing orchiectomy with insertion of a pedicled fibrofatty tissue graft to preserve scrotal cosmesis after bilateral orchiectomy. This type of procedure may be complicated by epididymitis, which can be minimized by performing a vasectomy at the time of the procedure. Advantages of a fibrofatty tissue graft over implants or prostheses are that there are no risks of developing autoimmune disorders, rupture, or migration complications. However, the remnant tissue does not reapproximate the size and texture of the normal testis as well as prostheses.

Again, the initial exposure to the testicles is the same as previously described for the anterior scrotal approach (see Fig. 58.1). Once the testicle is delivered to the wound, a vasectomy is performed including double ligation and division to minimize the possibility of postoperative epididymitis (6). A line of dissection between the cleavage plane of the testis and the epididymis is utilized (Fig. 58.11). Dissection is started at the head of the epididymis, and the epididymal tissue is clamped for hemostasis. Care must be taken to secure the spermatic artery entering the testis at a point between the midportion and the tail of the epididymis. The clamped epididymal tissue is ligated using a 3-0 Vicryl suture. Meticulous hemostasis is then obtained using electrocautery, and a running 3-0 Vicryl suture on a tapered needle is used to approximate the edges of the tunica albuginea over the raw surface of the epididymis (Fig. 58.12). The remaining spermatic cord and epididymis are replaced into the scrotum, which is closed as previously described.

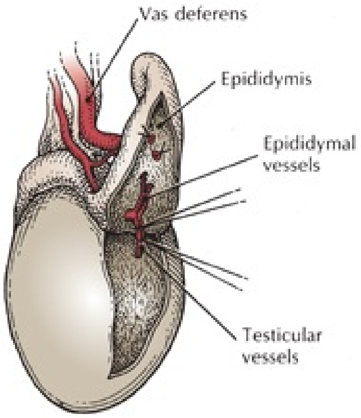

FIGURE 58.11 Dissection of the testis from the epididymis, ligating the epididymis with Vicryl suture.

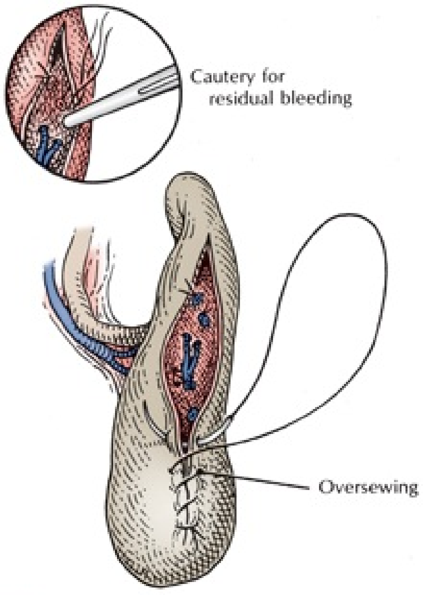

FIGURE 58.12 After removal of the testis and further hemostasis with electrocautery, the tunica of the epididymis is closed over the raw surface using a running suture.

OUTCOMES

Postoperative Care and Complications

Postoperative care similar to the procedure itself is straightforward. Analgesia with oral opioid derivatives may be required for 24 to 72 hours afterward. A sterile dressing is difficult to place over a scrotal incision and fluffs or unrolled gauze with a scrotal support is generally all that is required. Ice pack can be helpful in the immediate postoperative setting. If prosthesis or suspected infection is found, antibiotics should be continued in the postoperative setting.

Complications can include infection, edema, and the inadvertent removal of a testicular neoplasm through the scrotal approach, although the most common problem following these procedures is a scrotal hematoma. When they occur, they can be difficult but almost always resolve with conservative measures and rarely require re-exploration with evacuation of the hematoma. Several preventative measures to achieve adequate compression of the area postoperatively have been described, including turban-type dressings or compression of the scrotal wall over a gauze bolster as described by Oesterling (17). These techniques should not be substituted for obtaining meticulous hemostasis at the time of the procedure.

Infection, depending on the degree of severity, is managed by incision and drainage of any abscess pockets. This is followed by local wound care, which may include wet-to-dry dressing changes, sitz baths, and whirlpool with debridement of any devitalized tissue. Antibiotics can be used in cases where there is induration only and no abscess to drain or in combination with the incision and drainage procedure if needed. If antibiotics are used, they should be directed by the results of wound cultures.

If a testicular neoplasm has been inadvertently removed through a scrotal approach, the remaining inguinal spermatic cord should be removed as well as a wide excision of the scrotal scar. The hemiscrotum should also be removed if there was any known tumor spillage during the transscrotal procedure. This usually results in cure rates similar to those for conventional initial radical inguinal orchiectomy (18).

Results

The effectiveness of scrotal orchiectomy is dependent on the indication for the procedure. For those with metastatic prostate cancer, adequate hormonal ablation can be easily determined by measuring serum testosterone levels, which should be, castrate level within several hours after surgery (1). Prostate-specific antigen levels, patient symptoms, and patient survival may be followed to determine the procedure’s effectiveness in terms of disease control. For benign intrascrotal processes such as epididymoorchitis unresponsive to antibiotics or devitalized tissues secondary to torsion or trauma, simple orchiectomy is curative.

CHAPTER 59 RADICAL INGUINAL ORCHIECTOMY

DANIEL J. LEE AND DOUGLAS S. SCHERR

Testicular tumors are an uncommon and clinically heterogeneous group of tumors, accounting for approximately 8,000 new cases and 370 deaths in 2013 (1) and an incidence of 5 per 100,000 men. Ninety-five percent of testicular tumors are germ cell tumors (GCTs), with the remainder consisting of gonadal stroma and secondary tumors of the testis. Approximately 90% of the GCTs arise in the testis, with 2% to 5% appearing in extragonadal regions such as the retroperitoneum and mediastinum. The survival rates for testicular cancer have improved remarkably over the past 50 years with the development of cisplatin-based chemotherapy and multidisciplinary collaboration, from 60% to 65% in the 1960s to more than 90% currently. The improvements are especially noticeable in advanced and metastatic GCT, with survival rates improving from 5% to 10% to 80% to 90% before and after the use of cisplatin-based chemotherapy. Although testicular cancer is highly curable, inappropriate management can have drastic consequences on the long-term survival and morbidity. Surgical management remains an integral part in the management of testicular cancer, although the development of improved chemotherapy options, clinical staging, and imaging modalities has changed its role. In this chapter, we will review the indications, common surgical techniques, and their associated complications for radical inguinal orchiectomy.

DIAGNOSIS

Most testicular tumors present as a painless testicular mass. Until proven otherwise, a firm intratesticular mass should be considered suspicious for cancer and worked up accordingly. The differential diagnosis of a testicular mass includes tumor, epididymitis, epididymoorchitis, torsion, and, less frequently, hernia, hydrocele, spermatocele, varicocele, hematoma, and hematocele. Acute testicular pain is less common and can be caused by rapid expansion of the testis from an intratumor hemorrhage or infarction caused by rapid tumor growth. Pain is more commonly associated with nonseminomatous GCT (NSGCT) because these tumors tend to have rapid growth and high vascularity. A significant proportion of GCT will present with metastatic disease at diagnosis, with 67% NSGCT and 15% of seminomas. However, only 10% to 20% of those with metastatic disease will be symptomatic from their metastases, with symptoms such as abdominal pain, palpable neck mass indicating supraclavicular metastasis, flank pain from ureteral obstruction, lower extremity edema from compression of the inferior vena cava, back pain from involvement of nerve roots, or dyspnea and hemoptysis from pulmonary metastasis. Approximately 2% of men will present with gynecomastia, most commonly seen in Leydig cell tumors, from elevated levels of human chorionic gonadotropin (hCG), increased estrogen, or decreased androgen production. Two-thirds of men with GCT will have decreased fertility.

Delays in Diagnosis

Delays in diagnosis of testicular cancer remain a significant problem and can have significant impact on outcomes, especially in the population of young adult males. Up to one-third of testicular cancers were found to be initially misdiagnosed as an epididymitis or hydrocele, with a median delay of 75, 101, and 134 days for stage I, II, and III, respectively (2). Even patients with metastatic disease may undergo inappropriate treatment and unnecessary surgery, as Stephenson et al. (3) reported on 40 patients who underwent an unnecessary laparotomy prior to diagnosis of a testicular mass. In a review of the literature of 4,948 testicular cancer patients, Moul (4) reported a mean duration of symptoms of 26 weeks before diagnosis.

Scrotal Ultrasound

In men with a solid testicular mass, or unexplained scrotal signs or symptoms, a scrotal ultrasound should be performed especially because it is widely available, rapid, sensitive, noninvasive, and inexpensive. Intratesticular lesions, as small as a few millimeters, can be detected with high-frequency transducers (5 to 10 Hz) with a clear delineation of anatomy. GCTs are often hypoechoic on ultrasound, with NSGCT normally with a heterogeneous echotexture, whereas seminomas tend to have a more homogenous echotexture. The incidence of bilateral GCTs is approximately 2%, so both testicles should be evaluated at each scrotal ultrasound. Testicular microlithiasis does not have a clear association with GCTs and in isolation should not prompt further evaluation (5).

Tumor Markers

Tumor markers are essential in the diagnosis, prognosis, treatment, and surveillance of testicular cancer. Testicular tumor markers, including lactate dehydrogenase, α-fetoprotein, and hCG, should be obtained at diagnosis and after orchiectomy to monitor for response to chemotherapy and to monitor for signs of recurrence.

ALTERNATIVE THERAPY

Radical inguinal orchiectomy is the standard therapy for a solid intratesticular lesion; however, partial orchiectomy may be appropriate in certain specific situations. Patients with a solitary testis or bilateral testicular masses or those with a possibility of an epidermoid cyst or benign testicular tumor may be considered for a testis-sparing procedure. The selection criteria, technique, and outcomes of testis-sparing surgery are presented elsewhere.

Sperm Cryopreservation

Sperm cryopreservation should be recommended prior to orchiectomy for all men where future fertility is a potential concern, even if the contralateral testis appears to be normal (6).

Radical Inguinal Orchiectomy

Patients suspected of having a testicular neoplasm should undergo a radical inguinal orchiectomy with removal of the tumor-bearing testis and spermatic cord up to the level of the internal inguinal ring. This procedure allows histopathologic diagnosis, tumor staging, and can provide local control of the tumor with minimal morbidity if performed appropriately.

The procedure can be performed under general, spinal, or local anesthesia on an outpatient basis. With the patient in a supine position, the lower abdominal wall, penis, and scrotum are prepped in the sterile surgical field. An oblique skin incision is made in the inguinal area along Langerhans skin lines approximately 2 cm above the pubic tubercle, extending approximately 5 to 7 cm laterally from just above the pubic tubercle (Fig. 59.1). This incision can be extended onto the upper scrotum to facilitate removal of large tumors. Camper and Scarpa fascia are incised with electrocautery to the level of the external oblique aponeurosis. A scalpel is used to make a small incision in the external oblique aponeurosis halfway between the internal and external inguinal rings. Metzenbaum scissors are then inserted into the incision with the tips closed and are pushed upward against the aponeurosis toward the external inguinal ring and then laterally toward the internal ring, so that the external oblique fascia is tented over the length of the inguinal canal to help ensure that the ilioinguinal nerve is not injured (Fig. 59.2). The opening is then incised in the direction of its fibers to the level of the inguinal ring. The ilioinguinal nerve is then identified, dissected free of the cord, and can then be retracted out of the surgical field.

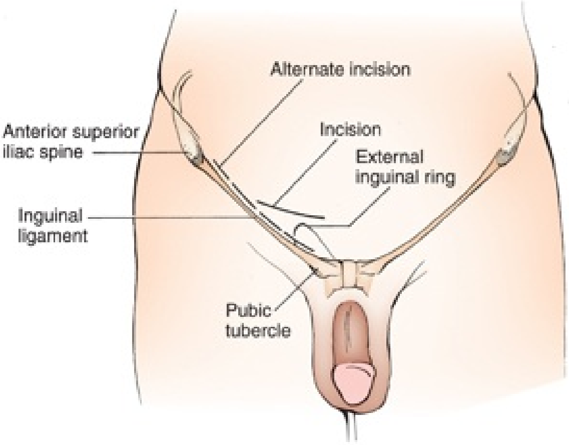

FIGURE 59.1 A 5- to 7-cm oblique skin incision is made in the inguinal area approximately 2 cm above the pubic tubercle provides adequate exposure with good cosmesis.

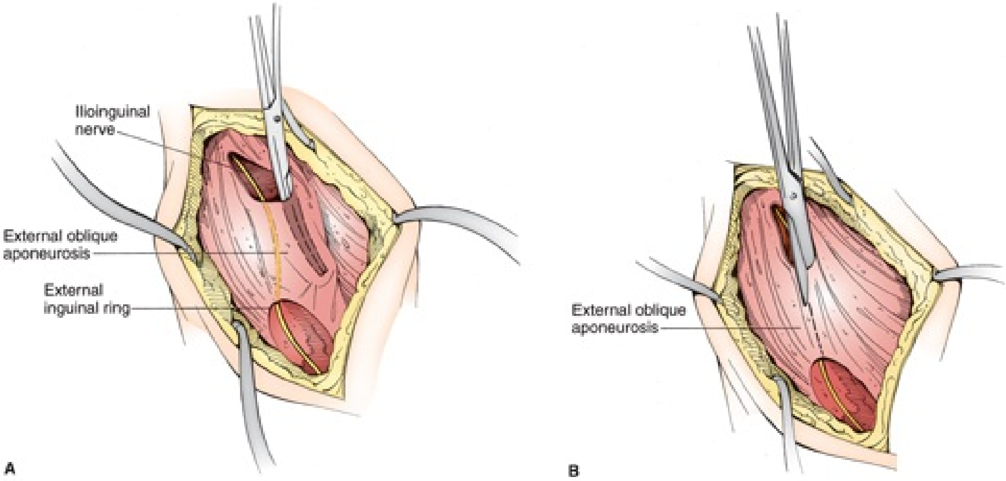

FIGURE 59.2 **A:** The external oblique fascia is tented over the length of the inguinal canal to help ensure that the ilioinguinal nerve is not injured. **B:** Using Metzenbaum scissors, the external oblique is incised and extended to the external ring.

The spermatic cord is then identified and bluntly mobilized from the inguinal ligament and floor of the inguinal canal using a finger wrapped with a gauze sponge, starting near the pubic tubercle (Fig. 59.3). The blunt dissection can be performed superiorly and inferiorly to the cord and can be facilitated using a Kittner sponge. After the spermatic cord is freed, a Penrose drain is passed around the cord. In approaching the internal ring, care should be taken to ensure that the inferior epigastric vessels are not injured. In addition, the spermatic cord should be inspected to ensure that an indirect inguinal hernia is not present. The spermatic cord is then occluded with a noncrushing clamp or a 0.5-inch Penrose drain encircled twice around the cord, tightened in a tourniquet fashion, and secured with a clamp at the level of the internal ring (Fig. 59.4).

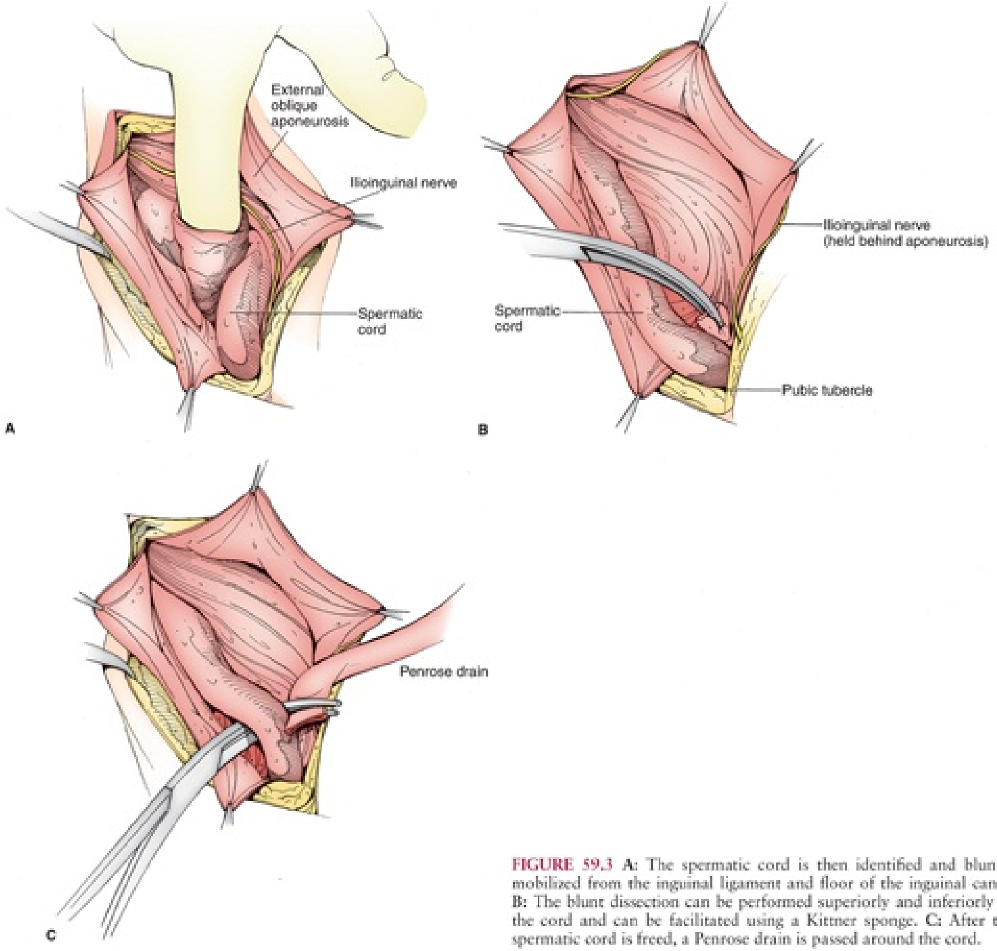

FIGURE 59.3 **A:** The spermatic cord is then identified and bluntly mobilized from the inguinal ligament and floor of the inguinal canal. **B:** The blunt dissection can be performed superiorly and inferiorly to the cord and can be facilitated using a Kittner sponge. **C:** After the spermatic cord is freed, a Penrose drain is passed around the cord.

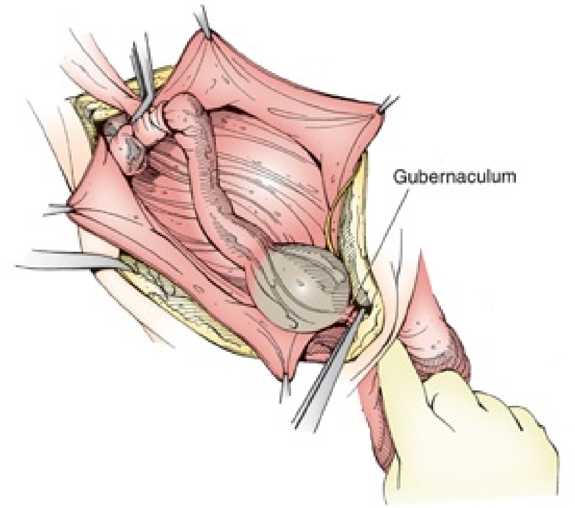

FIGURE 59.4 The spermatic cord is then occluded with a 0.5-inch Penrose drain encircled twice around the cord, tightened in a tourniquet fashion, and secured with a clamp at the level of the internal ring.

The testis can then be mobilized into a carefully draped off field by upward pressure on the external skin of the scrotum and coupled with gentle traction on the spermatic cord. The gubernacular attachments are then carefully cut using electrocautery or divided into two bundles and doubly ligated and divided, taking care not to rupture the mass or enter scrotal skin. If a diagnostic biopsy or a testis-sparing procedure is planned, the testis is cooled with saline slush; meticulous draping off is necessary before opening the tunica vaginalis and albuginea (7,8). The radical orchiectomy is completed by mobilizing the spermatic cord 1 to 2 cm inside the inguinal ring. The spermatic cord is divided into vas deferens and its vessels and internal and external spermatic vessels, which are each then double clamped at the level of the internal ring and proximal to the Penrose tourniquet with two Kelly or heavy right-angle clamps, with a third clamp occluding the cord distal to the Penrose tourniquet (Fig. 59.5). The spermatic cord is then transected and the testicle removed with the spermatic cord from the surgical field. The 0 silk ties are used to tie off the vas and its vessels and the spermatic vessels behind the most proximal clamp, and suture ligatures of 0 silk is used behind the most distal clamp. The sutures should be left long to help identify the stump of the spermatic cord if a retroperitoneal lymph node dissection (RPLND) is later performed. After the cord is securely tied off, it is allowed to retract back into the retroperitoneum. The floor of the inguinal canal and the everted scrotal wall are inspected closely to ensure that hemostasis is achieved. The wound and scrotum are then thoroughly irrigated. A testicular prosthesis can then be placed at this time or through a separate 3-cm incision in the scrotal inguinal skin fold. The ilioinguinal nerve is released, and the external oblique aponeurosis is closed with 3-0 Vicryl sutures, beginning at the level of the internal ring and extending medially as close to the pubic tubercle as possible (Fig. 59.6). The wound can be irrigated again, and Scarpa fascia can be closed with absorbable sutures. The skin incision is then closed with clips or a running subcuticular suture of 5-0 Vicryl or Monocryl. Compressive fluff dressings with a scrotal support may help minimize postoperative edema.

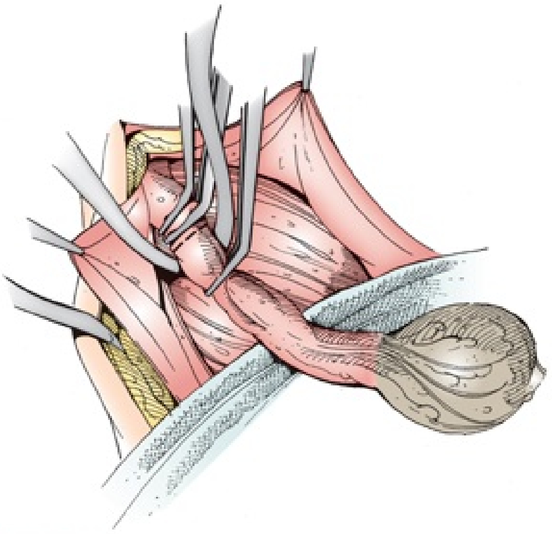

FIGURE 59.5 The spermatic cord is then double clamped at the level of the internal ring and proximal to the Penrose tourniquet with two Kelly or heavy right-angle clamps, with a third clamp occluding the cord distal to the Penrose tourniquet.

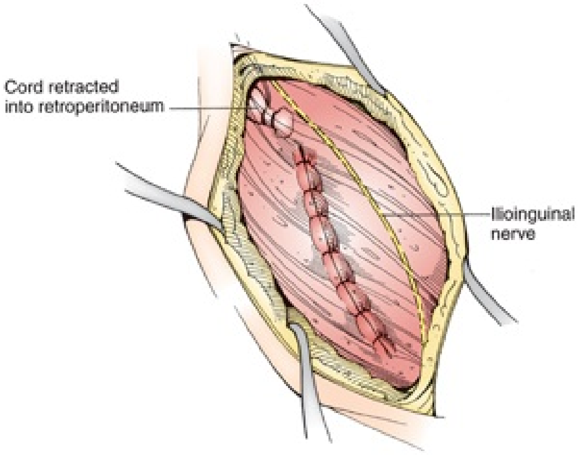

FIGURE 59.6 The stump of the cord retracts back through the internal ring into the retroperitoneum; one suture is left long. The external oblique fascia is closed with interrupted sutures placed at varying distances from the cut edge and completely closing the external ring.

COMPLICATIONS

Although complications with radical orchiectomy are infrequent, the most serious complication would be considered scrotal violation. Despite efforts to improve quality measures in the care of testicular cancer, suboptimal approaches to scrotal orchiectomy, such as scrotal orchiectomy, transscrotal biopsy, or fine needle aspiration, occur about 4% to 17% of the time (9,10). In a review of 206 cases of scrotal violation, Capelouto et al. (9) found an increased rate of local recurrence in scrotal orchiectomy compared to inguinal orchiectomy, 2.9% compared to 0.4%, respectively, but no difference in systemic recurrence or survival rates. Others have found that 11% of hemiscrotectomy specimens will have presence of tumor after scrotal violation (11). No testicular tumor should be approached transscrotally because of the risk of tumor contamination of the scrotum, risk of local recurrence, the potential for leaving spermatic cord behind, and potential alteration of lymphatic drainage of the testis. Patients with scrotal violation may benefit from the following guidelines:

- In patients with low-stage seminoma, radiation should be extended to include the ipsilateral groin and scrotum.
- In patients with low-stage NSGCT, the scrotal scar should be widely excised with the spermatic cord remnant at the time of RPLND.
- Patients who receive platinum-based regiments should have the cord stump removed at time of RPLND.

The most common complication remains postoperative bleeding, which may occasionally cause an intrascrotal or retroperitoneal hematoma. Dividing the cord into two or three bundles (vas and its vessels, internal spermatic vessels, cremaster bundle) and doubly ligating with 0 silk sutures minimizes this risk. The scrotum is an expansile organ with loose areolar tissue beneath the dermis and can allow a large hematoma to form because of a lack of tamponade. The scrotal hematoma can become quite firm, but as long as the hematoma does not become infected, it can be followed and will eventually regress. If the hematoma does become infected, it would usually require drainage. A retroperitoneal hematoma can be prevented with properly tied ligatures of the spermatic cord and care to avoid the epigastric vessels. Significant retroperitoneal hematomas can delay further therapy or be misinterpreted as metastatic disease, potentially resulting in unnecessary treatment. If the bleeding has stopped by the time it is discovered, the hematoma should ultimately be reabsorbed.

CHAPTER 60 ORGAN-PRESERVING SURGERY IN TESTICULAR TUMORS

AXEL HEIDENREICH

Testicular germ cell tumors (TGCTs) are the most common neoplasms in young men, with bilateral simultaneous and sequential tumors arising in 2% to 3% of patients. Bilateral orchiectomy is still recommended as the gold standard treatment; it results in infertility, lifelong dependency on androgen substitution, and psychological distress due to castration at a young age. Because most testicular cancer patients are going to be longtime survivors with modern therapeutic approaches, long-term morbidity should be omitted whenever possible; cure of cancer might only be achieved if quality of life following therapy can be restored to pretreatment levels. Considering these quality-of-life issues, organ-sparing surgical approaches have been developed in patients with bilateral testicular cancer or in selected patients with a germ cell tumor arising in a solitary testicle. In addition, any patient with a testicular tumor of unknown origin should be offered organ preservation (1) even in the presence of a normal contralateral testis if testicular ultrasonography is typical for benign tumors such as simple testicular cysts (Fig. 60.1) or epidermoid cysts (Fig. 60.2).

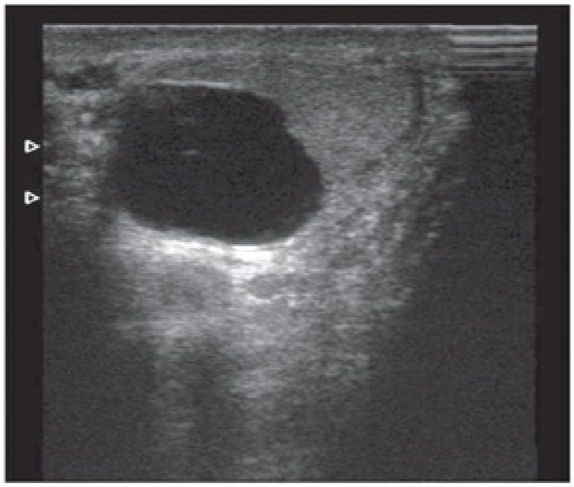

FIGURE 60.1 Ultrasound of simple testicular cysts.

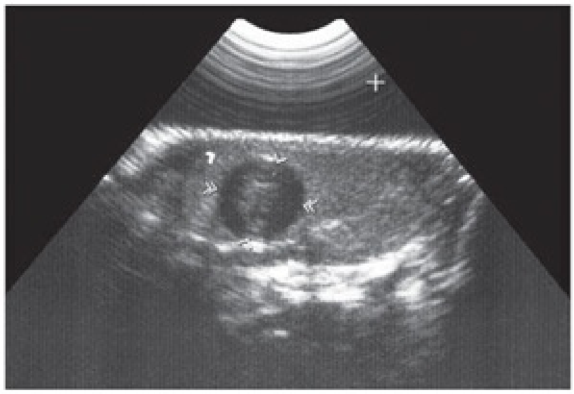

FIGURE 60.2 Ultrasound of epidermoid testicular cysts.

DIAGNOSIS

The diagnosis of testicular cancer is usually made by the appearance of a mass in the testicle that on ultrasonography appears solid or appears to have some cystic components (2). Scrotal magnetic resonance imaging appears only to be necessary if there is more than one lesion suspected or if there is a very high suspicion for a benign testicular tumor (Fig. 60.3). Serum markers, including β-human chorionic gonadotropin and α-fetoprotein, are routinely drawn prior to surgery.

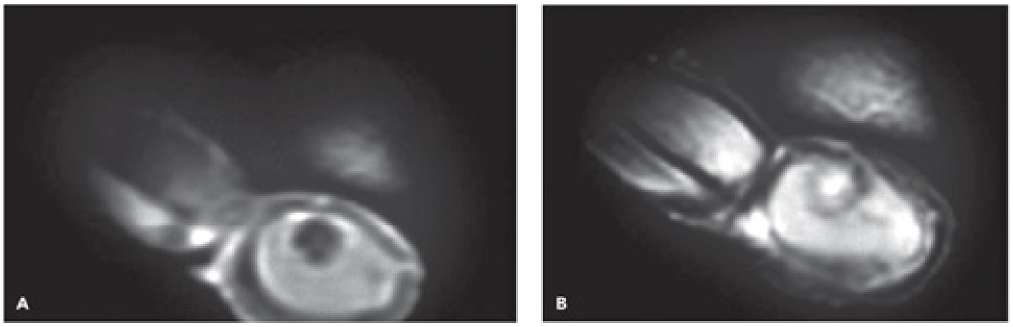

FIGURE 60.3 A and B: Scrotal magnetic resonance imaging only for very high suspicion for a benign testicular tumor.

INDICATIONS FOR SURGERY

Patients in whom preservation surgery is contemplated should have enough testicular parenchyma for maintaining physiologic testosterone synthesis, which requires that the diameter of the tumor should not exceed 2 cm (3,4). Preoperative serum testosterone and serum luteinizing hormone (LH) levels should be in the normal range. Elevated LH levels in the presence of normal testosterone levels indicate compensated Leydig cell insufficiency. These patients bear a high risk to develop hypogonadism with the need for androgen substitution following surgery. In addition, a semen analysis should be obtained to assess fertility and to discuss the option of cryopreservation (3,5). Also, testicular ultrasonography must be performed preoperatively because this usually represents the imaging modality of choice to assess the intratesticular location and diameter of the tumor. Scrotal magnetic resonance imaging appears only to be necessary if there is more than tumor suspected or if there is a very high suspicion for a benign testicular lesion (6).

ALTERNATIVE THERAPY

The alternative to testicular-sparing surgery is bilateral orchiectomy, which will require lifelong hormonal replacement. Other problems associated with bilateral orchiectomy include infertility and the psychological impact of the procedure on the patient, who is usually a young male.

SURGICAL TECHNIQUE

An inguinal approach is chosen (4) with the skin incision being made about two fingerbreadths above and parallel to the inguinal ligament (Fig. 60.4). The incision extends from the external inguinal ring cephalad for about 5 cm and is carried down to the external oblique fascia (Fig. 60.5). Care is taken not to injure the ilioinguinal nerve, which runs laterally just underneath the fascia.

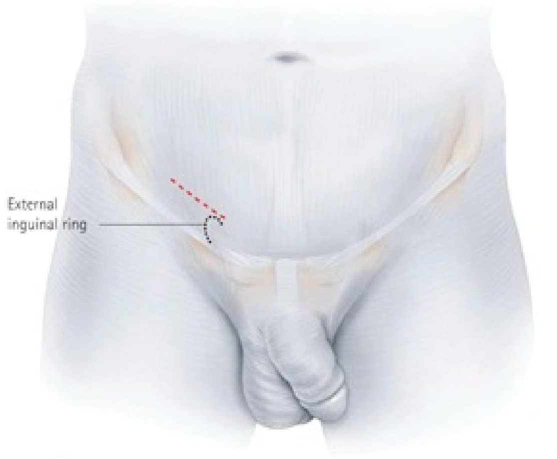

FIGURE 60.4 Inguinal incision for exploration of the testicle in relation to anatomic landmarks of the groin. (Copyright © 2012 by Jonathan Spitzer. Permission courtesy BJU International and Jonathan Spitzer, www.spitzer-illustration.com.)

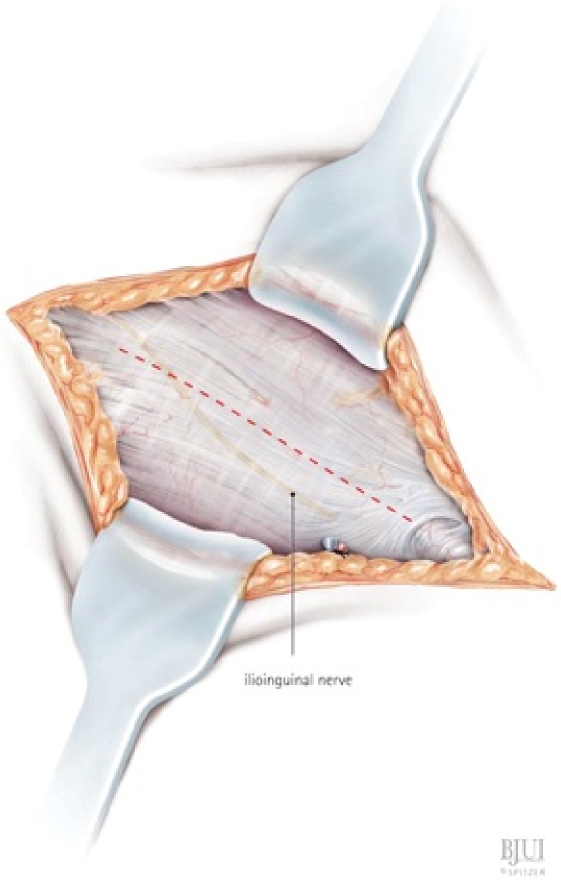

FIGURE 60.5 Incision of the external oblique fascia and its close relationship to the ilioinguinal nerve. (Copyright © 2012 by Jonathan Spitzer. Permission courtesy BJU International and Jonathan Spitzer, www.spitzer-illustration.com.)

The spermatic cord is identified and isolated at the level of the pubic tubercle (Fig. 60.6), secured with a half-inch Penrose drain, and mobilized back to the internal inguinal ring (Fig. 60.7). As in the case of radical orchiectomy, the spermatic cord might be cross-clamped with a rubber-shod clamp prior to delivering the testicle in the operating field. In this scenario, all following manipulations should be performed under cold ischemia by placing the testicle in crushed ice (1,7).

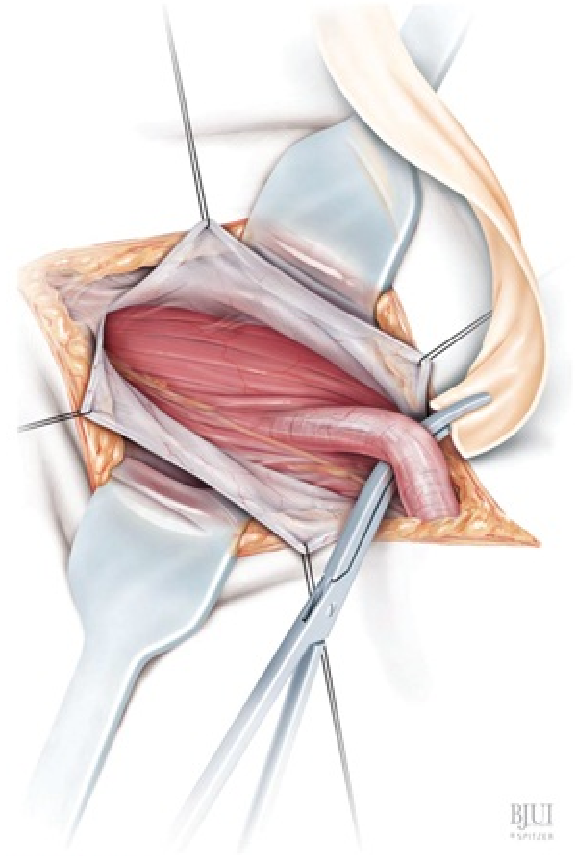

FIGURE 60.6 Delivery of the spermatic cord after the external oblique fascia has been opened. (Copyright © 2012 by Jonathan Spitzer. Permission courtesy BJU International and Jonathan Spitzer, www.spitzer-illustration.com.)

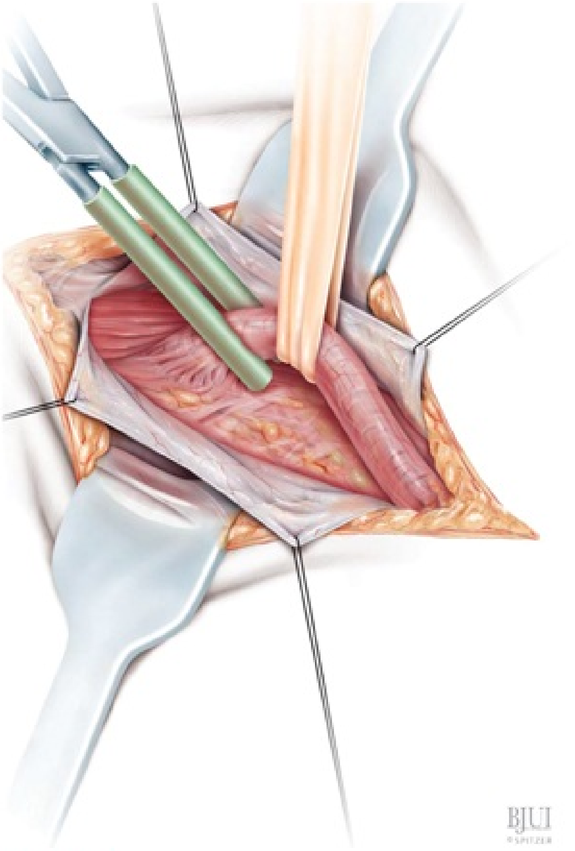

FIGURE 60.7 Mobilization of the spermatic cord up to the internal inguinal ring; the cord may be cross-clamped if desired. (Copyright © 2012 by Jonathan Spitzer. Permission courtesy BJU International and Jonathan Spitzer, www.spitzer-illustration.com.)

On the other hand, it is also possible to deliver the testicle into the operating field without cross-clamping the spermatic cord; we know that simple tumor cell shedding will not result in an increased frequency of distant metastases unless the tumor cells harbor molecular characteristics enabling them to adhere to the vascular endothelium, invade adjacent organs, and induce neovascularization. The testicle is delivered by slight traction on the spermatic cord and inversion of the scrotum; the gubernaculum is divided between two clamps and suture-ligated with 3-0 silk ties (Fig. 60.8).

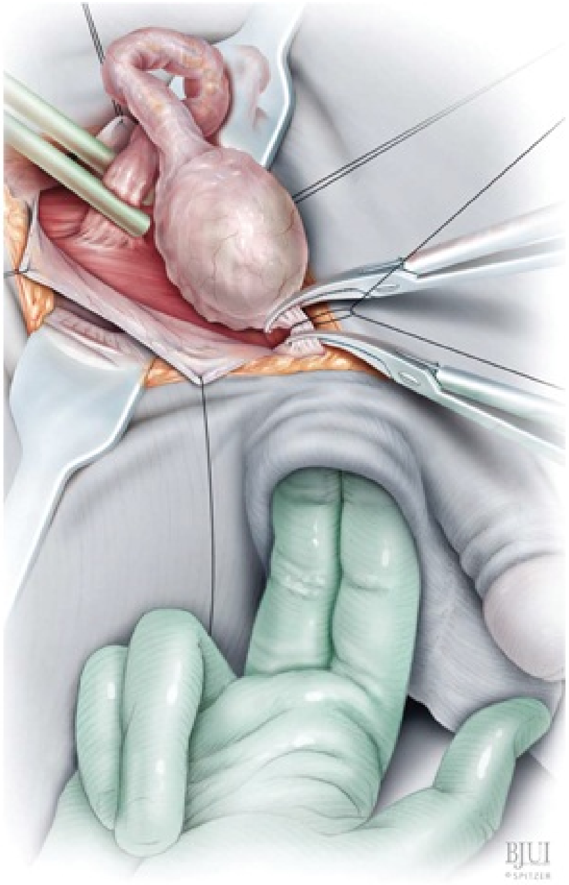

FIGURE 60.8 The testicle is delivered, and the gubernaculum may be divided and suture-ligated. (Copyright © 2012 by Jonathan Spitzer. Permission courtesy BJU International and Jonathan Spitzer, www.spitzer-illustration.com.)

The operating field is draped with laparotomy pads, and the tunica vaginalis is opened anteriorly; depending on the size and the intratesticular location of the tumor, it might be located underneath the tunica albuginea by simple palpation. In the presence of small, impalpable testicular lesions, intraoperative ultrasonography with a 7.5-MHz scanner and needle localization (7) is useful for detection (8).

The tunica albuginea is incised just above the tumor (Fig. 60.9). Use of an operating microscope under 6× to 10× magnification allows avoidance of subtunical vessels (9) and facilitates visualization of small impalpable tumors (7). Because small testicular lesions usually present with a pseudocapsule, the surrounding testicular parenchyma can be scraped away with the blade of a scalpel or a small sponge stick (Fig. 60.10). Once the tumor has been mobilized, its vascular pedicle is cauterized with a bipolar cautery and divided, and the tumor can be removed (Fig. 60.11). Following the enucleation procedure, four additional biopsies are taken from the tumor bed to exclude tumor infiltration (Fig. 60.12), and all specimens are sent for frozen-section examination (FSE). At least in our hands, FSE has turned out to represent a reliable technique to differentiate between benign and malignant tumors. Another biopsy is taken from the peripheral testicular parenchyma, fixed in Bouin or Stieve solution, and sent for pathohistologic analysis to exclude associated testicular intraepithelial neoplasia. After careful bipolar coagulation of small intratesticular blood vessels, the tunica albuginea is closed with a 4-0 Vicryl running suture (Fig. 60.13), the tunica vaginalis is closed with a Vicryl 3-0 running suture, and the testicle is replaced in the scrotum, taking care not to twist the spermatic cord. A formal orchidopexy for the testicle is not necessary. The skin is closed with an absorbable, intracutaneous running suture; usually, no drains are placed. Postoperatively, the patient should receive potent analgesics and antiphlogistics to reduce uncomfortable testicular pain.

OUTCOMES

Complications

Potential complications include hemorrhage and loss of the testicle. Eighty-five percent to 92% of patients have maintained adequate androgen levels (5).

Results

The initial study with a limited number of patients showed a 5-year survival rate of 92% and the maintenance of physiologic testosterone serum levels in 92% without the need for androgen substitution (5). These findings resulted in the German Testicular Cancer Study Group criteria for proper patient selection, surgical technique, and follow-up based on the review of a large patient cohort with a median follow-up of >8 years. The disease-free survival rate was 99%, local recurrences developed in 5.5%, and normal testosterone serum levels were maintained in 85% of the patients.

The use of testicular-sparing surgery in testicular cancer requires that there be close follow-up for possible recurrence. The best modality for local follow-up is transscrotal ultrasonography. We recommend the first ultrasound to be done 4 to 6 weeks postoperatively, a time when scar tissue has replaced the intraparenchymatous traumatic edema; thereafter, scrotal imaging should be performed at 2-month intervals for the first year to adequately document the developing scar tissue for further follow-up studies (5). In patients who have undergone local radiation therapy postoperatively, periodic ultrasonography can be safely omitted and the patients should be educated to self-palpate the testicle. In patients who have not undergone adjuvant local radiation, periodic ultrasonography should be performed twice annually due to the high risk of local recurrence. In patients who develop a local recurrence, secondary orchiectomy has to be performed and androgen substitution has to be initiated

(3,5,10).

In summary, organ-preserving surgery in patients with TGCTs is feasible in patients with bilateral testis cancer or germ cell tumor in a solitary testicle. The procedure should be performed in conjunction with biopsies of the tumor bed and the resection rim and frozen-section analysis as well as a biopsy of the peripheral parenchyma. Follow-up in these patients should be either postoperative radiation of the remaining testicle with 18 Gy or very close follow-up. As this is still a controversial procedure, it may be best performed in a center experienced in the management of testicular cancer.

CHAPTER 61 RETROPERITONEAL LYMPH NODE DISSECTION

SIMON KIMM AND JOEL SHEINFELD

The contemporary management of testicular germ cell tumors (GCTs), which incorporates significant advances in imaging, surgery, chemotherapy, and radiation therapy, has achieved high cure rates for this disease. But optimal outcomes for individual patients are highly dependent on nuances of management, underscoring the great importance of delivering the appropriate therapy, properly, and in the correct sequence (1). Failures of accurate staging, disciplined surveillance, and optimal treatment can lead to compromised chances for cure, long-term morbidity, and death.

Retroperitoneal lymph node dissection (RPLND) plays a key role in the management of testis cancer. When performed appropriately, it provides invaluable staging information, critical insight into tumor biology, and eradicates primary, chemorefractory, and potential sources of secondary cancers. Staging and prognostic information can be obtained through RPLND that exceed that of current imaging modalities. Standard axial imaging with computerized tomography (CT) or magnetic resonance imaging (MRI) understages 20% to 25% of patients with clinical stage (CS) I and overstages 15% to 35% of patients with CS IIA nonseminomatous germ cell tumor (NSGCT) (2,3). RPLND also plays a critical role as a therapeutic modality. In patients with low-stage NSGCT, cure rates approach 99% (4–6). In cases where the burden of retroperitoneal disease is low (pN1), RPLND monotherapy achieves cure in 90% of cases without additional chemotherapy, reduces the risk of retroperitoneal relapses to <2%, and reduces the burden of routine surveillance imaging (6,7). Although cure rates decline to <50% when RPLND is performed for higher volume disease (pN2), two cycles of adjuvant chemotherapy increases the cure rate to >98% (6,8,9). Suboptimal RPLND can result in increased relapse rates, late relapses, reoperative surgery, and decreased survival rates (10–12). Patients who must undergo reoperative retroperitoneal surgery after incomplete initial resections pay a particularly high price. After primary RPLND, reoperative RPLND leads to a 5-year disease-specific survival decrease from 99% to 86% (10). In the postchemotherapy setting, the 5-year disease-specific survival falls from 90% to 56% for patients requiring reoperative surgery (10).

RETROPERITONEAL LYMPH NODE DISSECTION BOUNDARIES

Most GCTs spread lymphatogenously in a predictable sequence from their sites of origin in the testis. Metastases usually occur in well-defined regions of lymph nodes in the retroperitoneum, subsequently progressing to thoracic sites in the lung, posterior mediastinum, and then to involve distant visceral organs (13). Distant metastases, without concomitant retroperitoneal disease, are rare (6). The contemporary understanding of testicular lymphatic drainage was established by important RPLND mapping studies performed by Donohue et al. (14), Weissbach and Boedefeld (15), and Ray et al. (13). Anatomic regions were described along with the most common landing zones for tumors that arise from the left or right testicle (Fig. 61.1). Right-sided testicular tumors disseminate initially to the interaortocaval, precaval, and preaortic nodal groups and have the ability to spread to contralateral lymphatic sites (13,16,17). The landing zone of left-sided tumors includes the para-aortic and preaortic lymph nodes, with a low incidence of contralateral spread (13,6,15,16).

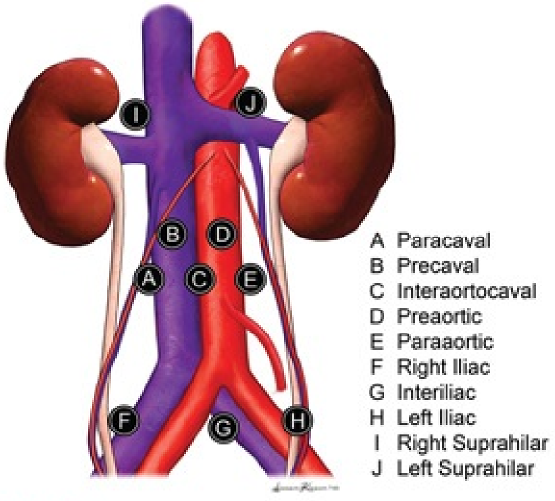

FIGURE 61.1 Anatomic regions of the retroperitoneal lymph nodes.

The standard bilateral RPLND includes the following boundaries: the renal vessels superiorly, the ureters laterally, the bifurcation of the iliac vessels inferiorly, and the prevertebral and psoas fascia posteriorly (Fig. 61.2). Although the early development of the RPLND included dissection of the suprahilar lymph nodes bilaterally, this has been shown to significantly increase chylous ascites and renovascular and pancreatic complications, with minimal oncologic benefit (4). Given the improvements in imaging, this element of the dissection is now omitted, except where known suprahilar disease exists in the postchemotherapy setting. Suprahilar metastases do occur, with the most common site of involvement the nodes of the retrocrural space (18).

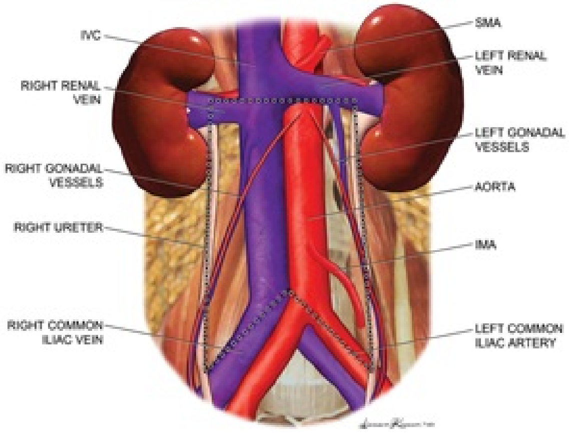

FIGURE 61.2 Boundaries of full-template RPLND. The renal vessels form the superior boundary, the ureters form the lateral boundary, and the bifurcation of the iliac vessels forms the inferior boundary. *IMA*, inferior mesenteric artery; *IVC*, inferior vena cava; *SMA*, superior mesenteric artery.

ANTEGRADE EJACULATION

Disruption of autonomic nerves in the retroperitoneum can lead to the loss of antegrade ejaculation, a complication that was noted in up to 90% of patients early in the development of the RPLND (19). The paired sympathetic chains along with their sympathetic ganglia, the postganglionic sympathetic fibers from T2 to L4, and the hypogastric plexus are essential in the process of seminal emission (Fig. 61.3). To decrease the risk of ejaculatory dysfunction, modified RPLND templates were developed based on retroperitoneal mapping studies (1,13,6,20,21). These templates altered the boundaries of the standard bilateral RPLND to minimize disruption to the hypogastric plexus and contralateral postganglionic sympathetic nerves below the inferior mesenteric artery (IMA) (Fig. 61.4). Although early reports suggested sustained oncologic outcomes, more recent studies reveal that modified template dissections could potentially miss a significant proportion of retroperitoneal metastatic disease. In a cohort of 500 patients with CS I or IIA NSGCT who underwent primary RPLND at Memorial Sloan-Kettering Cancer Center, the distribution of positive lymph nodes was analyzed and compared using five different modified template schemes (22). Depending on the template applied, 3% to 23% of metastases would be missed if a modified template was used (20). Moreover, 56% of these patients received adjuvant chemotherapy, which may have masked unresected disease and led to underestimation of the true rate of extratemplate disease. If all patients underwent full bilateral template resection, the rate of unresected disease would fall to below 3% (22,23). In a similar study of 269 patients who underwent postchemotherapy RPLND (PC-RPLND) for advanced disease, 7% to 32% of patients harbored extratemplate disease (24). These reports support the use of full, bilateral, infrahilar RPLND and suggest modified templates may inadequately treat the retroperitoneum. This leads to an increased burden of postsurgery surveillance, higher rates of postsurgery chemotherapy, and inferior long-term oncologic outcomes (21,23).

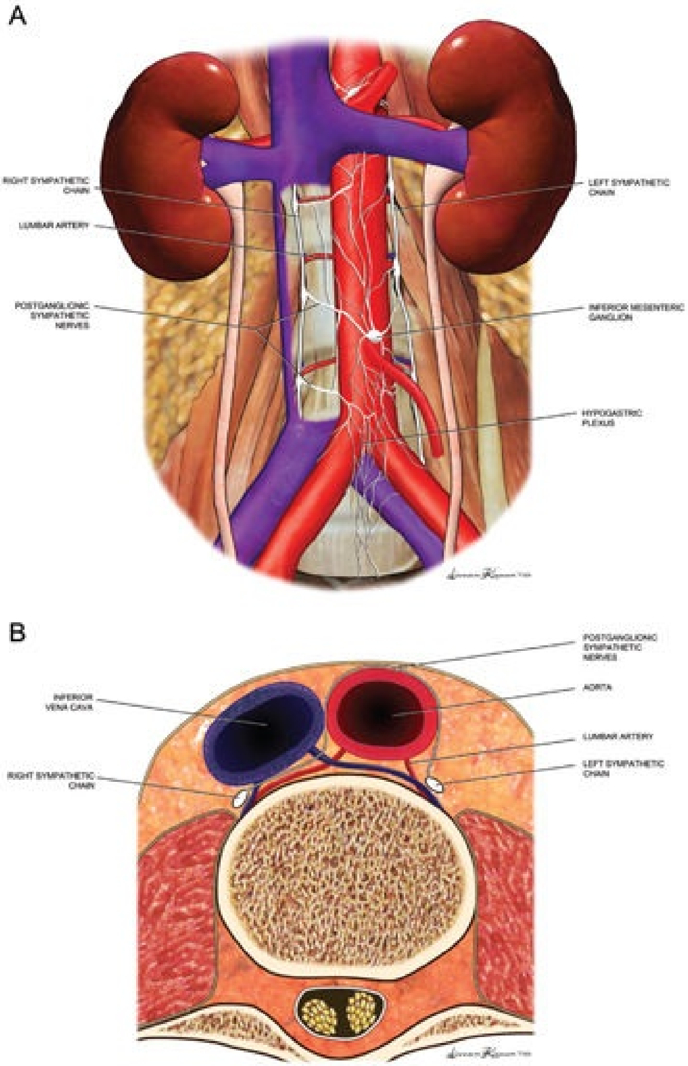

FIGURE 61.3 Schematic of retroperitoneal nerves. **A:** The sympathetic fibers innervating responsible for seminal emission emerge as postganglionic fibers from T12 to L3. The paired sympathetic trunks lie on the medial borders of the psoas muscle bilaterally. Fibers converge on the anterior surface of the aorta to form the inferior mesenteric and hypogastric plexuses. **B:** The right sympathetic trunk lies posterior to the IVC, and the left sympathetic trunk lies near the lateral border of the aorta. The lumbar branches of the great vessels run closely with the nerves and course medial to the sympathetic trunks as they course toward the vertebral foramina.

NERVE-SPARING RETROPERITONEAL LYMPH NODE DISSECTION

With advancements in the understanding of the neuroanatomic basis of seminal emission and ejaculation, critical nerves can be prospectively identified and spared without compromising the boundaries of resection. Each vas deferens and seminal vesicle is innervated by postganglionic sympathetic nerve fibers arising from the sympathetic chain from T12 to L3. The right sympathetic chain lies directly posterior to the inferior vena cava (IVC), whereas the left sympathetic chain lies posterior to the lateral border of the aorta (see Fig. 61.4B).

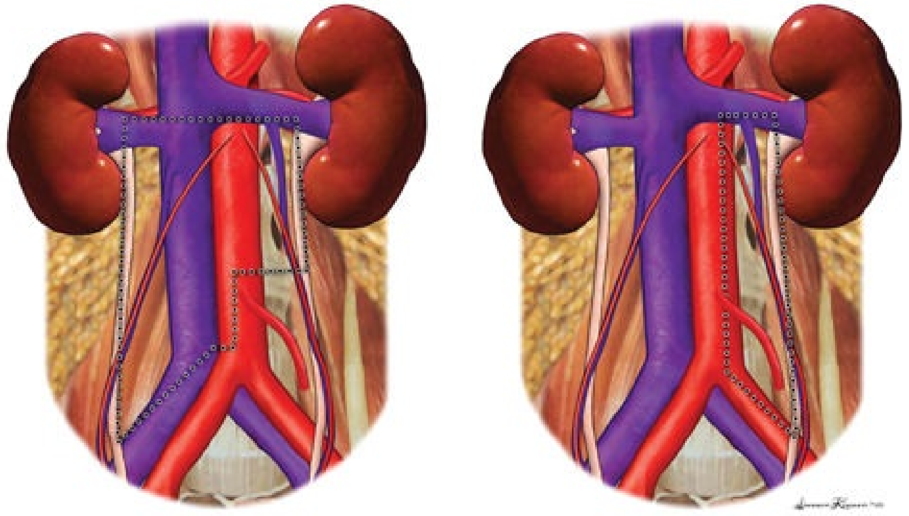

FIGURE 61.4 Right and left modified templates for RPLND. Several side-specific modified templates for patients with low-stage NSGCT have been proposed, with each including ipsilateral lymph nodes inferior to the renal hilum extending to the bifurcation of the iliac arteries. Right-sided templates include the interaortocaval region, and both avoid dissection below the contralateral IMA.

The postganglionic fibers emerge anterolateral to the lumbar vessels, from the lumbar foramina. The lumbar vessels emerge medial to the sympathetic trunks. Nerves from the right sympathetic trunk course from the medial border of the IVC anterolaterally over the aorta and converge with fibers from the left sympathetic trunk to form the plexus of nerves on the anterior surface of the aorta, including the hypogastric plexus. Due to this anatomic arrangement, dissection of the lymph nodes over the aorta, or the *anterior aortic split*, should be performed after the nerve fibers have been identified and isolated to prevent their unintended disruption (Fig. 61.5). After meticulous dissection, the sympathetic chains, the postganglionic sympathetic fibers, and the hypogastric plexus are preserved. This approach has yielded a postoperative return to antegrade ejaculation in 95% of patients undergoing primary RPLND and 79% in postchemotherapy RPLND (25–28).

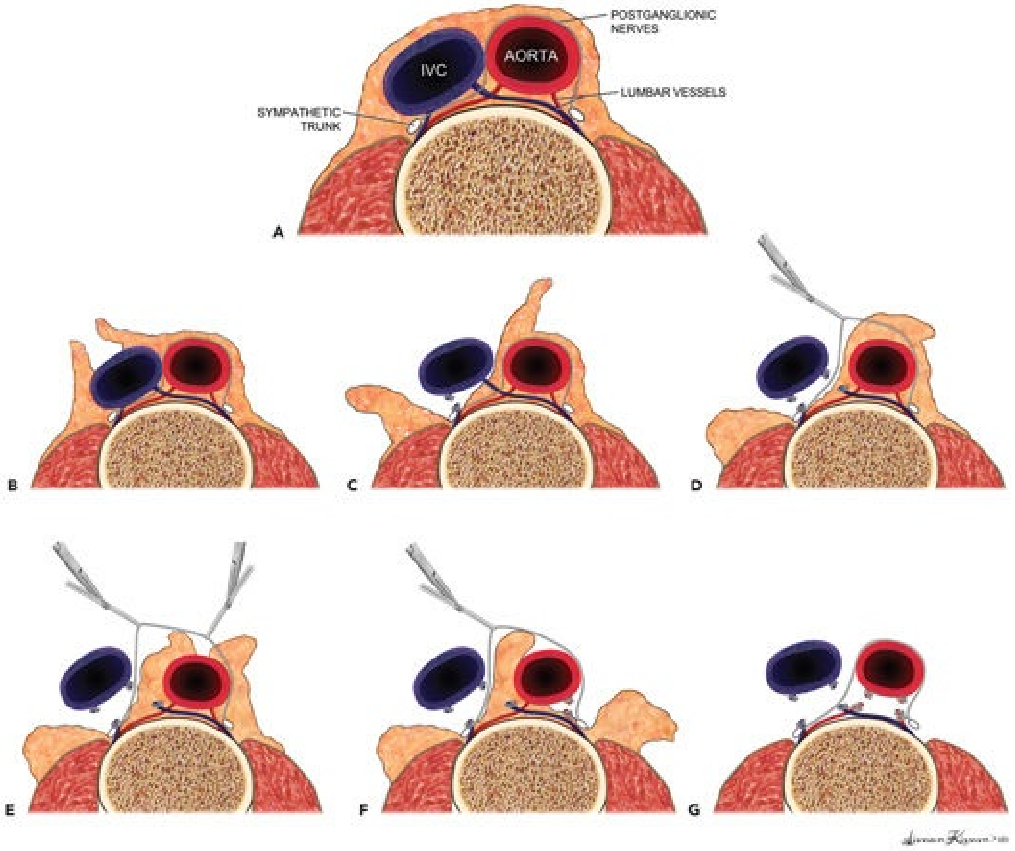

FIGURE 61.5 Split-and-roll technique of nerve-sparing retroperitoneal lymphadenectomy. **A:** The cross-sectional anatomy of the lymphadenectomy specimen. The split-and-roll technique is used to safely remove the specimen en bloc. **B:** The dissection begins with a "split" above the IVC. **C:** The sympathetic trunk is exposed, and the lumbar vessels are controlled near their insertion at the IVC and near the vertebral foramina. **D:** The postganglionic sympathetic nerves are prospectively identified and tagged with vessel loops. **E:** The anterior aortic split is made while protecting the sympathetic nerves. **F:** The para-aortic, preaortic, and interaortocaval lymph nodes are freed and lumbar vessels controlled and ligated. **G:** The specimen is removed en bloc with the posterior boundary marked by the psoas fascia and anterior spinous ligament. *IVC*, inferior vena cava.

SPERM CRYOPRESERVATION

Because even nerve-sparing RPLND does not guarantee preservation of antegrade ejaculation and because intraoperative findings may preclude a nerve-sparing procedure, all men in whom future fertility is a potential concern should be encouraged to cryopreserve sperm preoperatively (29).

Preoperative Preparation

Prior to surgery, patients should have up-to-date staging with a contrast-enhanced abdominopelvic CT or MRI within 4 to 6 weeks. These images are essential for surgical planning and should be evaluated for the extent of disease and the anatomy of the vessels and ureters. Variations and abnormal vascular anatomy is noted in approximately 20% of patients, such as accessory renal arteries or retroaortic left renal veins. Retroaortic renal vessels are easily misidentified and may be inadvertently divided, as they often resemble lumbar branches of the IVC. Partially and completely duplicated ureters must also be identified preoperatively. Serum tumor markers are ideally measured 7 to 10 days before surgery to ensure accurate staging. A high-fat diet is recommended for 2 days prior to surgery, which results in a milky white chyle that improves the visibility of retroperitoneal lymphatics and clipping of leaking lymphatic channels.

Perioperative Preparation

One hour prior to the initial incision, antibiotic prophylaxis is provided with a first-generation cephalosporin. General endotracheal anesthesia is induced with neuromuscular paralytics. Sequential compression devices are placed for deep vein thrombosis (DVT) prophylaxis. A Foley catheter is placed and connected to closed drainage. A nasogastric or orogastric tube is placed and low continuous suction initiated. The frame of the Gallagher retractor, which provides controlled exposure of the duodenum and pancreas, is attached to the surgical table. The skin of the chest, abdomen, and pubis is prepped and draped using sterile technique.

SURGICAL TECHNIQUE

Incision

The midline abdominal incision is the standard approach to RPLND. In certain situations, a thoracoabdominal incision may offer certain advantages if dissection above the renal vessels, thoracic cavity, or mediastinum is required (30). A scalpel is used to incise the dermis, with the incision extending from the xiphoid process to the symphysis pubis in the midline with a leftward deviation around the umbilicus (Fig. 61.6). The electrocautery is used to carry the incision through the subcutaneous tissue to the anterior rectus fascia. The fascia is cleared of fat and overlying tissue on either side of the linea alba to facilitate closure at the end of the case.

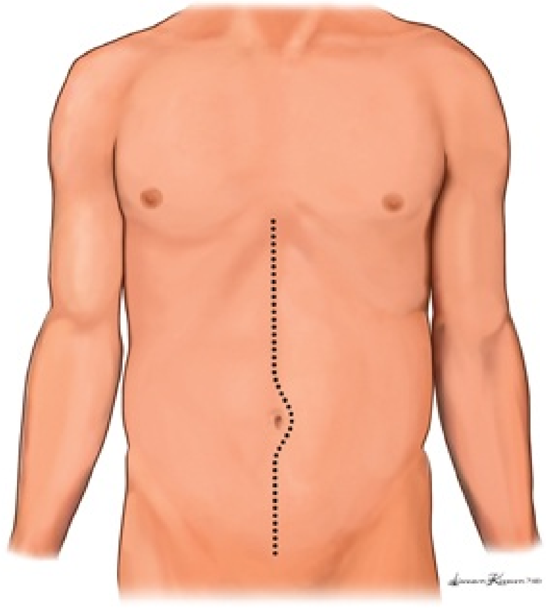

FIGURE 61.6 Incision. The standard approach is through an anterior abdominal wall incision extending from the xiphoid process to the symphysis pubis.

The peritoneum is sharply incised and opened. The falciform ligament is ligated with 0 silk ties, divided, and the distal segment excised from the anterior abdominal wall with the properitoneal fat. Complete removal allows for upward retraction of the liver without tension on the liver capsule, preventing a tear. Two Balfour self-retaining retractors are used for exposure. The crossbar of each is padded with a folded towel. The greater omentum and transverse colon are reflected cranially and out of the abdomen onto moist laparotomy pads on the patient’s chest (Fig. 61.7). Careful intraperitoneal exploration is performed to assess for evidence of visceral metastases. The position of the nasogastric or orogastric tube is confirmed.

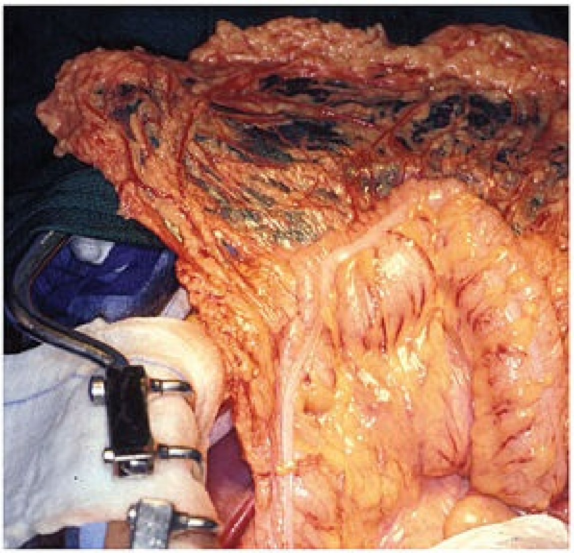

FIGURE 61.7 Reflection of the transverse colon and omentum. Care is taken to avoid traction injuries, and all structures are wrapped in saline soaked laparotomy pads and resting on towels.

Exposure of the Retroperitoneum

The root of the mesentery exposed by reflecting the small bowel superiorly and laterally. An incision is made in the posterior parietal peritoneum medial to the inferior mesenteric vein, extending from the ligament of Treitz down to the ileocecum carefully with the electrocautery. The peritoneal incision is then extended superiorly along the right white line of Toldt to mobilize the ascending colon (Fig. 61.8). Careful cephalad reflection of the small bowel and colon is performed, with the right gonadal vein serving as a landmark for the correct, avascular plane of dissection.

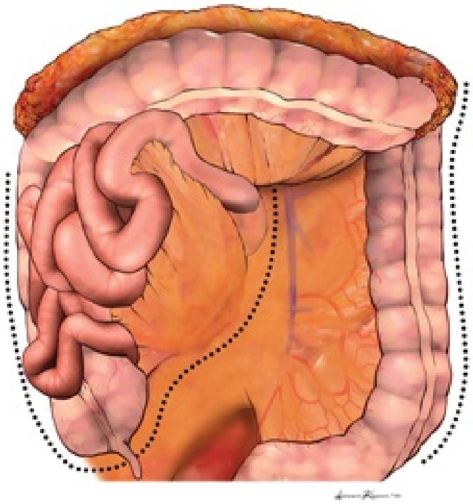

FIGURE 61.8 Posterior peritoneal incisions. Access to the retroperitoneum is achieved by extending an incision in the posterior peritoneum from the ligament of Treitz along the root of the mesentery to the ileocecal region. The IMV serves as an important landmark as this structure defines the left leaf of the posterior peritoneum. The line of Toldt on both sides mobilizes the ascending and descending colon.

A Kocher maneuver is used to mobilize the fourth segment of the duodenum and pancreas (Fig. 61.9). The undersurface of these structures are rich in lymphatic vessels, which must be meticulously clipped and divided (Fig. 61.10A). Electrosurgical dissection is avoided. Lymphatic vessel visualization is improved by a preoperative high-fat diet, which also helps to declare lymphatic leakage of chyle. The ultimate goal of this part of the dissection is exposure of the left renal vein, marking the superior border of the dissection on the left side (Fig. 61.10B). An important avascular plane of dissection is developed toward the left between the inferior mesenteric vein (IMV) and the left gonadal vein (Fig. 61.11). A thick condensation of lymphatics in this region is clipped and released to improve mobility and reduce traction to the distal pancreas. The undersurfaces of the pancreas and duodenum are held by connective tissue that is rich in lymphatics and must be controlled to prevent significant lymphatic leakage. These channels must be meticulously clipped prior to division (Fig. 61.12). Larger groups of lymphatic channels are ligated with 3-0 silk ties.

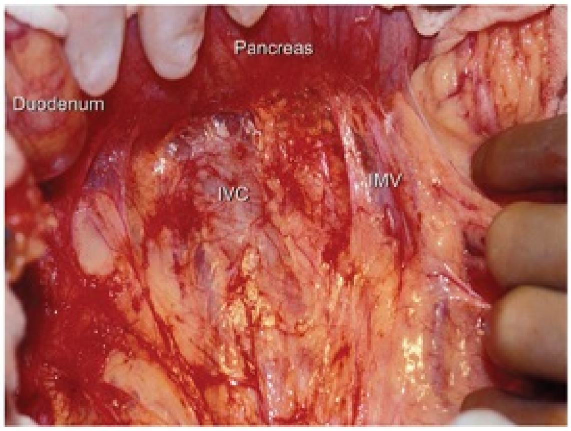

FIGURE 61.9 A Kocher maneuver is used to free the duodenum and pancreas, revealing the underlying great vessels and providing access to the superior border of the dissection. The second, third, and fourth segments of the duodenum and pancreas are reflected upward and out onto the chest wall. *IMV*, inferior mesenteric vein; *IVC*, inferior vena cava.

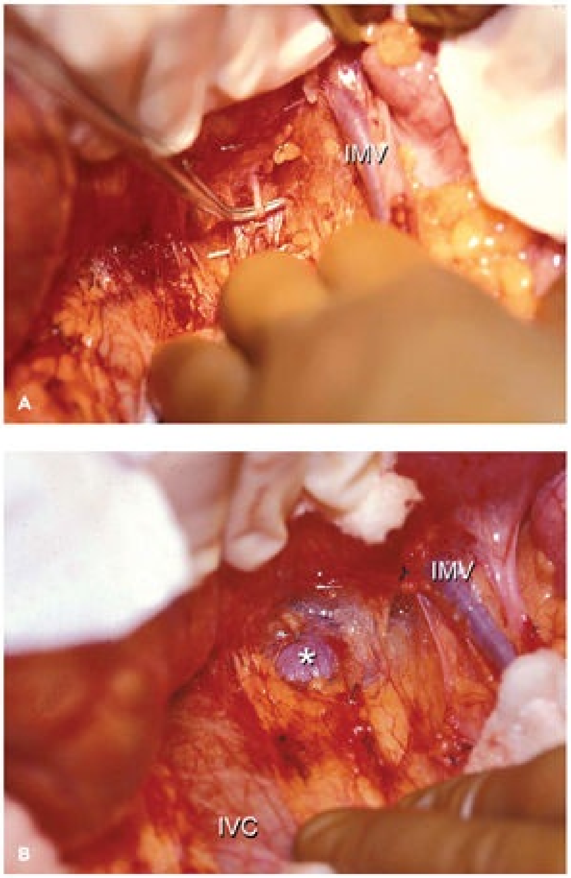

FIGURE 61.10 Retroperitoneal exposure. **A:** Large lymphatics found on the undersurface of the pancreas are divided with surgical clips or silk ties. **B:** The left renal vein (*asterisk*) is a key landmark and represents the superior boundary of the dissection. *IMV*, inferior mesenteric vein; *IVC*, inferior vena cava.

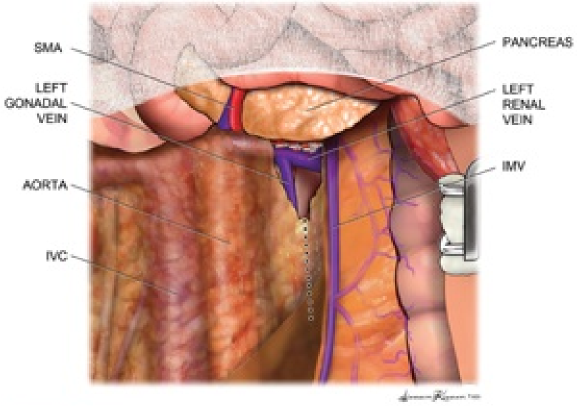

FIGURE 61.11 An important avascular plane between the left gonadal and IMV is developed. The mesentery of the colon lies anteriorly and Gerota fascia posteriorly. *IMV*, inferior mesenteric vein; *IVC*, inferior vena cava; *SMA*, superior mesenteric artery.

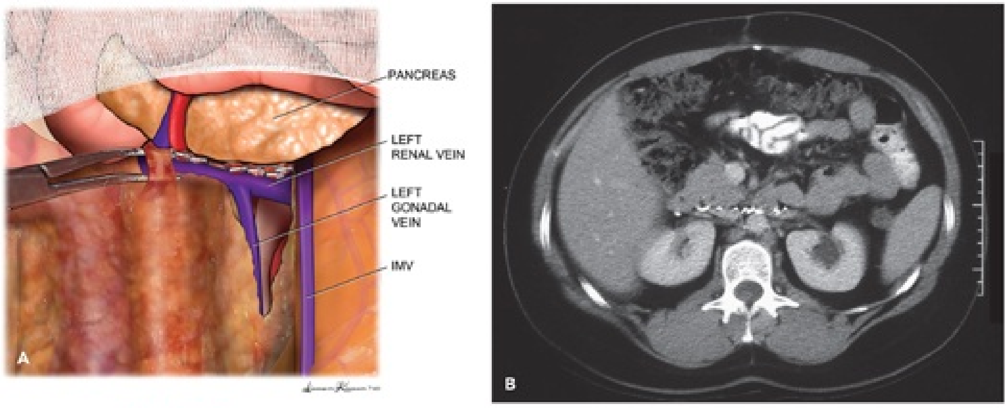

FIGURE 61.12 Clipping of lymphatics. **A:** Lymphatic channels on the undersurface are carefully controlled during exposure of the left renal vein. **B:** A postdissection CT scan shows a line of surgical clips with minimal lymphatic leakage. *IMV*, inferior mesenteric vein.

The small intestine, cecum, and right colon are reflected onto the chest wall to provide full exposure of the retroperitoneum (Fig. 61.13). The reflected intestine is wrapped with protective moist laparotomy pads. Retraction of the externalized viscera is maintained with the use of a Gallagher device with two self-retaining Deaver retractors (Fig. 61.14). Each retractor blade is padded with three additional moist laparotomy pads. Care is taken to ensure that there is minimal traction on the externalized structures, particularly of the superior mesenteric artery (SMA), duodenum, and pancreas. Periodic inspection of the bowel and assessment of SMA pulse should be performed to evaluate adequacy of blood flow to these reflected structures. The Deaver retractors are taken off traction periodically and only used during periods of active dissection where their use is required.

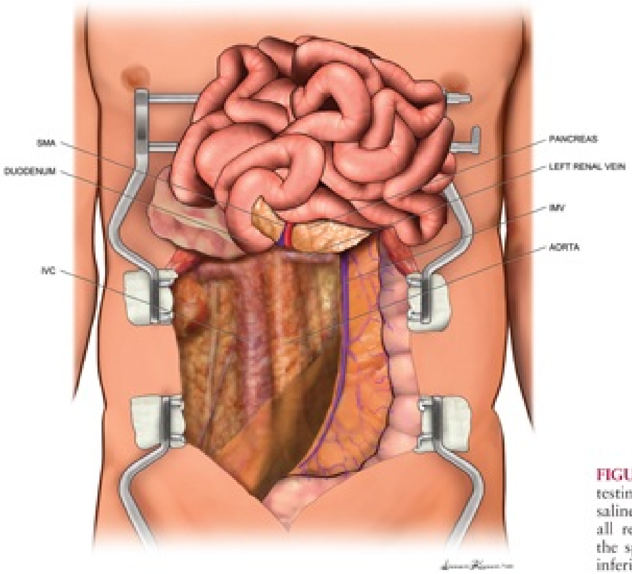

FIGURE 61.13 Retroperitoneal exposure. The small intestines are placed on the chest wall and protected with saline-soaked laparotomy pads. After careful inspection of all retractors, a split-and-roll technique is used to excise the specimen en bloc. *IMV*, inferior mesenteric vein; *IVC*, inferior vena cava; *SMA*, superior mesenteric artery.

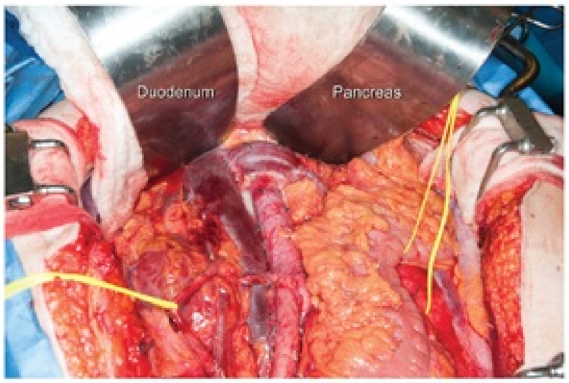

FIGURE 61.14 Gallagher retractor positioning. The Gallagher retractor is used to provide carefully controlled exposure during the superior dissection. The large Deaver retracting attachments each retract the duodenum and pancreas, and this retraction is released as the dissection moves to other areas.

The left white line of Toldt is incised, and the plane between the mesentery of the left colon and the left renal fascia is developed. The left colon is mobilized off the renal fascia and can be retracted both laterally and medially for exposure of the para-aortic region. If necessary, additional exposure of this area can be achieved by sacrificing the IMV or IMA. Collateral circulation from the marginal artery of the colon (Drummond) makes division of the IMA possible.

The ureters are identified near the common iliac vessels, encircled with vessel loops, and carefully mobilized proximally and distally. They are laterally retracted out of the dissection field (Fig. 61.15). These mark the lateral boundaries of the dissection. Feeding vessels and lymphatics to the periureteral tissue are carefully clipped and divided. The ipsilateral gonadal vein is dissected free at its origin, divided, and tucked away for subsequent resection. Prior to manipulation of the renal vessels, 12.5 g of mannitol may be administered intravenously. Papaverine should be available for direct application on the renal vessels should vasospasm occur.

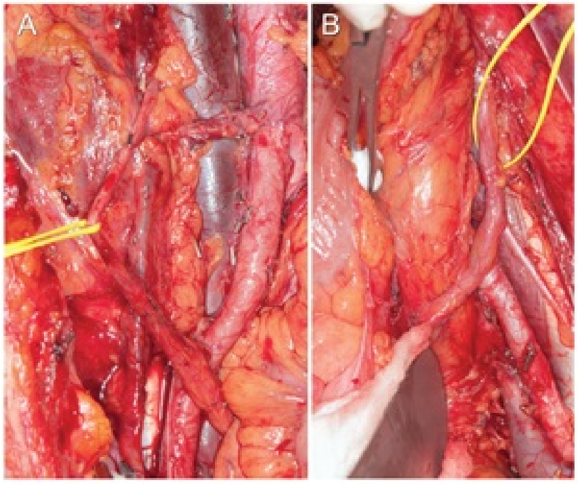

FIGURE 61.15 Lateral boundaries of the dissection. The left (**A**) and right (**B**) ureter are dissected free, encircled with vessel loops, and protected.

Lymphadenectomy

Adequate exposure is integral to the success and safety of this procedure, and the steps described earlier are undertaken to reveal the key structures of the retroperitoneum (Fig. 61.16). The lymph node dissection begins on the left renal vein, where the perivascular lymphatic tissue on the inferior border of the vessel is mobilized and the aortic surface exposed. Adrenal and lumbar branches are identified, ligated, and divided with 3-0 silk sutures. The dissection is carried toward the IVC. The first split-and-roll maneuver begins on the anterior surface of the IVC. The perivascular lymphatic tissue is split from the insertion of the left renal vein to the crossing of the right common iliac artery. This tissue is carefully freed from the IVC laterally and medially (Fig. 61.5A). The Penfield dissector is useful for atraumatically separating the lymph node packet away from the nerves and great vessels. Perforating vessels are commonly encountered, which are doubly clipped and divided. Lumbar veins are carefully identified, exposed, ligated, and divided between rows of surgical clips. Ligation of the lumbar veins prevents bleeding from inadvertent avulsion and increases the mobility of the IVC to enable complete removal of lymphatic tissue located posterior to the IVC and anterior to the anterior spinous ligament (ASL). Lumbar arteries that are identified are clipped with rows of multiple surgical clips. The arteries are not immediately divided but kept clipped in place temporarily to facilitate exposure. The right gonadal vein usually originates from the anterior surface of the IVC and should be doubly ligated with 3-0 silk ties and divided.

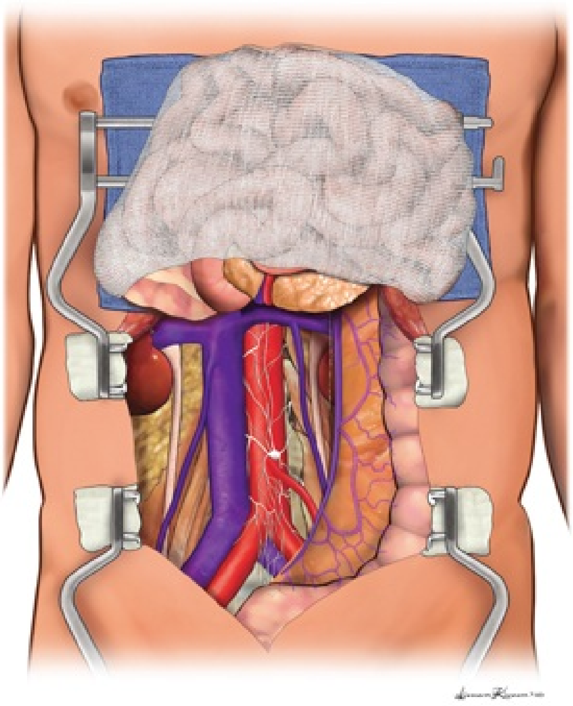

FIGURE 61.16 Retroperitoneal anatomy after exposure.

The nerves originating from the right sympathetic trunk emerge from the interaortocaval space on the medial border of the IVC are identified and marked with white vessel loops (Figs. 61.5 and 61.17). They are carefully dissected free of the precaval and interaortocaval lymph node packets and carefully retracted so that an anterior split can be made on the aorta without dividing the nerves (see Fig. 61.5). The Penfield dissector performs well in dissecting apart these structures. This split is extended from the left renal vein to the left common iliac artery. The gonadal arteries are ligated and divided at their origin. Care must be taken to preserve the hypogastric neural plexus. Lumbar arteries are ligated at their origin at the aorta. The crus of the diaphragm are visualized, and the large lymphatic channels traversing this region into the mediastinum are clipped (Fig. 61.18). Care is taken to ensure there is no leakage of lymph from the cisterna chyli, which is situated near the crus of the diaphragm and may appear as a saccular dilatation of the main lymphatic trunk. Once the IVC and aorta have been fully mobilized from their posterior attachments, the posterior lymphatic tissue is resected from the psoas fascia and ASL posteriorly, which should be completely visible at the conclusion of lymphadenectomy (Fig. 61.19).

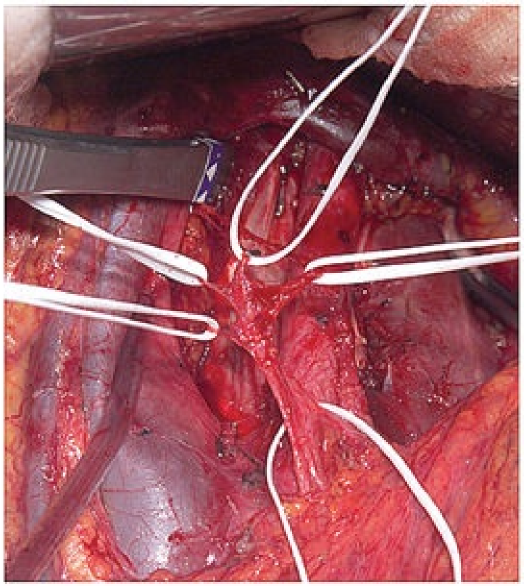

FIGURE 61.17 Postganglionic retroperitoneal nerves are prospectively identified, marked with vessel loops, and protected during lymphadenectomy.

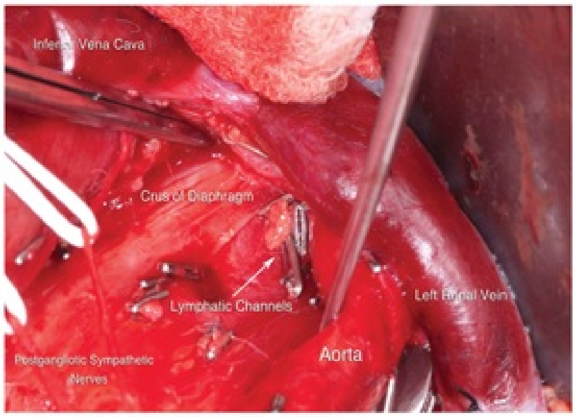

FIGURE 61.18 Large lymphatic channels are carefully ligated where they travel between the diaphragmatic crura into the mediastinum.

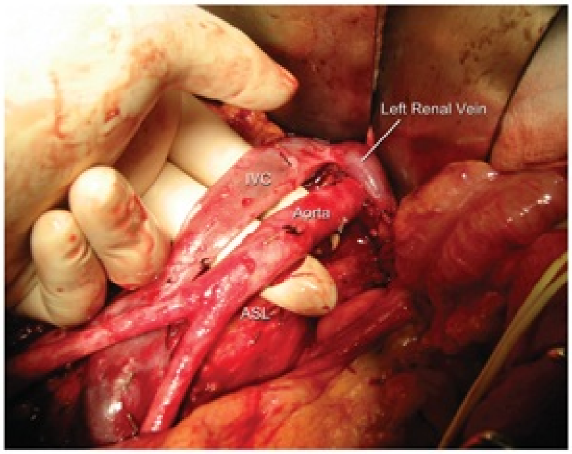

FIGURE 61.19 The posterior boundary of dissection is the psoas fascia bilaterally and the anterior spinous ligament (*ASL*). With careful control of the lumbar branches, the great vessels are fully mobilized. *IVC*, inferior vena cava.

The ipsilateral gonadal vessels are traced down to level of the internal inguinal ring, with all associated lymphatic vessels clipped and divided. The vas deferens is ligated and divided between 0 silk ties. The spermatic cord and surrounding fibroadipose tissues are then dissected free and excised in its entirety to avoid late paracolic recurrences (31).

Careful inspection of the dissection bed is performed and meticulous hemostasis and lymphostasis is performed. Lymphatic leaks are particularly problematic behind the right renal artery, the retrocrural space, and in the vicinity of the origin of the IMA. The skeletonized IVC and aorta are visualized, as is the underlying ASL. The sympathetic chains, the postganglionic sympathetic nerve fibers, and hypogastric plexus are inspected. The ureters, renal vessels, kidneys, pancreas, duodenum, and SMA are inspected for signs of injury (Fig. 61.20). Irrigation with a solution of sterile saline and hydrogen peroxide can be used to assist with hemostasis.

FIGURE 61.20 Full-template bilateral nerve-sparing RPLND. The ASL is exposed following removal of the lymph nodes. Note the relationship between the lumbar arteries and the left sympathetic trunk, as the vessels enter the lumbar foramina medial to the sympathetic trunk.

The intestine is brought down and the posterior peritoneum is reapproximated with running 2-0 chromic suture. The bowel is carefully placed in orthotopic position. The colon is replaced and the omentum is draped over the exposed peritoneal contents. No drains are used. The fascia is closed with 1-0 polydioxanone suture (PDS), with a series of interrupted figure-of-eight sutures along the entire length of divided fascia. Additional 1-0 PDS interrupted sutures are used intermittently for reinforcement of the closure. For patients with only a thin subcutaneous layer, the knots are buried. The subcutaneous tissue is copiously irrigated. A 3-0 Vicryl is used to close the subcutaneous layer, and skin staples are used to close the skin. A sterile dressing is applied.

Postoperative Care

Patients are extubated at the end of the procedure, and postoperative nasogastric tube drainage is not required except where extensive duodenal involvement or manipulation occurred. Fluid input and output are closely monitored with strict nursing documentation, daily weights, and physical examination. Patients who have undergone chemotherapy with bleomycin are particularly susceptible to potentially life-threatening pulmonary complications and require judicious fluid management. Postoperative tachycardia is common due to sympathetic nervous discharge and not an indication for aggressive fluid administration. As bowel function returns, the diet can be advanced, and length of stay typically ranges from 5 to 7 days.

Complications

RPLND is associated with several known major complications, which are closely associated with the burden of disease, the complexity of the procedure, and prior exposure to chemotherapy.

Vascular complications are rare in primary RPLND, but prior chemotherapy and/or bulky lymphadenopathy may significantly increase the risk of vascular injury (32). The SMA must be identified early and protected at all times. Injury to major, segmental, or accessory renal vessels can lead to loss of renal function, especially with large para-aortic masses involving the left renal hilum. In these difficult cases, adjunctive nephrectomy may be required (33). Bulky retroperitoneal lymphadenopathy can involve the IVC, and in the majority of cases where IVC invasion was present (67%), invasive teratoma or carcinoma was observed on pathology (34). This requires segmental resection of the IVC to ensure a complete resection, which involves careful sparing of key collaterals, and possible placement of an interposition graft (35).

Lymphatic leakage is inevitable despite meticulous lymphostatic surgical technique. Small lymphatic collections are commonly visible in postoperative imaging and are usually asymptomatic, benign, and self-limited. Rim-enhancing fluid collections are concerning for retroperitoneal abscess formation, especially if accompanied by symptoms of fever, chills, or pain. These are treated with antibiotics and percutaneous drainage. Significant leaks can lead to chylous ascites, which presents as abdominal distention, weight gain, sensation of fullness, and dyspnea (36). Chylous ascites can usually be managed conservatively with diuretics and initiation of a low-fat diet. A diet containing protein and medium-chain triglycerides are transported into the portal circulation and reduces flow through intestinal lymphatics (37). Intermittent paracentesis may be required. Where diet modification is insufficient, total parenteral nutrition may be used to further decrease lymphatic flow while supporting nutritional deficits (38). In certain cases, adjunctive use of octreotide has been shown to further diminish the output of chyle (39). Significant ascites that is refractory to conservative management may require a peritoneovenous shunt (34).

Traction on the duodenum and pancreas can result in a pancreatitis that is transient, characterized by nausea, vomiting, and elevated serum amylase and lipase. Bowel rest, fluid, and nutritional support may be used to conservatively manage this complication.

Bleomycin can cause a hypersensitivity pneumonitis that leads to lung fibrosis. Symptoms of chest pain and dyspnea can occur in delayed fashion, months after initial exposure. This pulmonary toxicity is lethal in less than 1% of patients receiving three cycles of bleomycin, etoposide, and cisplatin and increases to 1% to 2% after four cycles (40,41). Acute respiratory distress following bleomycin exposure may be linked to high intraoperative oxygen tension and should be avoided (42). Most important is careful fluid management, which is essential both intraoperatively and in the postoperative period (43). Pulmonary physiotherapy and early ambulation are important adjuncts in the reduction of pulmonary complications. Patients with active pneumonitis require treatment with corticosteroids.

CONCLUSION

RPLND plays a critical role in the staging, prognostication, and treatment of testis cancer. Although early outcomes for modified template RPLND in the primary or postchemotherapy situations have appeared favorable, longer term follow-up with larger cohorts of patients are necessary to assess rates of recurrence. The standard of care for PC-RPLND remains full bilateral RPLND, which achieves optimal cancer control rates and when combined with techniques for the prospective identification and sparing of autonomic nerves achieves excellent rates of antegrade ejaculation.

CHAPTER 62 TORSION OF THE TESTICLE

DIANA K. BOWEN AND ROBERT E. BRANNIGAN

Testicular torsion is a true urologic emergency, requiring a provider to arrive at a timely diagnosis with a fast transition to surgical intervention in order to prevent testicular injury or necrosis. It is a clinical problem in both pediatric and adult urology, with a recent population-based study giving a yearly incidence of 3.8 in 100,000 for males younger than 18 years old (1). This predicts that 1 in 1,500 males will undergo surgery for torsion by that age, compared to older estimates of 1 in 4,000 for men younger than 25 years old (2). Despite wide recognition of this condition, 30% to 41% all cases will have a nonviable testis at the time of surgery and undergo orchiectomy (1,3,4). Ramifications of delayed treatment include atrophy, possible testicular loss, decreased endocrine function, and reduced sperm count and future fertility. If torsion is suspected, emergent scrotal exploration should be undertaken given that even partial necrosis has been seen to occur as early as 4 hours (5,6). The injury to the testis occurs from ischemia as well as reperfusion from reactive oxygen species (7).

There is a bimodal incidence of torsion with peaks at 1 month of age and a second at 12 years, thought to reflect the clinical distinction between extravaginal torsion in the perinatal period and intravaginal torsion in older children. In this way, the anatomy of a testicular torsion is correlated with the expected age of the patient—the point of difference is whether the torsion occurs above or below the reflection of the tunica vaginalis (Fig. 62.1). Intravaginal torsion results from a twist in the spermatic cord within and not involving the tunica vaginalis. Also known as a “bell clapper deformity,”, it is hypothesized to be due to an abnormally high insertion of the tunical attachments to the testis and epididymis so that there is incomplete attachment (Fig. 62.2). Intravaginal torsion is seen in the older age group primarily, although can be seen rarely in the perinatal period. Surprisingly, autopsy studies report the incidence of a bell clapper deformity to be as high as 13% in normal subjects, thus unlikely to account solely for the cause of torsion (8). Individuals with undescended testes are also presumed to be at a higher risk although this is from only a handful of accounts and has not changed the current recommendations that infants undergo orchidopexy at the age of 6 to 12 months. At this time, no other predisposing factors can be definitively linked with testicular torsion.

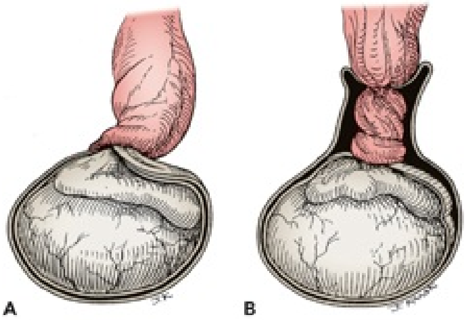

FIGURE 62.1 **A:** Extravaginal torsion. The tunica vaginalis is involved with the twist of the spermatic cord. **B:** Intravaginal torsion involves the spermatic cord below the reflection of the tunica vaginalis onto the spermatic cord. (Adapted with permission from Marshall, Fray F. *Operative Urology*. Philadelphia: WB Saunders, 1991:537. Copyright 1991 W.B. Saunders Co./Elsevier.)

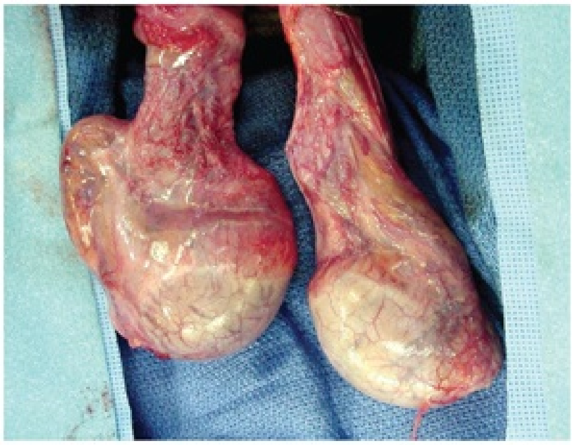

FIGURE 62.2 The patient's right testicle demonstrates a "bell clapper" deformity with anomalous attachment of the spermatic cord and testicle. The patient's left spermatic cord and testicle does not exhibit the bell clapper deformity. (Courtesy of Elizabeth B. Yerkes, MD.)

Extravaginal torsion, however, is a twist of the testis, cord, *and* tunica vaginalis due to deficient attachment of the gubernaculum to the dartos, and thus, it is much more likely to occur in the perinatal period. Possible predisposing factors include a large birth weight and difficult delivery, but these remain only postulations (9,10). Extravaginal torsion encompasses perinatal cases, of which an estimated 72% occur in utero and present as a "vanishing" nonpalpable testis at birth (11). The remaining important minority of cases present variably depending on the timing of the event and may be insidious. Suggestive findings at birth include an indurated, erythematous scrotum, a dark discoloration with or without edema, and/or a coexisting hydrocele. Often, the infant will be asymptomatic.

DIAGNOSIS

Clinical Presentation

The presenting signs and symptoms vary significantly by the type of torsion and therefore often the age of the patient; however, a sudden onset of pain and/or an abnormal hemiscrotum with a high-riding testis should always be concerning for testicular torsion.

Intravaginal Torsion

The description of sudden-onset unilateral testicular pain is a classic history for intravaginal testicular torsion. Nausea and vomiting are often present as well. On physical exam, the hemiscrotum can be swollen and edematous, and there may be evidence of a high-riding testis or horizontal lie. Lack of a cremasteric reflex, defined in one study as less than 0.5 cm elevation, has been highly associated with torsion, with positive predictive values of 43% to 83% and negative predictive values of 96% to 98% (12). However, the presence of a reflex does not rule out torsion (13). There is no single feature predictive of torsion, but a combination of two or three of these should be considered highly predictive (12).

Intermittent torsion is often a difficult clinical problem, as there may be no evidence at the time of evaluation of torsion. Patients may have recurrent bouts of pain that resolve rapidly and can occur with any time pattern. Making diagnosis even more difficult is that often ultrasound does not show evidence of reduced blood flow and typical physical exam findings, such as the cremasteric reflex, may not be present, even during a bout of pain (14). Bilateral elective orchidopexy can be considered based on a high degree of clinical suspicion.

Torsion of Appendage

Torsion of a testicular appendage is often characterized by a gradual onset and few systemic symptoms. Although the four testicular appendages that have been identified—the appendix testis (hydatid of Morgagni), the appendix epididymis, the paradidymis, and the vas aberrans of Haller—are all susceptible to torsion, the most commonly involved is the appendix testis. In the pediatric age group, appendiceal torsion is nearly as common as testicular torsion and accounts for 20% to 40% of acute scrotum cases (15). Early in the course of torsion of the appendix testis, physical examination may reveal a tender mass located at the upper pole of the testicle, sometimes adherent to the overlying skin. The testicle will usually have a normal orientation and the cremasteric reflex intact (13). There may be a tender mass located superiorly on physical exam, but torsion of the testicle and appendage can become clinically indistinguishable with time. Imaging with Doppler ultrasound frequently shows a hyperechoic mass at the upper pole of a normal-appearing testicle. Therapy consists of bedrest, scrotal elevation, and nonsteroidal anti-inflammatory agents as needed. Symptoms should begin to resolve within 1 to 2 weeks as the infarcted appendage is gradually resorbed. If testicular torsion cannot be ruled out with certainty, urgent surgical exploration is needed.

Extravaginal Torsion

In prenatal torsion, the first newborn exam will usually reveal a firm scrotum that is indurated and either erythematous or with a darker hue than the contralateral side (Fig. 62.3). Often, this is an isolated finding and the infant will not be systemically symptomatic. This is in opposition to postnatal torsion, which is new in onset after birth, and more likely to be accompanied by irritability and crying. The decision to operate in the perinatal period is controversial depending on the timing of findings and age of the patient. There is a conceptual difference between prenatal and postnatal torsion stemming from the fact that prenatal torsion is rarely salvageable and thus exposes an infant often within the first month of life to the risks of general anesthesia and surgical complications. Kaye et al. (10) advocates that infants found to have a unilateral prenatal torsion be treated with orchiectomy and contralateral orchidopexy after 1 month of age, as the risk of complications is greatest before this time period. On the other hand, bilateral prenatal torsion (or any bilateral torsion for that matter), and unilateral postnatal torsions should be taken for immediate exploration and potential orchidopexy. The argument against delaying exploration in prenatal cases is both the possibility of salvage, albeit low, as well as the possible occurrence of bilateral synchronous or asynchronous testis torsion, which may not be as rare as previously thought (16).

Differential Diagnosis

The differential diagnosis for testicular torsion includes infection or inflammation (epididymo-orchitis), scrotal edema, hernia or hydrocele, torsion of the appendix testis, or trauma. It is especially important to be aware that torsion can occur in the setting of a trauma, potentially clouding the diagnosis. A more gradual onset of pain and urinary symptoms or a history of urinary tract infections are suggestive of epididymo-orchitis, which is commonly confused with torsion. Finally, torsion of a testicular appendage can present similar to testicular torsion, but the treatment for the former is purely conservative thus diagnosis is paramount. The pathognomic finding of an appendage torsion is the blue dot sign, which is the appearance of a small 1- to 3-mm palpable “dot” that has a bluish hue beneath the characteristically thin scrotal skin.

Diagnostic Modalities

Laboratory Testing

Basic laboratory testing includes a urinalysis to investigate for infection or hematuria. If an infection is considered, a urine culture, complete blood count (CBC), and serum chemistry may be indicated.

Ultrasound

In the mid-1990s, color Doppler ultrasound (CDUS) was introduced as an important tool in the diagnostic workup of torsion, and its use has steadily increased. Lack of intratesticular blood flow is the characteristic finding (Fig. 62.4). However, reports of an unacceptably high rate of false-negative exams remain, with an overall sensitivity ranging from 69% to 95% (17–21). This is likely due to the period of time before arterial blood flow ceases due to venous congestion and worsening edema. Some studies have suggested certain findings can increase the sensitivity for torsion such as noting a reversal of diastolic flow in the Doppler waveform or heterogeneous echotexture that may be predictive of eventual testicular loss (10,22). In addition, with high-resolution ultrasound (HRUS) that uses a higher frequency (10 to 20 mHz), visualization of the spermatic cord has been suggested as an adjunct. Kalfa (19) suggested the appearance of a cord twist on HRUS that looked like a whirlpool or “snail-shaped” mass was suggestive of torsion, although this is not 100% and more robust studies are needed to corroborate this finding (Fig. 62.5). Consideration should thus be given to perform the scrotal US exam up to the level of the internal ring for a more thorough evaluation of not just the testis but also the spermatic cord.

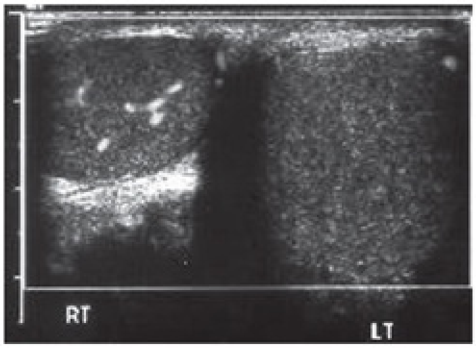

FIGURE 62.4 Doppler ultrasound of the scrotum showing a left testis with no blood flow adjacent to a normal-appearing right testis with blood flow. (Courtesy of Dennis Liu, MD.)

Time delay before the operating room is an important consideration with the use of ultrasound. One study found a 2.6 times greater length of time until the patient was taken to the operating room and questioned whether scrotal ultrasound should be routinely performed. In a prospective study of 236 patients with suspected testicular torsion (23) spanning 17 years, the authors noted a less than 15-minute estimated additional time for obtaining an ultrasound. All patients underwent surgical exploration, and the authors found a 100% sensitivity and 75.2% specificity, indicating that their high volume and tertiary care expertise were likely important factors in delivering this expedited care. More specifically, at this center, a senior urologist who was experienced in ultrasound performed the study during the initial triage in concert with ongoing preparations for surgery (23). This is an interesting paradigm, especially given the recent increase in urologists obtaining scrotal ultrasonography certification. However, until more prospective trials prove that the use of ultrasound does not significantly delay surgical exploration, urologists should not routinely depend on scrotal ultrasonography in determining whether or not to emergently operate.

Nuclear scintigraphy has been used historically in the evaluation of torsion, with less common use at this time. It is still employed, albeit rarely, as a diagnostic modality at some centers, where it is primarily used in children and adolescents as an adjunct in cases with equivocal results on scrotal ultrasonography (10). Drawbacks of nuclear scintigraphy include excessive length of time to perform the examination, radiation exposure with this test, and the low degree of sensitivity for testicular torsion. Magnetic resonance imaging (MRI) is not practical as it requires availability of the scanner and a lengthy time for the exam.

The drawbacks of ultrasound (time, operator dependency, false negatives) have led some to investigate other modalities that may be used clinically by first-line providers to expedite care. These techniques ideally would require less training than ultrasound and be readily available, such as near-infrared spectroscopy (NIRS), akin to pulse oximetry that measures oxygenation within seconds. NIRS uses infrared light to obtain continuous, noninvasive transcutaneous monitoring of deep tissue oxygen saturation in the testis (24). It promises a quantitative measurement of oxygen saturation versus a qualitative evaluation on Doppler ultrasound. An animal study showed that torsion was the most likely diagnosis with an oxygen saturation difference of 12% between the affected and contralateral testicle and that cases of torsion exhibited a rapid and sustained deterioration (25). From this, a pilot feasibility study was performed that identified all 16 surgically confirmed cases of an acute testicular torsion when the affected testis oxygen saturation was greater than 11.5 units lower than the contralateral testis (26). This is a promising area of investigation that may aid in a more rapid diagnosis and treatment plan than ultrasound currently allows for in equivocal clinical cases of suspected torsion.

INDICATIONS FOR SURGERY

At this time, there is no role for medical treatment or described medical adjuncts such as pentoxifylline and nitrous oxide in the treatment of torsion. Other agents thought to prevent testicular injury from reperfusion injury after torsion, including antioxidants such as N-acetylcysteine and *Rhodiola rosea*, have been studied in animal models but are investigational at this stage. Importantly, all of these adjuncts have been studied in combination with surgical intervention (27,28).

If there is a strong suspicion for testicular torsion based solely on history and physical exam in a child, adolescent, or adult, the patient should be taken immediately to the operating room for scrotal exploration. Manual detorsion is often attempted prior to operating, and the technique is described classically as "opening a book" based on the assumption that both testes twist medially or "inward" (the right clockwise and the left counterclockwise). However, a 2003 retrospective review of 186 torsions showed that lateral twisting occurred in approximately one-third of cases and moreover that resolution of symptoms after manual detorsion did not correlate with the presence or absence of persistent torsion upon surgical exploration (6). Thus, manual detorsion and any resulting relief should not delay nor negate an expeditious trip to the operating room.

The timing of operative intervention in extravaginal torsion is more controversial. The likelihood of testicular salvage and contralateral torsion in the time it takes to go to the operating room must be weighed against the risks of neonatal anesthesia, especially if not to be performed at a center with a specialized pediatric anesthesia team. Arguments for elective exploration include the fact that most cases do occur prenatally, that in most cases the affected testicle is *not* salvageable (<5% are salvageable), and that asynchronous torsion is very rare. However, proponents of a more aggressive approach who advocate for urgent or emergent surgery point to several recent studies that indicate asynchronous torsion may occur more frequently. These authors assert that the clinical signs of torsion may be subtle, delayed, and easily overlooked by even the most observant parents (9,16). In summary, any bilateral neonatal torsion or postnatal torsion (new evidence of torsion after a normal birth exam) are indications for emergent exploration; however, the timing of a prenatal torsion (i.e., one found at birth) is debatable.

Preoperatively, the patient and/or family should be counseled on the risks and benefits of the surgery, including options of contralateral fixation and/or testicular prosthesis placement should orchiectomy be necessary. Any prior pertinent surgeries such as hernia repair should be discussed. Perioperative antibiotics for skin prophylaxis are appropriate.

SURGICAL TECHNIQUE

The surgical technique is detailed in Figure 62.6. The patient is positioned on the operating table supine and the scrotum cleaned in the usual sterile fashion with an antiseptic solution such as Betadine or chlorhexidine gluconate. In older children, adolescents, and adults, a midline scrotal incision following the median raphe or a transverse incision in the correct hemiscrotum following the natural rugae of the scrotum are both appropriate. Electrocautery is used to dissect through the dartos layers maintaining good hemostasis and the tunica vaginalis is then identified. The testis and cord are delivered from the scrotum and a longitudinal incision is made in the tunica vaginalis to expose the testis and spermatic cord. The spermatic cord is inspected, and the presence of twists, the direction (medial or lateral) of twists, the number of twists, and the color of the testis—often black or dark purple if ischemic—are all noted (Fig. 62.7). Inspection and palpation for any masses or other suspicious findings should be performed. The testis is detorsed; wrapped in a warm, moist gauze; and set aside; attention is then turned to the contralateral scrotum and orchidopexy on that side to allow time for revascularization and reassessment of the torsed testicle for viability after this.

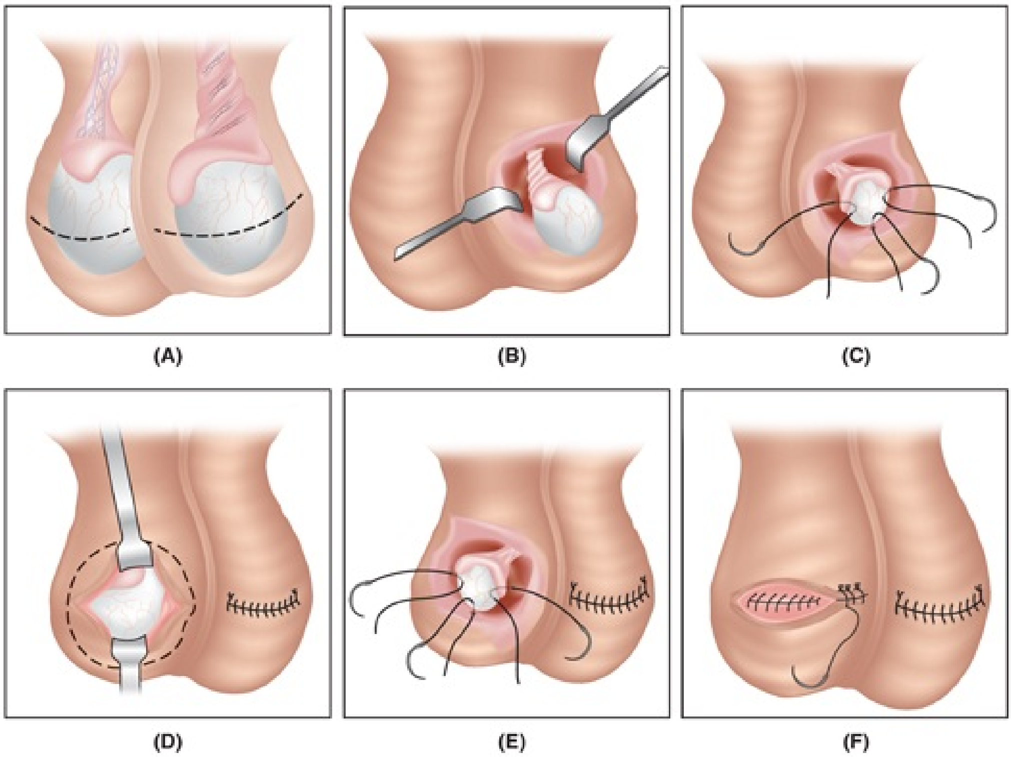

FIGURE 62.6 Steb-by-step scrotal exploration and orchidopexy for testicular torsion. A: Incision. B: Exposed testicle with twist in cord. C: *Arrow* showing untwisting. D: Three-point fixation with needles. E: Sutures tied down—with contralateral incision. F: Closed incision (dartos).

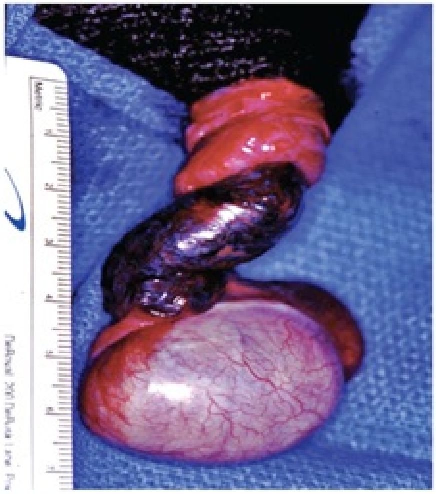

FIGURE 62.7 Intraoperative photograph demonstrating intravaginal testicular torsion, with discolored and edematous spermatic cord tissue evident distal to the twist. (Courtesy of Dennis Liu, MD.)

An important point of difference in the initial approach for infants is that an inguinal incision has been historically favored over a scrotal incision, as a hernia or rarely a tumor can be encountered and may be better handled with an inguinal incision. Despite this recommendation, surveys have found that 67% to 75% of urologists will actually perform a scrotal incision in perinatal torsion. This is postulated to be due to the increasing use of ultrasound to preoperatively rule out tumors and the ease of this surgical approach (11,29).

In cases of intravaginal torsion, bell clapper deformities usually exist bilaterally, thus it is advisable to routinely fixate the contralateral side. The same especially holds true for perinatal torsion with lower salvage rates, as often the goal of surgical exploration is to protect the normal contralateral side from an asynchronous torsion. The contralateral testis is delivered either through the same midline scrotal incision or a mirroring transverse incision in the contralateral hemiscrotum or inguinal region for infants (as previously discussed). The tunica vaginalis is opened longitudinally, everted posteriorly, and the edges then approximated. The tunica albuginea is then sutured to the dartos with either two or three separate interrupted sutures for stable fixation, thus minimizing the risk of future torsion. Eversion of the tunica vaginalis is an important step that helps eliminate the possibility of a future intravaginal torsion. Interestingly, several studies have shown that creation of a subdartos pouch is the most effective method to prevent retorsion, and this approach should be considered in the event of suture fixation failure with retorsion (30,31). There is debate about the best type of suture to use to secure the testis to the dartos tissue, namely absorbable versus nonabsorbable suture. Although in published series, authors have postulated a higher rate of retorsion with the use of absorbable sutures, retorsion has been shown to occur with both nonabsorbable and absorbable sutures (31,32). At this time, one is not recommended over the other. After inspecting carefully for hemostasis, the dartos is closed with a running 3-0 chromic suture in a locking fashion for hemostasis. We close the scrotal skin with a 4-0 Monocryl running horizontal mattress suture (see Fig. 62.6).

Next, the affected testis is readdressed and the decision to salvage the testis is made based on the perceived improvement in its color after revascularization. A fasciotomy can additionally be made in the tunica albuginea to decompress the testis and help assess blood flow. Every effort should be made to salvage the testis if even only mild improvement is seen after reperfusion, given the potential impact on future fertility and endocrine function. If the testis is deemed viable, the fasciotomy is then closed primarily with 4-0 chromic suture. Prior to this, a testicular biopsy may be taken and sent to pathology to assess for necrosis in a testis that is borderline, but this typically does not affect intraoperative decision making. The testis is placed back in the scrotum with attention paid to its correct alignment. As described with the contralateral side, a two- or three-point fixation is performed and the dartos and scrotal skin closed.

Interestingly, the use of a tunica vaginalis flap has been recently advocated in the pediatric literature to loosely cover a tunica albuginea fasciotomy and thus minimize the risk of increased intratesticular pressures (i.e., testicular compartment syndrome) sometimes seen in the setting of torsion (33). This compartment syndrome is theorized to occur after prolonged ischemia time, as there is resulting increased blood flow after the cord is untwisted and edema builds within the relatively inelastic tunica albuginea. Follow-up studies of this technique are equivocal at this time and long-term results are needed.

If a testis appears necrotic and does not improve with detorsion or fasciotomy over a period of several minutes, then it is deemed nonviable and should be removed to avoid continued pain and risk of infection.

Placement of a testicular prosthesis at the time of orchiectomy in adolescents and adults has traditionally not been done presumably due to the risk of infection or lack of preoperative discussion; however, there is no robust data to support the former paradigm. In fact, a recent series involving 12 pubertal patients whom had concurrent prosthetic placement within the tunica vaginalis revealed no infectious complications or erosion at a mean follow-up of 4.8 months (34). The authors note that instead of placing the prosthesis in a subdartos pouch, they fixed it near the cord stump and then secured it with preplaced tunical sutures (34). This study, combined with established data for prosthetic placement after radical orchiectomy for cancer, indicate that there may be a role for concurrent prosthetic placement, and this should be discussed preoperatively. If a testicular prosthesis is to be placed, a saline-filled silicone prosthesis is appropriate.

Complications of Procedure

Complications of the orchidopexy procedure include wound infection, pain, and scrotal hematoma. Long-term complications include necrosis of the testicle and retorsion.

OUTCOMES

Outcomes after surgical intervention for testicular torsion are focused on hormonal function, fertility potential as reflected by semen parameters, and viability of the testis. The primary determinants of testicular viability are the degree to which the spermatic cord twists and the duration of torsion. The literature reports low salvage rates in newborns (as low as 5%); however, these accounts do not always distinguish between prenatal and postnatal torsion. Long-term assessment of fertility in patients with perinatal torsion is lacking. Outside of this group, Workman and Kogan (35) found that patients who underwent surgery within 6 hours of onset had testicular salvage rates of 83% to 97%. This figure dropped to 55% to 85% between 6 and 12 hours of onset, and after 24 hours, the salvage rate fell to less than 10%. However, testicular salvage does not necessarily imply normal testicular function. Based on animal models, Turner et al. (36) showed that torsion can permanently affect fertility, despite the prompt return of blood flow, due to subsequent oxidative stress and germ cell apoptosis within the testis occurring with neutrophil recruitment. There appears to be possible contralateral dysfunction from unknown mechanisms but theorized to be due to immunologic mechanisms, previous episodes of silent intermittent torsion, or reflex vasoconstriction of the contralateral testis (7).

Testicular torsion is known to have deleterious effects on many semen parameters including sperm count, motility, and morphology, and these changes are associated with the duration of torsion and the degree of eventual atrophy (8,37,38). Despite this, torsion appears to play a small role in overall fertility, as only less than 1% of all adult males with infertility will have torsion as the main diagnosis (7). Sperm antibodies occur in 0% to 11% of patients with torsion; however, Arap et al. (39) studied 24 patients after testicular torsion and showed no correlation with antisperm antibody levels and duration of ischemia or treatment. They also showed that patients maintained normal hormone levels, and they reported that although sperm quality was preserved in most patients, those treated by orchiectomy presented better morphology compared with the orchidopexy group (39).

CONCLUSIONS

Testicular torsion remains a surgical emergency. A high index of suspicion on history and physical exam are sufficient to explore the patient surgically.

CHAPTER 63 SCROTAL TRAUMA AND RECONSTRUCTION

K. JEFF CARNEY AND GERALD H. JORDAN

The anatomy of the male genitalia is quite complex. In the scrotum, there are multiple fascial layers (Figs. 63.1 and 63.2). From the standpoint of trauma, however, most of the fascial layers are relatively unimportant. The Buck fascia is related to the deep penile structures and is important in the containment of periurethral processes or the occasional hematoma associated with injury to the corpora cavernosa and/or corpus spongiosum. In the scrotum, the analogous fascia to the Buck fascia—the external spermatic fascia—is usually uninvolved with scrotal trauma (see Fig. 63.2).

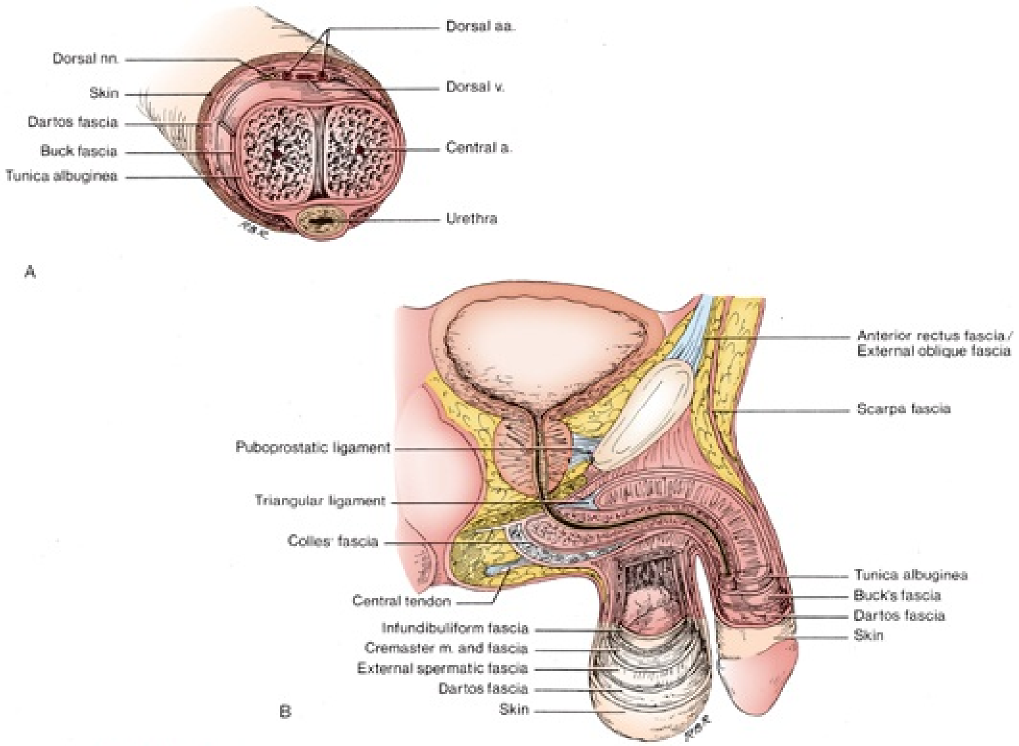

FIGURE 63.1 **A:** Cross section of the penis illustrating the fascial and structural components of the shaft of the penis. **B:** Sagittal section of the pelvis demonstrating the fascial layers and structural component.

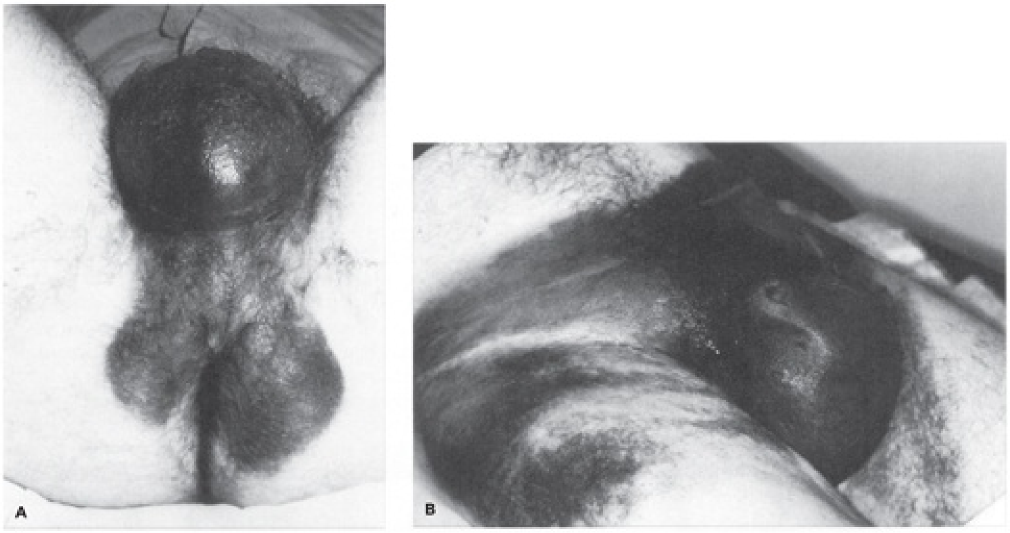

FIGURE 63.2 **A:** Perineal view of a trauma patient illustrating a hematoma contained by Colles fascia (classic butterfly hematoma). **B:** Same trauma patient illustrating the containment of the hematoma by the extended Colles layer, that is, the fascia lata of the thigh and extending onto the abdomen beneath the Scarpa fascia.

Culp (1) has classified injuries to the external male genitalia into five categories: nonpenetrating, penetrating, avulsions, burns, and radiation injuries (both direct and indirect). Nonpenetrating injuries result from either a crushing or sudden deforming force to the scrotum. These forces can cause severe damage to the internal structures without disrupting the skin. With any nonpenetrating trauma to the scrotum or perineum, one must suspect and rule-out injury to the corpus spongiosum and urethra.

DIAGNOSIS

The vast majority of penetrating injuries to the genitalia require surgical exploration, irrigation, a careful search for and removal of foreign-body material, anatomic repair, and drainage (Level of Evidence, LOE 4) (2). With traumatic injuries to the genitalia, the importance of a careful and thorough search for retained foreign body cannot be overstated. Torn and shredded fragments of clothing are commonly found in the wound and if missed can lead to sequelae of poor wound healing and recurrent abscess formation. In our current litigious environment, a missed foreign body following “surgical wound exploration” can be difficult to defend. Because these are often very dirty wounds, at our institute, we prefer the Pulsavac wound irrigation and debridement system to assist with a thorough wash out of the traumatized region.

Penetrating trauma to the genitalia may also involve the urethra. If there is any suspicion of urethral injury, a retrograde urethrogram or cystoscopy should be performed. Saline should be used for irrigation in these cases. Because of the position of the urethra beneath the scrotum and perineum, significant penetrating injuries to the scrotum can also often spare the urethra.

Avulsion injuries of the genital skin most frequently involve the loose hanging scrotal skin. Genital skin avulsion injuries are most commonly seen with either rapid deceleration injuries such as motorcycle accidents, when the rider is thrown over the handlebars and his clothing is caught on various stationary components of the motorcycle handlebars, or related to industrial equipment accidents, when the patient’s clothing becomes entangled in machinery and forcefully ripped away from the body. The loose scrotal tissues ensnare, and as the clothing is ripped off, so is the loose genital skin. These avulsion injuries vary from minimal injuries, which are essentially nothing more than jagged lacerations, to emasculating injuries, which take not only the skin but also the deep structures. Usually, with most scrotal injuries, the testicles are not involved or avulsed. Their mobility and the strength of the tunica albuginea afford the testicles protection. Most avulsion injuries fortunately occur along superficial avascular planes between the scrotal dartos and the external spermatic fascia, taking only the skin and the scrotal dartos fascia/tunica dartos and leaving the underlying Buck fascia of the penis and the external spermatic fascia and tunica vaginalis surrounding the testicle intact. Rarely, the testicle ensnares in the skin and is avulsed. In most cases of avulsion, bleeding is not a problem because the skin and fascia are avulsed in a relatively avascular plane between the fascial structures related to the deep structures and the superficial fascia.

Thermal burns to the genitalia are usually not isolated injuries but reflective of a more extensive area of body burn, as a rule of thumb, exceeding 40% of total body surface area. Genital burns are often seen following entrapment within a burning automobile or the spilling of hot cooking grease during transport. Chemical burns are in general only superficial and involve the skin. Thermal injuries can be deep, but often, even with extensive deep burns proximate to the genitalia, the multiple clothing layers (i.e., underwear and other clothing) afford some degree of protection of the genitalia. Electrical burns disseminate via the deep vascular and neurologic structures, and what may appear to be a minimal burn to the skin and scrotum may have associated significant deep injury, which can be devastating. Usually, however, the deepest burns associated with electrical contact occur at the site of the current inflow and the ground site. These sites are usually not the genitalia. However, it is not uncommon to have thermal burns in concert with electrical burns, as frequently the clothing is ignited by the electrical spark. Thus, with electrical burns, fortunately, if the genitalia are involved, it is usually a more superficial process.

For the most part, genital burns are managed like all other burns with a few exceptions. Debridement of the glans penis should be approached cautiously, and early aggressive, overzealous debridement of the glans penis should be avoided in favor of a wait-and-see approach to allow for demarcation. The abundant vascularity of the glans penis often allows for surprising delayed healing with excellent cosmetic results superior to those obtained from split-thickness skin grafts (STSGs). Urinary catheter insertion for fluid monitoring is almost always required in burn patients. In the case of severe genital burns, a suprapubic cystostomy can be placed in its typical location even if the suprapubic area is badly burned. If a urethral Foley catheter is used for fluid monitoring, it is important to continually reassess the necessity of the urethral Foley and to keep the penis secured to the abdomen in the anatomic position. Pressure from prolonged urethral catheterization of the edematous, compromised genital tissue, especially if the catheter is positioned in the customary dependent position and secured to the leg can result on pressure necrosis of the ventral urethra and urethral-cutaneous fistula (Fig. 63.3 Fig. 63.4 Fig. 63.5).

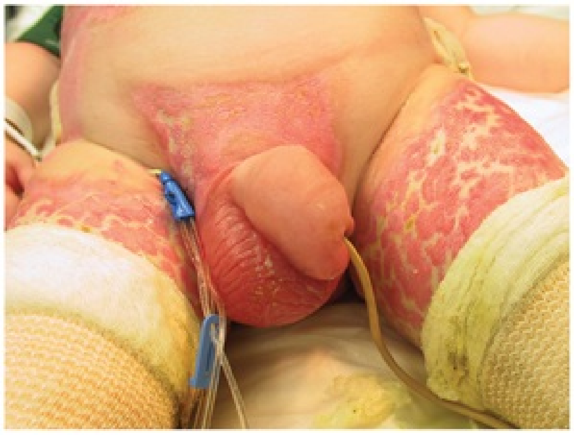

FIGURE 63.3 Second and third degree burns to the genitalia, with significant edema of the penile shaft skin. The utilization of a foley catheter with genital burns should continually be reassessed for removal after 48 to 72 hours or for conversion to suprapubic cystostomy to avoid urethral-cutaneous fistula.

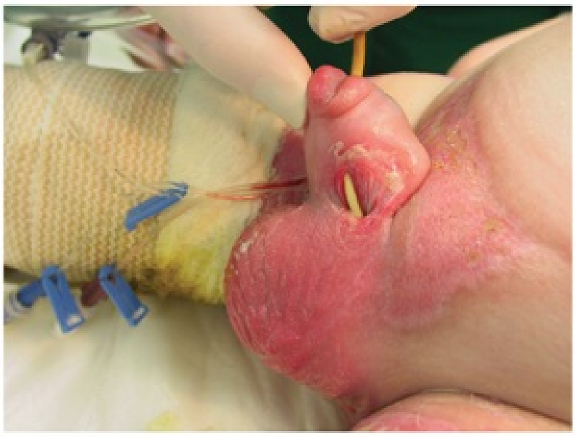

FIGURE 63.4 Urethral-cutaneos fistula as a result of second and third degree genital burns, to prevent this complication the use of urethral foley catheters should continually be reassessed after 48 to 72 hours with conversion to suprapubic cystotomy if longer periods of catheterization are necessary.

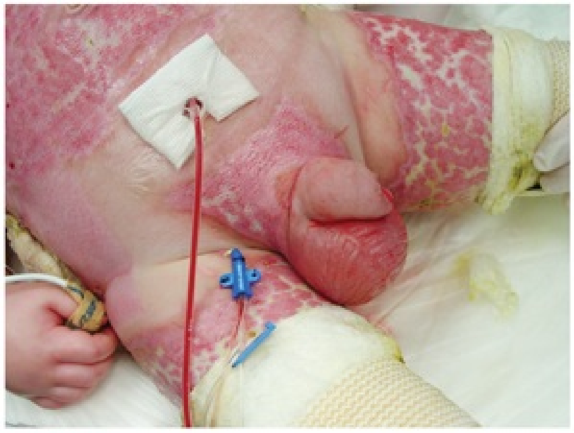

FIGURE 63.5 Suprapubic cystostostomy placed after urethral-cutaneous fistula due to second and third degree general burns.

Radiation injuries to the genitalia can occur either from direct exposure to the genitalia or from delayed effects of the radiation on the venous and lymphatic drainage. Complications of direct radiation injury to the genitalia are now uncommon, as radiation for penile lesions is rarely undertaken. The secondary effects of radiation, as seen in the scrotum, are usually manifested by chronic lymphedema, lymphangiectasia, and, in some cases, chronic recurring cellulitis.

To this list of traumas must be added the patient who has required significant debridement because of rapidly progressive, multiorganism fasciitis (Fournier gangrene). Fournier gangrene is often seen with processes of the anus or rectum, such as perianal abscess. Likewise, processes involving the urethra, such as urethral stricture with periurethral abscess, can accompany Fournier gangrene. Fournier gangrene is often associated with other comorbidities, such as diabetes mellitus and alcoholism. Given this multifactorial etiology, the associated comorbidities, and the rapid spread, these patients are best managed with a multispecialty approach involving urologists, general surgeons, and intensive/critical care specialist.

The necrotizing process can progress rapidly in a matter of only a few hours. Additionally, many of these patients present late; hence, aggressive and extensive surgical debridement (LOE 2) is required and can be lifesaving. At our institute, we take a more aggressive initial approach to debriding the necrotic tissue associated with necrotizing fasciitis than we do for burn patients. This aggressive debridement of necrotic tissue usually leaves a significant defect for the surgeon to reconstruct after the acute process is controlled (2). If the fasciitis is associated with pathophysiology of the urethra (i.e., stricture with perforation, extravasation, and abscess) and/or anus, then these situations must be managed and resolved before reconstruction (3). Urinary diversion in the form of a suprapubic cystostomy and fecal diversion via a colostomy are commonly required in management of the acute process. Recently, there have been descriptions of the use of unprocessed honey to augment or provide an alternative treatment to wide surgical excision. Honey apparently contains antimicrobial agents and enzymes to digest necrotic tissue as well as to promote epithelial growth (4).

Also, in recent years, we have seen several patients who have attempted to enhance the size and bulk of their genitalia with the injection of lipid-containing substances such as paraffin or petroleum jelly or inert substances such as silicone. In these cases, one is often confronted with a fulminant cellulitis that must be treated with broad-spectrum antibiotics. Later, one sees a sclerosing granulomatous process that can be troubling to the patients. In some cases, the skin must be excised along with the deeper involved structures, but it is not unusual to be able to excise the deep process and leave the skin that survives either on its random dermal blood supply or, in some cases, on the tunica dartos fasciocutaneous blood supply.

A contusion of the scrotum, that is, a scrotal hematoma, can be confused with a fracture of the testicle. The latter injury implies disruption of the tunica albuginea of the testicle. With a scrotal contusion, the hematoma usually is noted to be posterior and lateral to the testicle (Fig. 63.6), whereas with fracture of the testicle the parenchyma of the testis is not normal and is often associated with a hematocele if the visceral tunica vaginalis remains intact (Fig. 63.7). Physical examination remains the cornerstone in the diagnosis of blunt testicular trauma. However, the use of ultrasonography in the diagnosis of testicular trauma can be helpful in situations when the physical examination is difficult to perform or interpret. Ultrasonography is the most sensitive and specific imaging technique, with heterogeneity of the parenchyma of the testicle suggestive of testicular rupture (LOE 2) (2). In the presence of penetrating trauma to the genitalia, a cystoscopic evaluation or retrograde urethrogram is always indicated because of the close proximity to the urethra. In all cases of genital avulsion, other than a simple scrotal avulsion, a complete evaluation of the urethra must be done, along with a rectal examination and possibly flexible sigmoidoscopy.

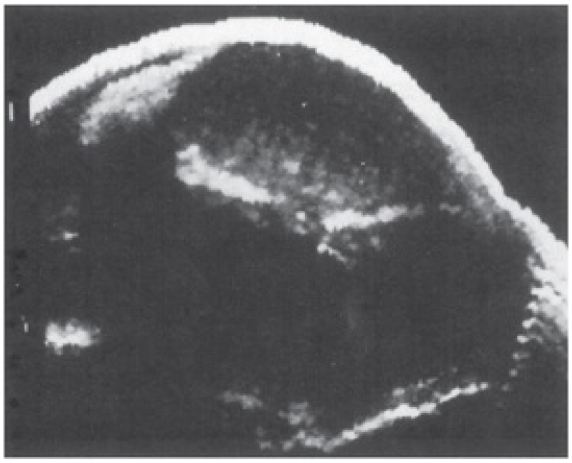

FIGURE 63.6 B-scan ultrasound demonstrating the classic distribution of a scrotal contusion (scrotal wall hematoma). Note the testis displaced anteriorly, with the hematoma contained in the multiple fascial layers of the scrotum.

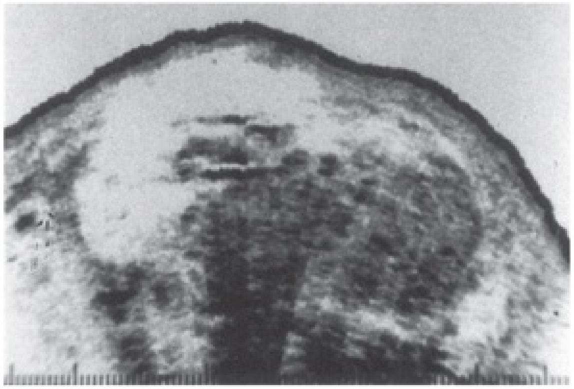

FIGURE 63.7 B-scan ultrasound of a patient with a fracture of the testicle. Note the disrupted parenchymal pattern of the testicle, the hematocele, and the demonstration of extruded seminiferous tubules within the hematocele.

INDICATIONS FOR SURGERY

Exploration of the scrotum is indicated if the patient has sustained either blunt or penetrating injury to the testicle (LOE 3) (2). Scrotal reconstruction is required following complex lacerations and avulsion injuries. If a patient has required excision for chronic cellulitis, lymphangiectasia, and lymphedema, STSG reconstruction of the scrotum is very effective and provides cosmetically very acceptable results. Meshing STSGs used for scrotal reconstruction allows for increased coverage, drainage of potential hematoma, and seroma accumulations, and the meshed graft mimics the natural rugae of the scrotum after it has healed. If the lymphedematous process is due to a local process, often the lateral scrotum and the posterior scrotum are spared from disease and uninvolved because the posterior scrotum is drained by the perirectal lymphatics. In these cases, lateral scrotal flap reconstruction is often very effectively employed.

If, however, the process causing the scrotal lymphedema is “systemic” (i.e., Charles disease, secondary to pelvic irradiation, etc.), then STSG reconstruction is always the best approach(5). Thicker grafts (0.016 to 0.02 inch) transport more collagen and elastin fibers and generally provide for superior elasticity and better cosmetic results. One word of caution, the lymphatics of the skin are carried in the reticular dermis (the deep layer of the dermis). So if a thick STSG is used to reconstruct the genitalia, in cases where the etiology of the scrotal lymphedema is systemic, then lymphedema can significantly recur in the graft. Therefore, for genital lymphedema secondary to systemic etiology, a thinner STSG (0.012 to 0.014 inch) is preferable. One must also be careful of the patient with scrotal lymphedema without “involvement of the penile skin”; following scrotal reconstruction, often the penile skin becomes edematous. Following burn injury to the genitalia, almost always graft reconstruction can be undertaken, and it offers extremely good functional and cosmetic results.

ALTERNATIVE THERAPY

Contusions of the scrotum are usually treated with bedrest, ice packs, analgesia, and scrotal elevation. Scrotal elevation can be accomplished very efficiently with a Bellevue-style (a taped suspensory dressing to elevate the scrotum) bridge or with scrotal support.

SURGICAL TECHNIQUE

Scrotal Hematomas and Blunt Testicular Injury

There is little to be accomplished in exploring the scrotal hematoma secondary to external blunt trauma, as the hematoma is usually disseminated throughout the highly elastic layers of the scrotum and does not form a drainable hematoma per se (1). On the other hand, if there is a testicular injury, exploration and repair of the testicle is indicated (Fig. 63.8). Exploration consists of exposure of the testicle. The space of the tunica vaginalis is opened; the hematocele is drained; the exposed, necrotic, seminiferous tubules are debrided; and the tunica albuginea is closed. The remaining viable testicular tissue should be salvaged for endocrine function and psychological impact (LOE 2) (2). A 3-0 or 4-0 polydioxanone or Monocryl suture is easy to handle, glides smoothly through the tissues without dragging and gathering the tissue, and performs well for repairing the tunica albuginea. The tunica albuginea is tough and fibrous, an RB-1 or SH needle works well for its closure. The parietal tunica vaginalis is left open and is reflected in typical bottleneck fashion as is done for a hydrocele repair. The scrotum is drained, and the skin closed with 3-0 polyglycolic acid (PGA) suture, chromic suture, or Monocryl. Alternatively, in cases of testicular fracture secondary to either blunt or penetrating injury, if the defect in the tunica albuginea is too large to allow for primary closure, one can cover the defect with a tunica vaginalis graft or island flap.

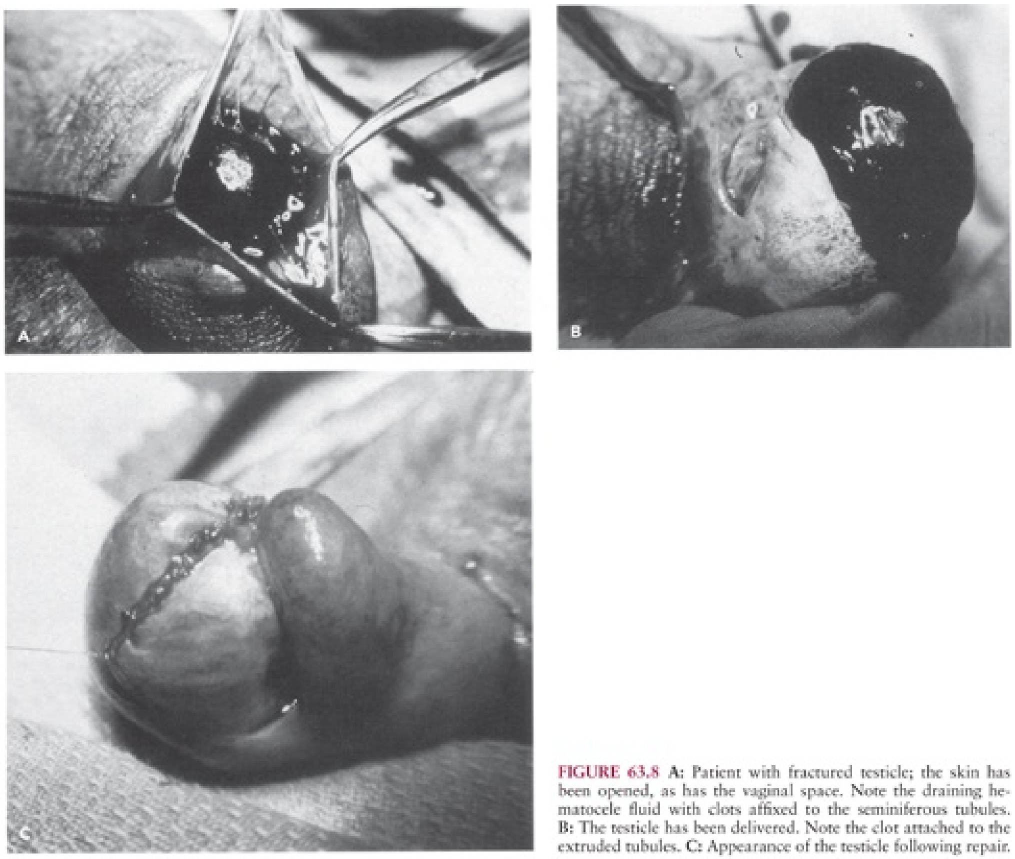

FIGURE 63.8 **A:** Patient with fractured testicle; the skin has been opened, as has the vaginal space. Note the draining hematocele fluid with clots affixed to the seminiferous tubules. **B:** The testicle has been delivered. Note the clot attached to the extruded tubules. **C:** Appearance of the testicle following repair.

Penetrating Injuries to the Genitalia

Penetrating injuries have been subclassified as either simple or complicated. By and large, complicated injuries imply urethral involvement, amputation, or near-total amputation, and with regard to the scrotum, they imply amputation of or injury to the testicle, with or without amputation of the overlying scrotal skin (Fig. 63.9). Simple lacerations are managed with thorough washout, primary closure, and drainage if indicated. In the case of amputation of the testicles, testicular microreplantation has been performed in high-volume academic centers, including vasovasostomy, along with reapproximation of the vasculature of the spermatic cord (Fig. 63.10). The testicle is placed, as quickly as possible, in a sterile bag in saline-soaked gauze, and that bag is placed in a second bag filled with saline slush for cold preservation. Unlike amputation of the penis, where successful replantation has been done as long as 18 to 24 hours from the injury, the testicle must be replanted by 6 to 8 hours due to the very high metabolic rate of the testicular tissue.

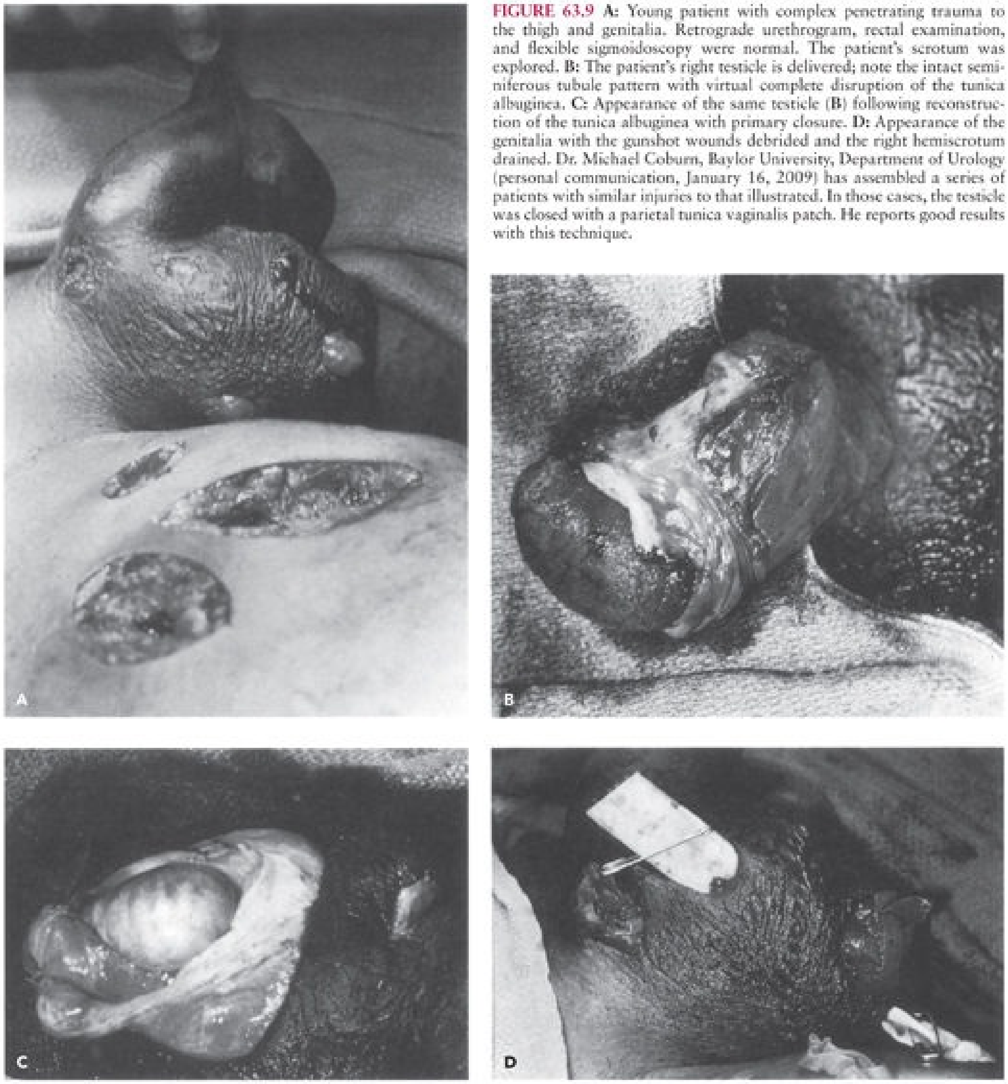

FIGURE 63.9 **A:** Young patient with complex penetrating trauma to the thigh and genitalia. Retrograde urethrogram, rectal examination, and flexible sigmoidoscopy were normal. The patient's scrotum was explored. **B:** The patient's right testicle is delivered; note the intact seminiferous tubule pattern with virtual complete disruption of the tunica albuginea. **C:** Appearance of the same testicle (**B**) following reconstruction of the tunica albuginea with primary closure. **D:** Appearance of the genitalia with the gunshot wounds debrided and the right hemiscrotum drained. Dr. Michael Coburn, Baylor University, Department of Urology (personal communication, January 16, 2009) has assembled a series of patients with similar injuries to that illustrated. In those cases, the testicle was closed with a parietal tunica vaginalis patch. He reports good results with this technique.

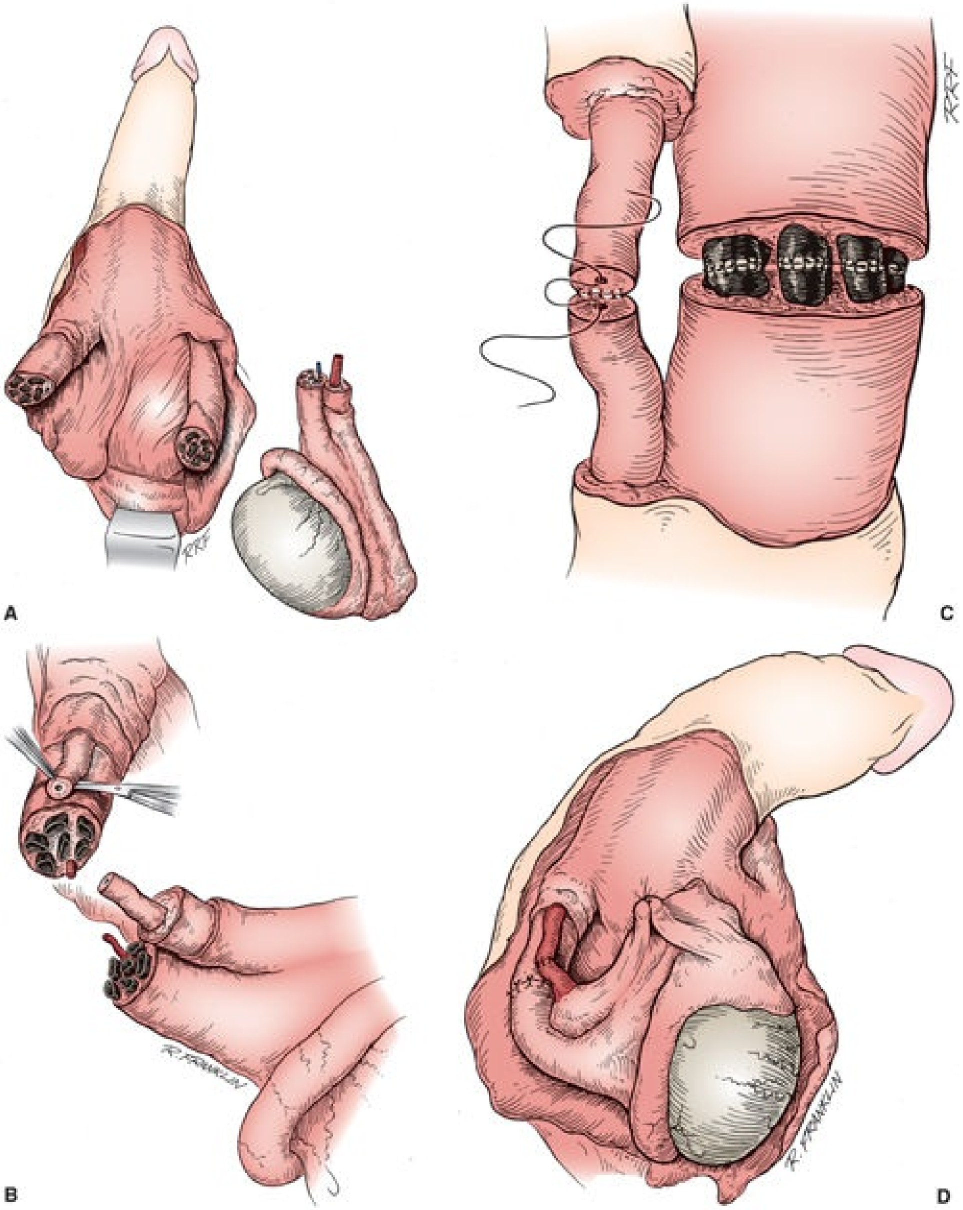

FIGURE 63.10 **A:** Appearance of a patient following bilateral testicular amputation and scrotal amputation. The patient presented with only his right testicle. The left testicle could not be found at the trauma scene. **B:** The right testicle is reanastomosed to the left (longer) spermatic cord. **C:** Note the appearance of the debrided spermatic cord and the debrided distal spermatic cord going to the testicle. Vasovasostomy was performed with a two-layer microscopic technique. Microscopic coaptation of the spermatic artery and multiple spermatic veins was performed. **D:** Appearance of the replanted testicle before closure of the scrotum.

In cases where the amputated testicle is traumatically avulsed and forcefully ripped away from the body, replantation is not an option. During the avulsion injury, the vasculature is stretched before giving way to the force, the anatomic structures are torn and ragged, and the endothelial damage can be significant and unpredictable.

Even with clean-cut amputations, there can be some difficulty in identifying the vessels in the spermatic cord, although they are somewhat compartmentalized. Identifying the artery proximally is not too difficult, and identification of the distal artery in the severed organ can be aided by examining the relationship of the compartments to the vas deferens. Coaptation of the artery and a number of veins is optimal using 9-0 or 10-0 Prolene, depending on the size of the respective vessels. Vasovasostomy can be done using 9-0 or 10-0 Prolene or nylon sutures, either with a classic microscopic two-layer technique or a single-layer “tricorner” technique, depending on the surgeon’s preference.

The replanted testicle should not be covered with a skin graft because an unsuccessful replantation will result in necrosis and infection, thereby leading to graft failure. The replanted testicle should either placed in a thigh pouch for possible later liberation or, if there is some remaining redundancy of the scrotum, covered primarily with reapproximation of the remaining scrotal tissues. Alternatively, we have left the replanted testicle out and dressed it with wet-to-dry saline gauze; this allows for easy visual inspection and Doppler examination in the crucial few days following the replantation. If left out, we secure the testicle to a nearby structure (i.e., inner thigh, scrotal wall, etc.) to prevent torsion.

Obviously, if the patient arrives without his amputated testicle, then hemostasis must be ensured. Usually, the vessels are in spasm, but they clearly can come out of spasm later. The wound should be thoroughly irrigated and, if contaminated, packed initially and later closed by secondary intention. If the wound is clean, then primary closure or primary grafting can be performed.

Avulsion Injuries

Small scrotal avulsions are managed as simple lacerations with either primary or delayed closure and drainage, as would be indicated for any laceration (LOE 3; Fig. 63.11) (2). The scrotum is very forgiving, so that in cases of primary closure, "loose" reapproximation can be performed to allow for better drainage without compromising cosmetic results. For larger injuries, many experts recommend a delayed approach, allowing time for complete demarcation (Fig. 63.12). The area of the avulsed scrotum should be managed with cold saline packs and observed over 12 to 24 hours. Clear demarcation will occur and allow the surgeon to debride only the tissue that is nonviable. Debridement with closure is then performed (LOE 3) (2). Although allowing time for demarcation is clearly sound surgical principle and works well in patients of Caucasian descent, in reality, our institute is an inner-city facility treating primarily minorities of African descent with dark skin pigmentation. Hence, nonviable skin edges remain difficult to discern even with delayed management. The loose, viscoelastic scrotal skin is forgiving, and usually, primary closure can be accomplished even with substantial skin loss up to 60%. Postoperatively, the testicles should be kept in the dependent position so as to serve as natural tissue expanders during the healing process, thereby resulting in excellent final cosmesis.

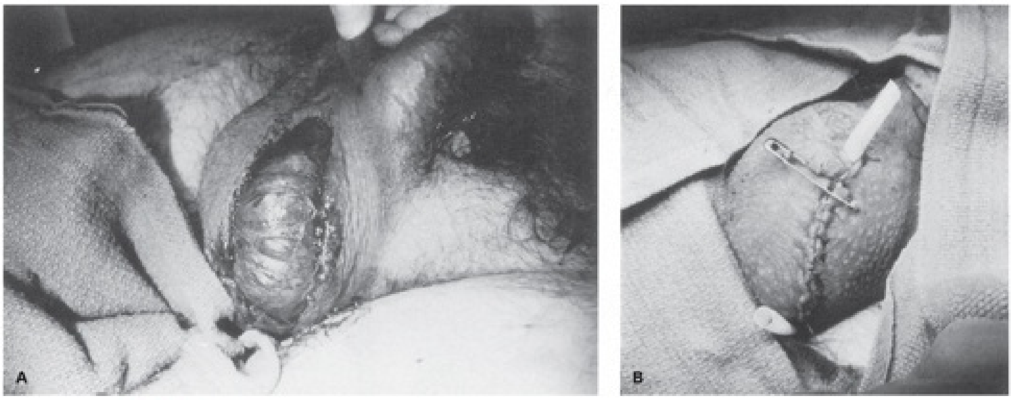

FIGURE 63.11 **A:** Appearance of a left scrotal avulsion injury. The patient was injured in a motorcycle accident in which his trousers were ripped off as he departed the motorcycle. **B:** Appearance after closure. Primary closure is performed with drainage.

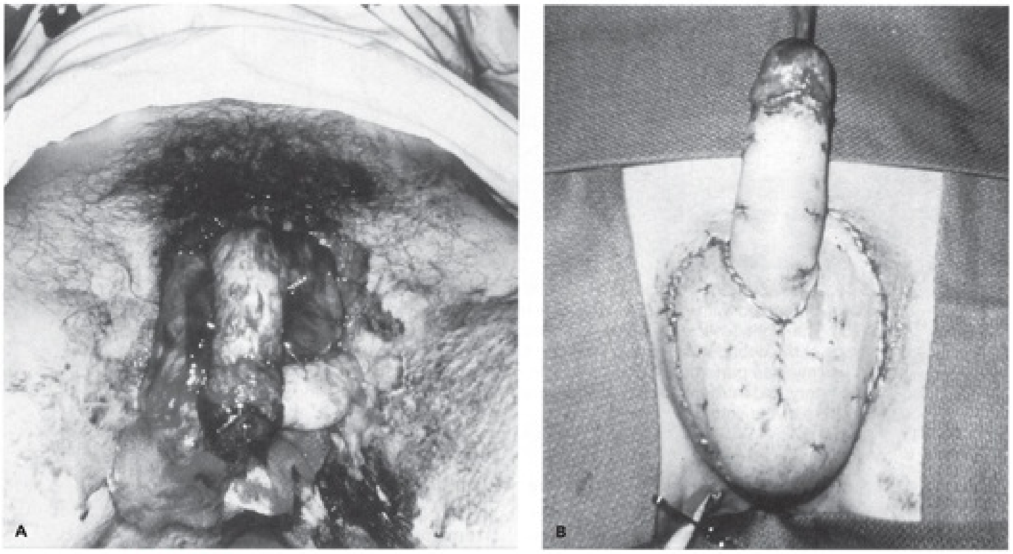

FIGURE 63.12 **A:** Large avulsion injury of the genitalia. The patient was injured when his clothing was ensnared in the power takeoff mechanism of a tractor. Note the exposed shaft of the penis and the exposed testicles bilaterally. **B:** The appearance after reconstruction with an STSG. The patient was observed for 24 hours, allowing the wounds to demarcate. In this case, both the shaft of the penis and the scrotum were reconstructed with a sheet STSG.

If a primary closure cannot be accomplished with the remaining scrotal tissue, then the surgeon has several options. One option is to place the testicles in thigh pouches to be later liberated and replaced to the area of the scrotum. The preferable option is to perform a primary reconstruction of the scrotum using a contiguous, meshed, STSG. Air-driven dermatomes work best for STSG harvest, and either 2- or 3-inch wide blades perform the best. The graft should be harvested 0.016 to 0.020 inch thick (thicker STSGs minimize contracture by transporting more collagen and elastin and generally provide for better cosmetic results, except in the case of lymphedema secondary to systemic disease, that is, “Charles disease,” secondary to pelvic irradiation in which case a thin graft 0.012 to 0.014 inch is preferable) and then meshed to a 1.5- to 1.0-inch or a 1:1 ratio. The testicles must be sutured together and fixed in midline position using permanent suture or absorbable suture that is slowly absorbed so that they do not migrate beneath the graft. Likewise, in cases of Fournier gangrene, where the testicles are left exposed and grafting may be delayed for 7 to 10 days, it is very important to suture the exposed testicles together to prevent torsion during the dressing changes. The meshing of the graft will increase its surface area, allow for escape of serum and blood products from beneath the graft, allow the graft to configure better to the complex contours of the underlying testicles, and provide a final cosmetic result resembling the natural scrotal rugation. When applying the skin graft, 4-0 or 5-0 chromic suture is preferable. To avoid lifting the graft off of its bed, one should start suturing by first passing the suture through the graft. That is, suture from graft to the skin edge or deep tissue. This will peg the graft into place and make suturing easier by preventing the graft from being lifted off of its bed. The sutures should be placed through the skin tissue bridges of a meshed graft and not through the holes in the meshed graft. For best results, sutures should be placed 0.5 cm to 1 cm apart. The tunica vaginalis space can be left open, and the graft is then applied immediately to the tunica albuginea of the testicles, suturing it to the surrounding skin, or closed. It is our personal opinion that the graft takes better and the cosmetic results are superior in cases where the tunica vaginalis can be preserved and the graft applied to the tunica vaginalis rather than the tunica albuginea. As is typical in reconstructive surgery, we learn to work with whatever healthy tissue we have remaining. It is the opinion of some authors that grafting directly on the visceral tunica vaginalis or tunica albuginea can lead to a situation where there is chronic testicular pain. In order to avoid this complication, when suturing the testicles together, it is important to take superficial bites of the cremaster fibers and avoid deep bites which could incorporate nerves. This has not been the author’s (GHJ) experience. Unless the wound is markedly contaminated, cases so managed have yielded very successful results.

In cases of genital grafts, the dressing is of utmost importance. The grafts should be bolstered using Xeroform gauze or one of the other commercially available fine-meshed gauzes applied directly to the graft, with Dacron batting soaked in mineral oil placed over the finely meshed gauze. Lately, we have favored the use of the high-density polyethylene sheeting (N-TERFACE, Winfield Laboratories, Inc, Richardson, Texas) to prevent adherence and subsequent graft displacement with bolster removal. The bolster is held in place with 4-0 chromic sutures. Unless there is an associated urethral injury, the patient can be “diverted” with a soft Foley catheter. In patients in whom the avulsion injury extends near to the anus, colostomy may be required to prevent wound soilage. It must be emphasized that local skin flaps are not recommended for primary closure in these cases.

In patients in whom the avulsion injury is tantamount to emasculation, these injuries are often associated with significant injuries to the adjacent tissue. Reconstruction assumes a very secondary position, as these patients require lifesaving steps. The vast majority of these patients will require colostomy, suprapubic cystostomy, and multiple dressing changes over the posttrauma course, and they often present with significant bleeding.

In general, the scrotal skin is highly distensible, and even a small fragment can be expanded to cover a large defect with a good functional result because the testicles serve as natural tissue expanders. Even in cases where 60% of the scrotal tissue is lost, primary reapproximation can still be performed. There has been concern regarding the effect of implantation of the testes in thigh pockets on spermatogenesis, although there are few clinical data to support this concern. When performing testicular thigh pouches, a large enough space deep to the subcutaneous fat and superficial to the fascia lata of the thigh should be created so that a standard surgical lap pad can easily fit into this space. A slightly anterior position for testicular placement is preferable. If placed too posteriorly, the patient tends to sit on the testicles, and because many patients requiring testicular thigh pouches are obese, diabetic patients with Fournier gangrene, if placed too medial, the testicles can rub together during ambulation. Hence, we prefer a slightly anterior placement.

Genital Burns

The emergency therapy of genital burns is similar to that for any burn. The scrotum can be dressed, open, with topical antibiotic ointments such as Silvadene, or a closed antibiotic dressing regimen can be used. The integrity of the urethra must be determined when the patient presents. A Foley catheter can be placed in the patient who has burns to his genitalia. If there is evidence of urethral burn, then most would suggest diversion with suprapubic cystostomy. If the burns to the genital and perineal area are extensive, then an occasional patient will require colostomy. If the subscrotal urethra is involved in the burn, no attempt at initial reconstruction should be made. In the case of the infant or young male, the move to a suprapubic tube should be made quickly if the need for a urethral catheter is at all prolonged.

In the case of severe genital burns, a suprapubic cystostomy can be placed in its typical location even if the suprapubic area is also badly burned. If a urethral Foley catheter is used, it is important to continually reassess the necessity of the urethral Foley and to keep the penis secured to the abdomen in the anatomic position. Pressure from prolonged urethral catheterization of the edematous, compromised genital tissue, especially when the catheter is positioned in the customary dependent position and secured to the leg can result in pressure necrosis of the ventral urethra and urethral-cutaneous fistula. If the urethra is involved, either from the initial burn or as a result of delayed pressure necrosis, the urine is best diverted through a suprapubic cystostomy and urethral reconstruction delayed.

The genital tissues are remarkably vascular. Debridement of the genitalia, in general, should be accomplished carefully. Aggressive debridement should be avoided, as many of the tissues will recover and are nonreproducible. Whirlpools and tank soaks are useful for gentle debridement and cleansing, and they may be done early on, two to three times per day.

Chemical burns rarely involve the structures deep to the skin and are managed with copious irrigation and then as with a thermal burn (LOE 4). If a patient has evidence of an electrical burn to the area of the genitalia, the patient must be observed for 12 to 24 hours and then explored. In electrical burns, the initial management is aimed at debridement, and reconstruction can be offered later as the situation dictates (Fig. 63.13).

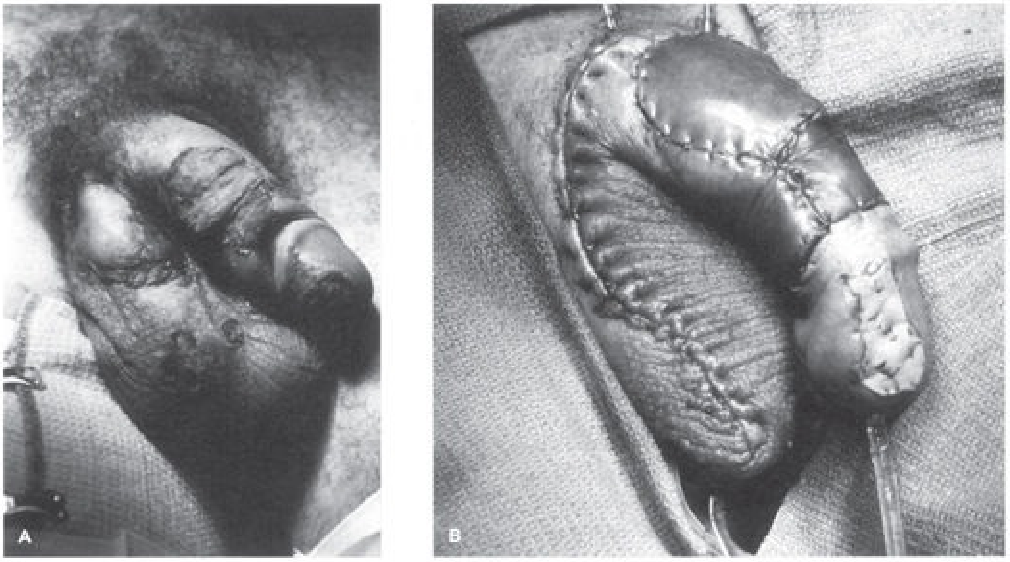

FIGURE 63.13 **A:** The appearance of the genitalia in a patient who was burned in a steam-line accident. Note the burns to the glans, the dorsum of the shaft of the penis, and the right hemiscrotum. **B:** In this particular case, reconstruction of the glans was accomplished with a small STSG. Reconstruction of the shaft of the penis was accomplished with a penile skin island flap; the patient was uncircumcised, and the ventral skin was mobilized to the dorsum. The scrotal burn was completely excised, and primary reconstruction of the right hemiscrotum was accomplished. This particular patient demonstrates all of the possibilities for reconstruction following burn debridement.

Radiation Injuries

In the case of scrotal lymphedema and recurrent cellulitis, all layers of the scrotum should be excised to the level of the external spermatic fascia (Fig. 63.14). It is not uncommon for the patient also to have large hydroceles due to lymphatic occlusion (5).

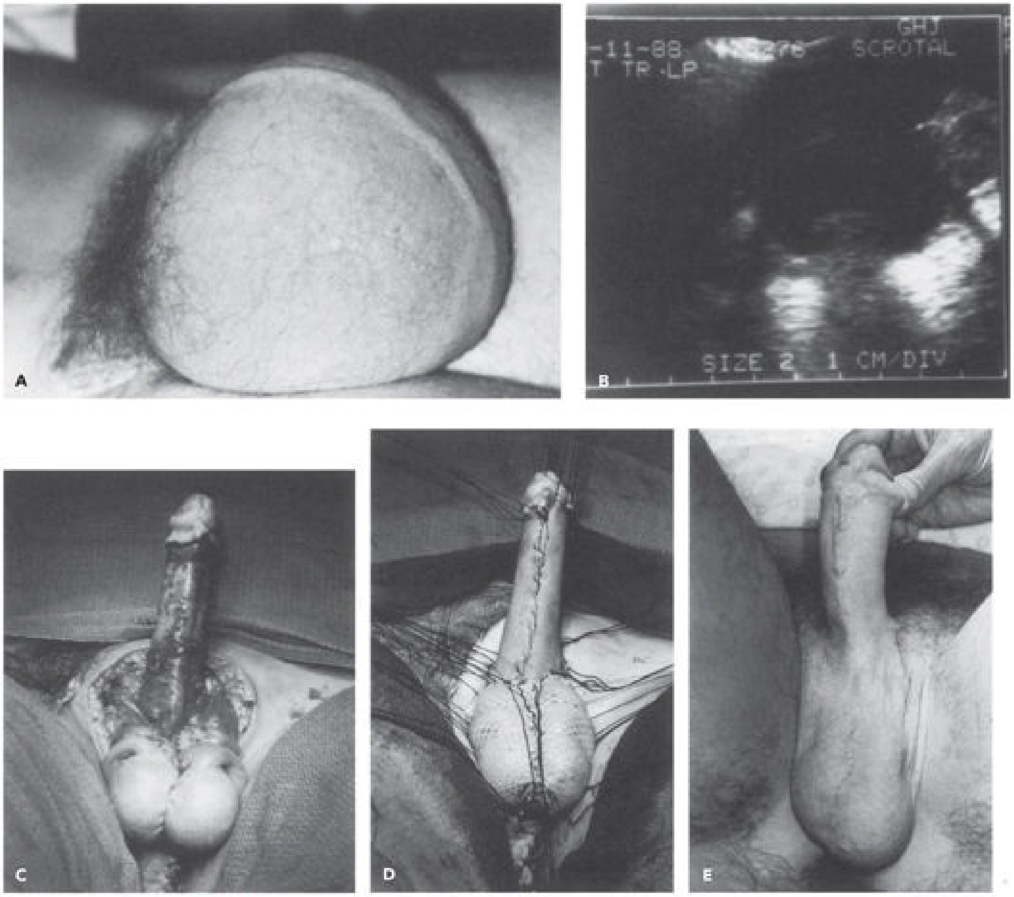

FIGURE 63.14 Appearance of a young man with chronic genital lymphedema following irradiation therapy for Hodgkin lymphoma. **A:** Appearance of the massively lymphedematous scrotum. **B:** B-scan ultrasound demonstrating the large hydrocele. Note the normal testis posteriorly. **C:** Appearance of the genitalia after debridement of the lymphedematous tissue. Note that orchidopexy has been performed. **D:** Immediate appearance following reconstruction of the shaft of the penis with an STSG and reconstruction of the scrotum with a meshed STSG. **E:** Appearance of that same patient 6 months postoperatively. Note the small amount of residual lymphedema of the preputial cuff. Further note the redundant appearance of the scrotal graft.

The tunica vaginalis space should be opened and the parietal tunica vaginalis then reflected and incorporated in the orchidopexy. Reconstruction can be accomplished, using a thin STSG (0.012 to 0.014 inch thick), as already discussed, and on the scrotum, these grafts can be meshed as discussed earlier. In addition, the meshing seems to improve the cosmetic result by giving the appearance of the normal scrotal rugations (6). Full-thickness skin grafts should not be used. The cosmetic results achieved in these patients, so reconstructed, are excellent. The use of lateral scrotal flaps as mentioned previously is worthy of consideration in properly selected patients (Fig. 63.15). Radiated patients in general are not candidates because the problem is with the “systemic” lymphatic drainage and not just the lymphatics of the skin per se.

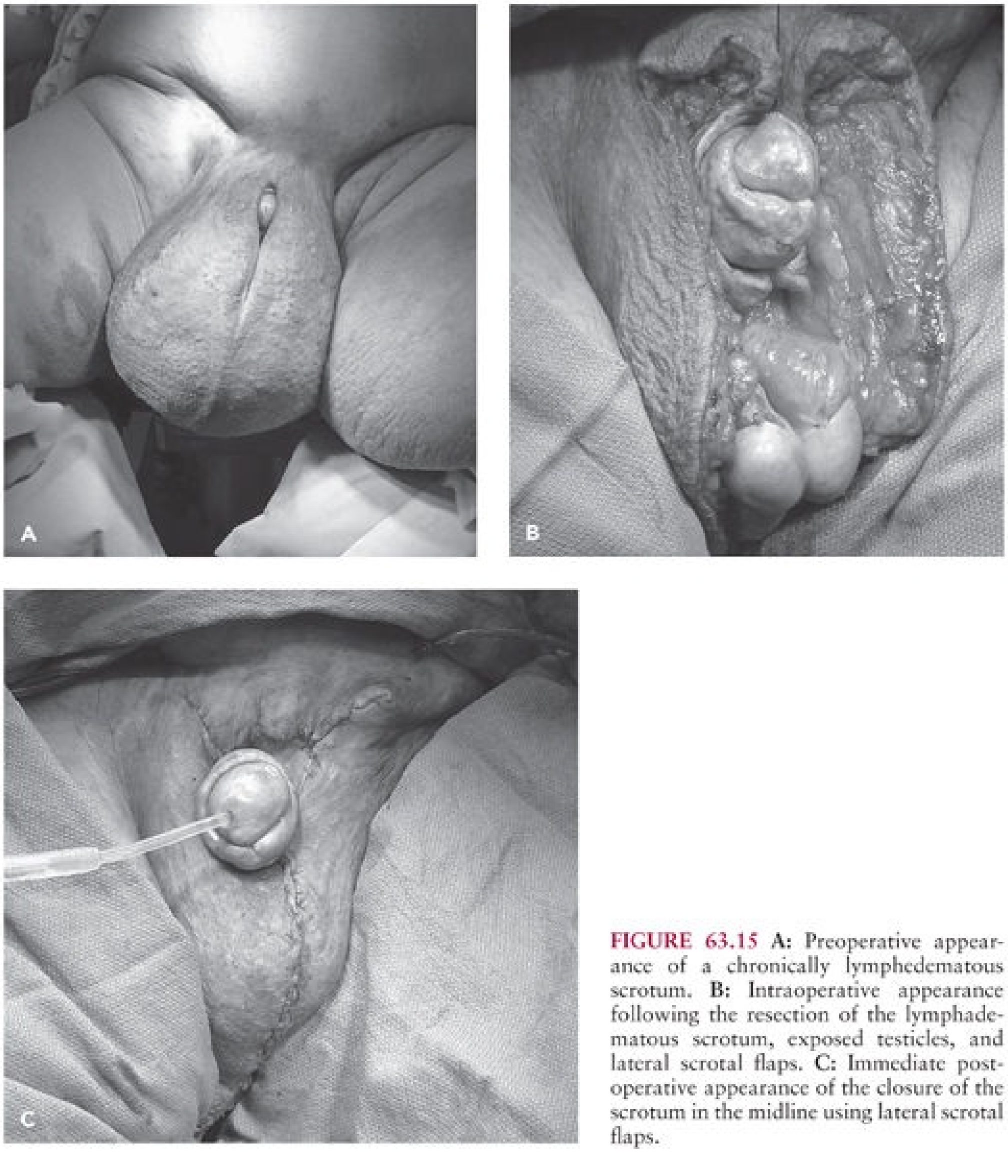

FIGURE 63.15 **A:** Preoperative appearance of a chronically lymphedematous scrotum. **B:** Intraoperative appearance following the resection of the lymphadematous scrotum, exposed testicles, and lateral scrotal flaps. **C:** Immediate postoperative appearance of the closure of the scrotum in the midline using lateral scrotal flaps.

Fournier Gangrene

If the primary process has resulted in extensive debridement of the scrotum, the testicles can be placed in thigh pouches with the intention of later replacing the testicles in their normal anatomic area and for scrotal reconstruction. The author's (GHJ) preferred approach was described by McDougal and Persley (7) and is illustrated in Figure 63.16. The lateral defects on the thigh can often be closed primarily or can be grafted (7,8).

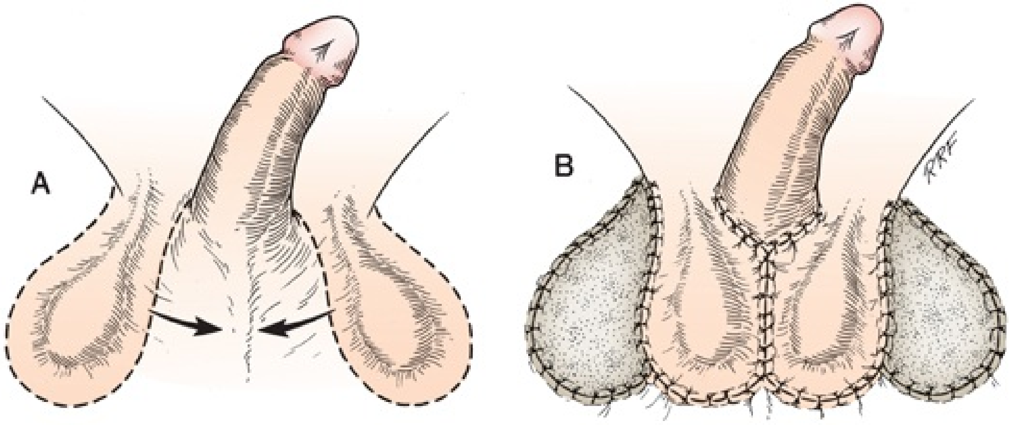

FIGURE 63.16 Technique after McDougal for liberation of testicles that have been placed in thigh pouches. Note that the testicles are mobilized with random thigh skin flaps and transposed to the midline to reconstruct the scrotum. The lateral defects can be closed per primam or can be grafted. The *arrows* indicate medial rotation of lateral thigh flaps after liberation of the testicles from thigh pouches.

For most patients, however, the scrotal excisions do not necessitate placing the testicles in thigh pouches, but instead they can be dressed in the wound (9). These patients often require multiple dressing changes and wet-to-dry debridements. These techniques can be used in combination with negative pressure dressings or vacuum-assisted closure (VAC) devices to reduce the defect size more quickly, although it can be difficult to obtain a good seal when using vacuum-assisted devices on the scrotum or testicles and the negative pressure can cause testicular pain. When reconstruction is undertaken, the testicles must be fixed in their normal anatomic position. It is our custom to open the parietal tunica vaginalis and reflect it, and, as already described, graft techniques can be utilized to restore the scrotum. Although local flaps can be used, the cosmetic results achieved with local flaps are usually less than optimal in most of these circumstances when compared to reconstruction techniques utilizing STSGs. Interestingly, these mesh STSGs not only remain supple but in many cases (as has been shown) will actually become redundant because the testicles themselves serve as natural tissue expanders.

OUTCOMES

Complications

Complications of scrotal trauma and reconstruction are primarily related to inadequate appreciation of the degree of injury with subsequent necrosis of additional skin. It is important for the surgeon to adequately debride the devitalized skin, which may require more than one trip to the operating room. The failure of a skin graft to take is usually a result of technical errors, infection, the accumulation of fluid under the graft, an inadequately prepared poor graft bed, or sheering forces with continual slippage of the graft over the bed, which does not allow capillary ingrowth. In order to prevent these complications, we perform proper and thorough debridement and preparation of the graft bed, provide appropriate antibiotic coverage, mesh the graft at a 1:1 ratio, utilize a sufficient number of suture to contour the graft and secure the graft into place, and apply bolster dressing, additionally weeks our patients on bedrest for 5 days postoperatively in order to to protect against graft loss secondary to motion and sheering forces.

Results

As with most surgical conditions, prompt diagnosis and management of acute testicular injuries is paramount to maintaining testicular function. Burns, avulsion, and radiation injuries require aggressive debridement of devitalized tissue to minimize infection and to prepare a healthy graft bed. Reconstruction of the scrotal skin, most often performed with meshed STSG, offers excellent graft take and survival with acceptable cosmetic results in closing the resultant defect.

SECTION VI ■ PENIS AND SCROTUM

Section Editor: RAMÓN VIRASORO

CHAPTER 64 ■ PENILE AND SCROTAL ANATOMY

JONATHAN N. WARNER AND RICHARD A. SANTUCCI

PENILE ANATOMY

Structure

The penis is composed of the corpus spongiosum, the paired corpora cavernosa, and the glans penis (Fig. 64.1). Each of the three corporal bodies is attached to the pelvis. First, the paired crura of the corpora cavernosa are firmly adherent to the inferior edge of the pubic arch. These dense fibrous chambers extend distally until the level of the pubic symphysis, where the two crura join at the penile hilum to form the dorsal aspect of the pendulous portion of the penis.

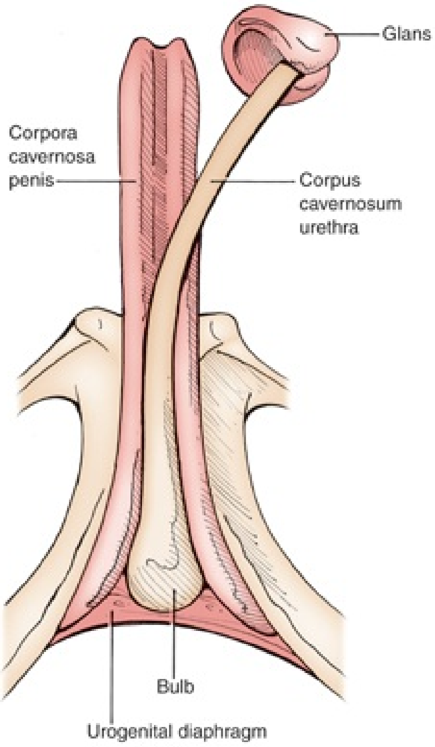

FIGURE 64.1 Anatomy of the three corporal bodies comprising the penis.

The corpus spongiosum begins proximally as the dilated bulb and then tapers to join the ventral side of the corpora cavernosa at the hilum, completing the pendulous portion of the penis. Proximally, the bulb is adherent to the central tendon, securing it to the perineal body. The bulb can be accessed through a perineal incision as in artificial urinary sphincters, male slings, and bulbar urethroplasties (Fig. 64.2). Distally, the spongiosum dilates into the glans penis, which covers the tips of the corpora cavernosa completing the glans portion of the penis. The most proximal part dilates circumferentially forming the corona of the glans. Each of the three chambers has its own blood supply and can be dissected from the other for complex epispadias repair (Fig. 64.3).

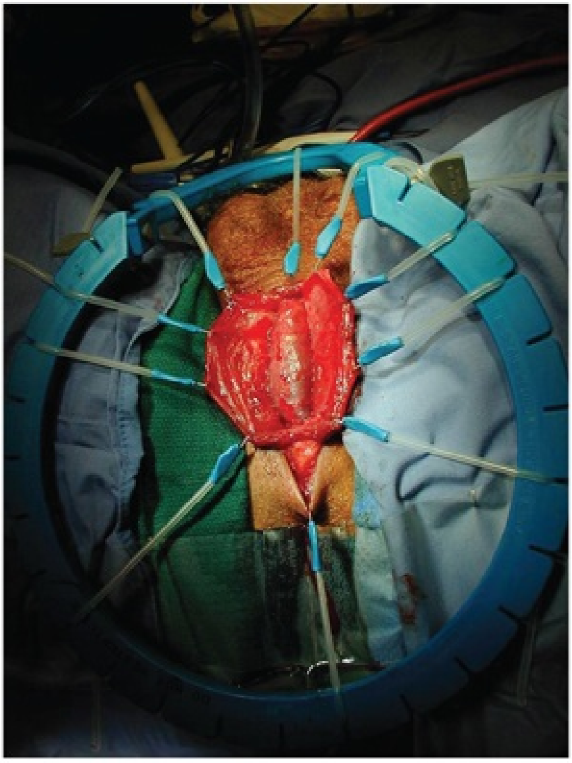

FIGURE 64.2 Perineal dissection showing the bulbar urethra, note the dissected and split bulbocavernosus (bulbospongiosus) muscle.

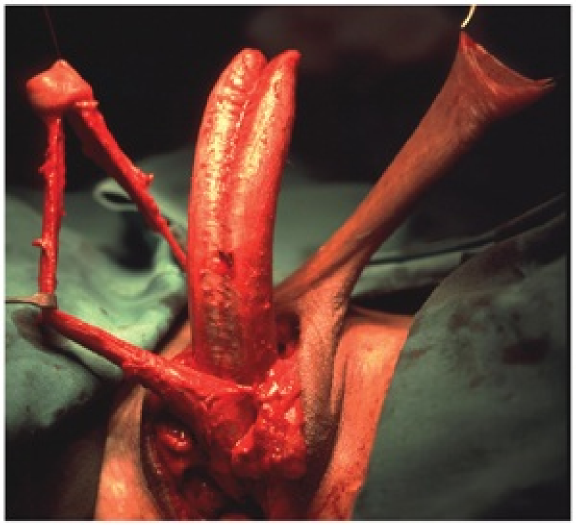

FIGURE 64.3 Complete penile disassembly during a complex epispadius repair. This highlights the completely separate blood supply of (a) each corpora, (b) skin, and (c) corpora spongiosum (including urethra and glans cap). (Photo courtesy of Dr. Miro Djordjevic.)

The outer layer of each corpora is called the tunica albuginea. The tunica of the cavernosa is a dense two-layered fibrous structure. The paired cavernosa share a common outer longitudinal sheath and an inner circular sheath that is only shared at the medial surface. The shared medial surface is called the septum (Fig. 64.4). The tunica is the layer inflicted by scar and plaque in Peyronie disease (Fig. 64.5), believed to occur between the two layers, commonly at the septal insertion (1). Conversely, the tunica of the spongiosum is only composed of a circular layer and is thus much thinner than that of the corpora cavernosa.

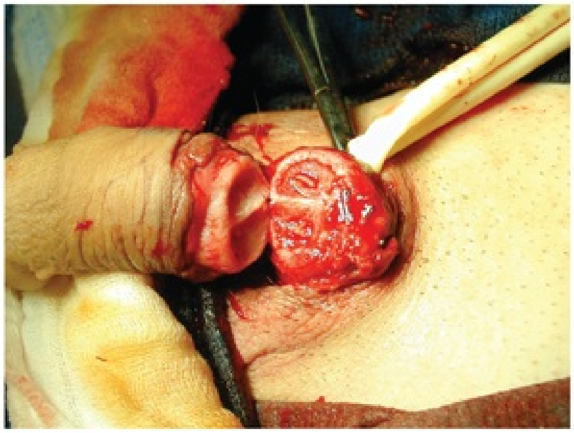

FIGURE 64.4 Penile amputation showing the corpora cavernosa, septum, and erectile tissue. The cavernosal arteries, dorsal artery, and dorsal vein have been clipped during repair. The urethra (not seen) has been repaired.

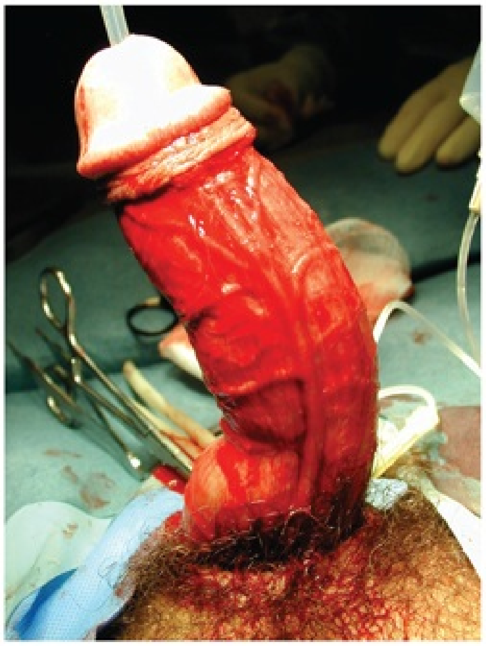

FIGURE 64.5 Degloved penis showing left lateral curvature due to Peyronie plaque in the tunica albuginea. Note normal superficial dorsal vein anatomy and the subtle appearance of the penile dorsal nerves.

Buck fascia covers the two cavernosal bodies and then splits ventrally to encircle the spongiosum. In the perineum, Buck fascia fuses with the tunical layer. Covering the crural fascia is the ischiocavernosus muscle. This muscle compresses the erectile bodies, potentiating an erection. The fascia of the bulb of the spongiosum is covered by the bulbocavernosus muscle. When contracted, this muscle will also potentiate an erection but further acts to express semen and urine. Distally, Buck fascia fuses with the corona of the glans. This margin can be accessed to insert malleable prosthesis for erectile dysfunction. Fibers from the pubic symphysis fuse with the dorsal aspect of Buck fascia forming the suspensory ligament.

Buck fascia is covered by a loose connective tissue called dartos fascia. Dartos fascia is in communication with Colles fascia of the perineum, Scarpa fascia of the abdomen, and the dartos layer of the scrotum (Fig. 64.6). Thus, injury deep to Buck fascia, as in penile fractures, will result in a hematoma confined to the penis (Fig. 64.7), whereas injury to the tunica and Buck fascia will have the potential to spread into the perineum, laterally to the fascia lata, and cephalad over the abdominal wall (Fig. 64.8). The dartos layer allows the skin to move freely over the shaft of the penis.

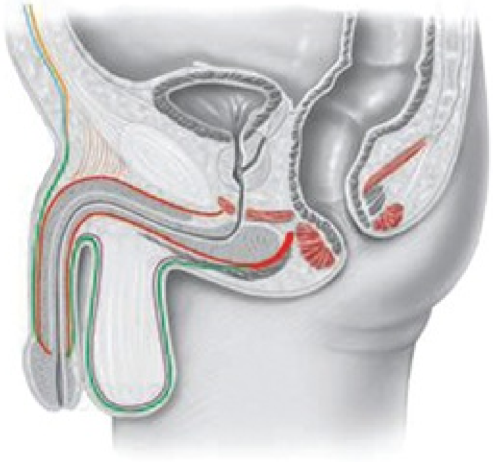

FIGURE 64.6 Diagram of sagittal section showing the fascial planes of the male external genitalia, perineum, and lower abdomen. (From Hohenfellner M, Santucci RA. *Emergencies in Urology*. Heidelberg, Germany: Springer, 2007. © Copyright, 2007 Dr. Markus Hohenfellner, with permission.)

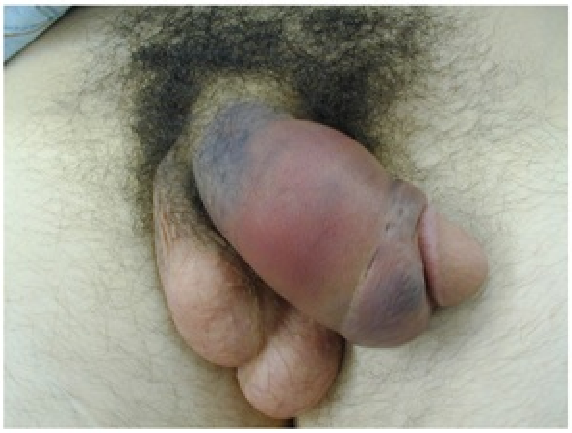

FIGURE 64.7 Penile hematoma consistent with penile fracture deep to Buck fascia.

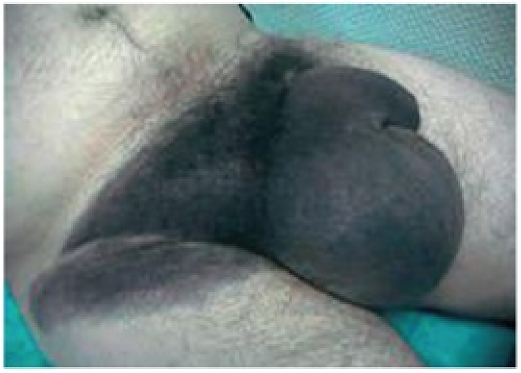

FIGURE 64.8 Pelvic fracture consistent with injury to Buck fascia confined deep to the dartos, Colles, and Scarpa fascia.

The skin of the penis is thin, devoid of fat and hair, and highly elastic. The only glands are those that produce smegma at the coronal margin. At this margin, the penile skin folds over itself covering the glans and forming the foreskin or prepuce. The inner surface of the prepuce is thinner than the outer surface. The skin thickness distinction is important when performing a circumcision because one wants to leave a margin of the inner, thin layer intact to secure to the outer thicker layer. The frenulum of the prepuce is located ventrally and medially, extending from the corona to the urethral meatus of the glans. The frenulum is the most distal component of the median raphe, which extends from the urethral meatus down the shaft of the penis, over the medial scrotum and to the perineum. The median raphe serves as a good entry point to the underlying structures. The skin of the glans is tightly adherent to the underlying tunica of the spongiosum and clinically indistinguishable. This layer can be divided to gain access to the tip of the cavernosa as may be necessary when performing a cavernoglandular shunt for priapism (2). Correction of priapism may also require a perineal approach, so the proximal bulb may be anastomosed to the cavernosum allowing the blood to flow out of the cavernosa into the spongiosum (Fig. 64.9).

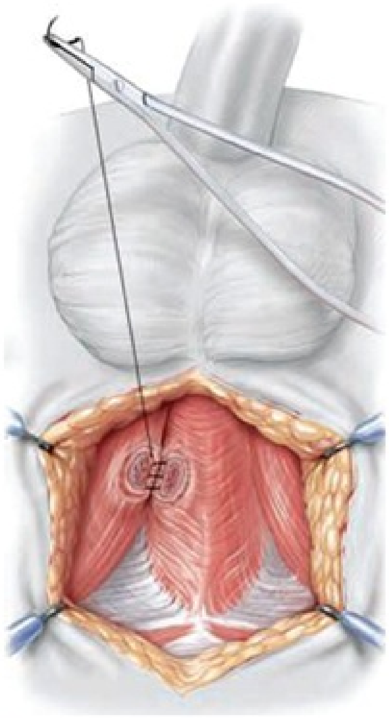

FIGURE 64.9 Cavernosospongiosal shunt highlighting the different venous drainage of the corpora cavernosa and the corpora spongiosum of the penis. (From Hohenfellner M, Santucci RA. *Emergencies in Urology*. Heidelberg, Germany: Springer, 2007. © Copyright, 2007 Dr. Markus Hohenfellner, with permission.)

The paired chambers of the corpus cavernosa envelope erectile tissue, which serves to produce a rigid penis during an erection. The thick tunica of the cavernosa is capable of holding high pressures, ensuring a firm erection. The erectile tissue is supported by trabeculations extending from the inner sheath to the septum. The trabeculae are composed of elastic fibers, arteries, and smooth muscle fibers. The gross appearance is spongy due to the trabeculae. The arterial branches, called the helicine arteries, either open directly into the endothelial lined sinusoids or supply the stroma of the erectile tissue. Distally, the septum between the two chambers of the cavernosum is incomplete, allowing communication of the sinusoids. This is why during penile injection with vasoactive agents only one chamber needs to be injected.

The corpus spongiosum supports the anterior urethra. Beginning in the dilated bulbar urethra at the level of the perineal body, it tapers near the penile hilum to the pendulous urethra and then dilates again at the fossa navicularis before reaching its narrowest point at the meatus. The spongiosum and the glans also contain erectile tissue. The sinusoids are larger, and the tunica is much thinner. Therefore, the spongiosum does not play as vital role in the rigidity of an erection. Instead, the glans provides a cushion from the underlying rigid cavernosal bodies. In addition, the glans is rich in nerve endings aiding in stimulation. An anterior urethral stricture often occurs when there has been scarring to the spongiosal erectile tissue and the urethral mucosa resulting in a narrow lumen (Fig. 64.10).

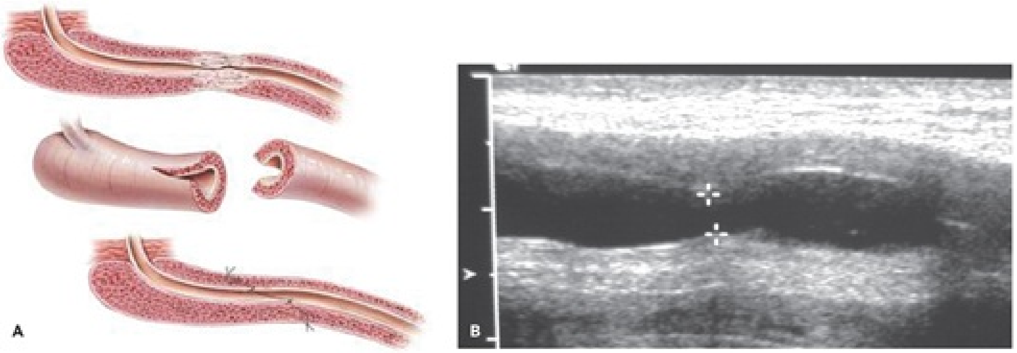

FIGURE 64.10 **A:** Urethral stricture, showing urethral lumen narrowing and spongiofibrosis, treated with excision and anastomosis. (From Hohenfellner M, Santucci RA. *Emergencies in Urology*. Heidelberg, Germany: Springer, 2007. © Copyright, 2007 Dr. Markus Hohenfellner, with permission.) **B:** Ultrasound findings of a urethral stricture showing urethral lumen narrowing.

Blood Supply and Lymphatics

The internal pudendal artery, a branch of the internal iliac artery, travels through Alcock canal and sends the inferior rectal artery, posterior scrotal artery, and the perineal artery. Alcock canal, and its contents, is a common test question for urologists. The internal pudendal artery then terminates as the common penile artery. Three branches arise from the penile artery (Fig. 64.11). The bulbar artery pierces the spongiosum near the perineal body at the posterolateral margin and supplies the urethra, the spongiosum, and the glans. The second branch is the cavernosal artery that pierces the dense sheath at the penile hilum and travels in the center of the erectile tissue where it branches to supply the sinusoids (Fig. 64.12). Finally, the dorsal artery of the penis passes between the crura and inferior to the pubic bone to run deep to Buck fascia where it sends circumflex branches to the spongiosum and cavernosal branches to aid in erections. Additionally, there is often an accessory pudendal artery originating from the obturator or inferior vesical artery, which passes anterolateral to the prostate and then under the pubic arch with the dorsal vein (3). These accessory branches may be vital to erectile function, and if compromised or sacrificed during prostatectomy, the patient may be rendered impotent. The arterial supply to the penile skin is based on the external pudendal artery, a branch of the femoral artery (4). These branches are vital to perform fasciocutaneous flaps for penile reconstruction (Fig. 64.13).

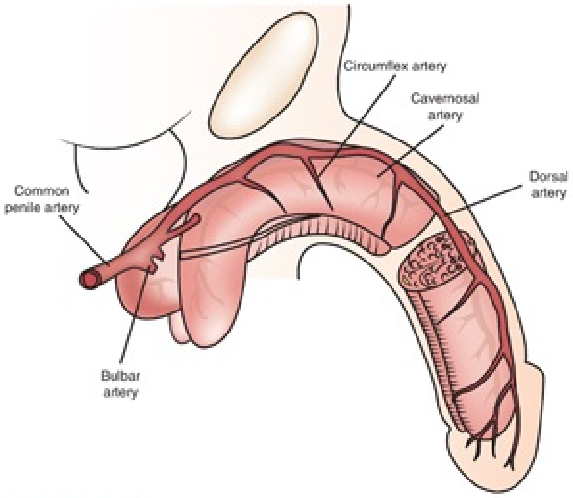

FIGURE 64.11 Illustration of the common penile artery and the three branches: bulbar artery, cavernosal artery, and the dorsal artery.

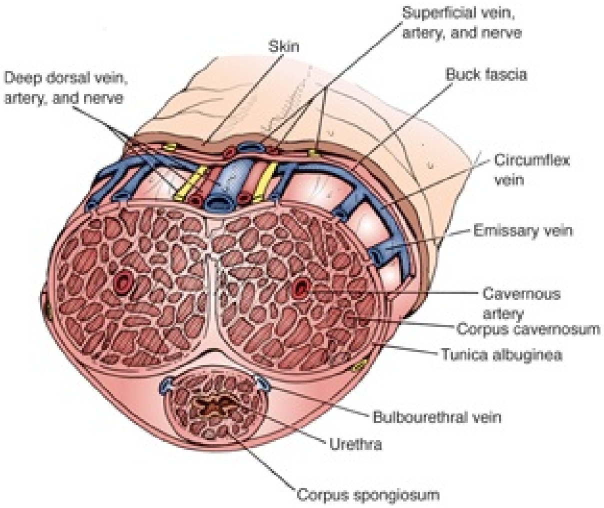

FIGURE 64.12 Cross section of the penis demonstrating the fascial layers as well as vascular and neural anatomy.

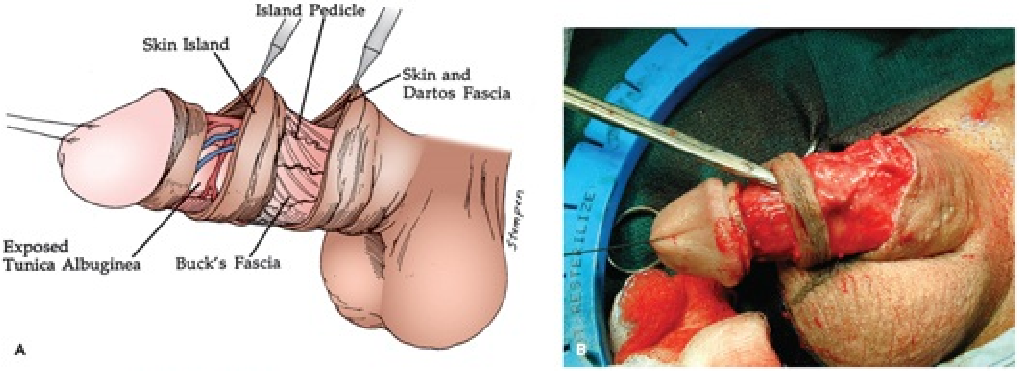

FIGURE 64.13 A: Diagram of a fasciocutaneous flap for use in urethral reconstruction. B: Operative demonstration of fasciocutaneous flap. The flap is dissected off the tunica albuginea (*below*) and then the penile skin (*above*) is carefully dissected off the dartos layer, preserving it. The flap's blood supply is found in the intact dartos layer.

The venous drainage of the penis is divided into the superficial dorsal system, the deep dorsal system, and the crural vessels (Fig. 64.14). The deep dorsal vein begins at the base of the glans in the retrocoronal plexus. From here, the dorsal vein travels deep to Buck fascia between the paired dorsal arteries. Along its path, it receives circumflex veins from the spongiosum until it travels under the pubic bone and joins the periprostatic plexus. The cavernosal sinuses drain to a subtunical venous plexus, which then sends emissary veins through the tunica of the cavernosa to join the circumflex veins. The emissary veins travel at an oblique angle through the tunica and are compressed during an erection to aid in blood trapping within the cavernosa. The circumflex veins are found in the distal two-thirds of the penis only. More proximally, at the hilum and the crura, the emissary veins coalesce to form the cavernosal veins and crural veins, respectively. These veins then pass between the bulb and the crura to drain into the periprostatic plexus or the internal pudendal vein. The superficial dorsal vein drains the skin of the penis and ultimately empties in the superficial external pudendal vein and then to the saphenous vein (Fig. 64.15).

FIGURE 64.15 Superficial arterial and venous drainage of the penis and scrotum.

The lymphatic drainage of the penis is primarily to the superficial inguinal lymph nodes. There is no reliable laterality of the lymphatic drainage of the penis. This becomes important in penile cancer cases, mandating bilateral lymphadenectomy when indicated.

Innervation

The pudendal nerve travels through Alcock canal and enters the perineum posterior to the ischial tuberosity. The tuberosity can be used as a landmark to perform a pudendal nerve block. With a finger in the rectum, the tuberosity can be palpated. Using a long 20-gauge needle popped deep to the sacrospinous ligament and posteriorly, laterally, and medially to the tuberosity, 10 to 15 mL of local anesthetic can be injected bilaterally to numb the entire perineum and penis.

The bulbospongiosus muscle and the ischiocavernosus muscles are innervated by the deep branch of the perineal nerve, a branch of the pudendal nerve. The pudendal nerve then terminates in the dorsal nerve of the penis which runs lateral to the artery beneath Buck fascia. The dorsal penile nerve supplies the majority of the skin of the penis and the glans. This nerve is targeted for a penile block by placing a needle at the junction of the pubic bone and cavernosal bodies, deep to Buck fascia at the 10 and 2 o’clock position (Fig. 64.16A and B). After aspiration, up to 10 mL of local anesthetic can be injected. This will control the majority of the nerve supply to the penis. The skin of the base of the penis is supplied partially by branches from the ilioinguinal nerve. A superficial ring block can target these nerves not covered by the penile nerve block. It is important to remember that epinephrine containing anesthetics should be avoided in the penis.

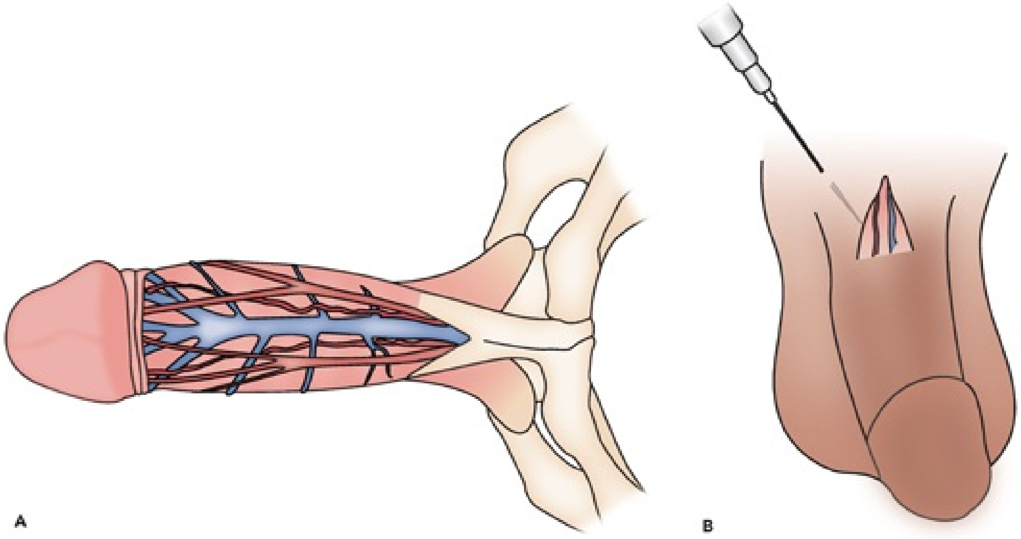

FIGURE 64.16 Diagram of penile nervous anatomy and penile block. A: Dorsal view of penile neurovascular bundle. B: Penile block at 2 and 10 o'clock position

The cavernous nerve carries autonomic fibers, running posterolateral to the prostate, and piercing the pelvic floor where it then penetrates the crura and innervates the erectile tissue. The sympathetic component leads to constriction and maintains a flaccid state. The parasympathetic fibers allow smooth muscle and endothelial relaxation contributing to filling of the sinusoids, ultimately leading to an erection.

SCROTAL ANATOMY

Structure

The scrotum serves as a fibromuscular sac to support the testes. It lies posterior and inferior to the penis, beginning at the level of the pubic symphysis and ending at the midperineum. The layers of the scrotum are based on those of the abdominal wall. However, these layers are difficult to discern clinically. These layers can be simplified into the skin, the dartos, and the tunica vaginalis. The dartos layer of the scrotum contains smooth muscle fibers to control the tone of the scrotal skin. The tunica vaginalis layer surrounds the testicle in a parietal and visceral mesothelium-lined sac that has a thin layer of fluid between to allow the testicle to move freely other than the posterolateral attachments. Excess fluid in the layer between the parietal and visceral tunica vaginalis results in a hydrocele. At the posterolateral surface of the testicle, it is adherent to the wall of the scrotum at its mesentery. Inferiorly, the testicle is adherent to the scrotum via the gubernaculum. If the attachments are absent, the testicle may be free to rotate around its central axis resulting testicular torsion (Fig. 64.17).

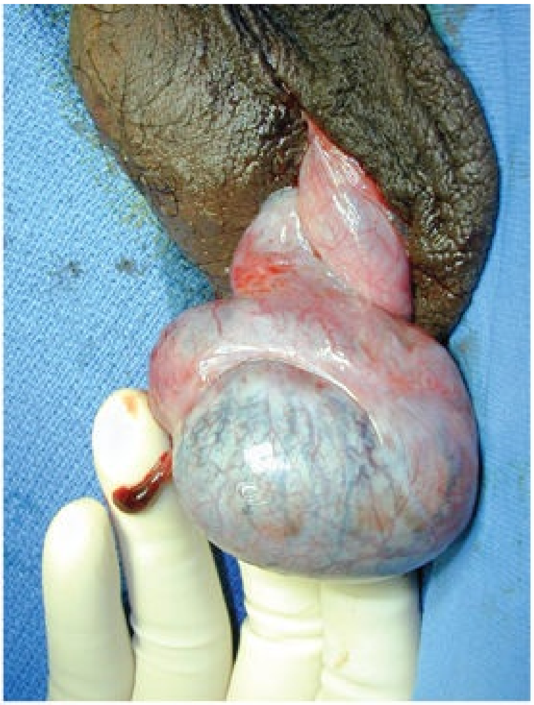

FIGURE 64.17 Testicular torsion, note the twisting of the cord. Also showing an incidental appendix epididymis.

Deep to the visceral layer of tunica vaginalis is the tunica albuginea of the testicle. At the posterolateral margin, the tunica albuginea is covered by the epididymis. Here, the tunica invaginates into the testicle, creating the mediastinum. Many septa extend from the mediastinum creating multiple lobules to encompass the seminiferous tubules. These tubules combine and expand near the mediastinum to form the efferent ductules in a network known as the rete testis. The ductules then enter the head of the epididymis, where they further enlarge, and ultimately end in the single convoluted epididymal duct, that forms the body and tail of the epididymis. Near the end of the tail of the epididymis, the epididymal duct thickens and expands to form the vas deferens (Fig. 64.18A and B). An epididymal cyst forms when the duct becomes enlarged. The vas deferens extends from the base of the testicle and passes superiorly as part of the spermatic cord. The spermatic cord also consists of the testicular artery, the pampiniform plexus, the internal spermatic fascia, cremasteric muscle fibers and fascia, and the external spermatic fascia (Fig. 64.19). During a vasectomy, the vas deferens is divided in the upper scrotum as it runs with the spermatic cord after dissecting the surround muscle and fascia off the vasa. Two commonly encountered embryologic remnants are the appendix epididymis and the appendix testis. The appendix epididymis is a remnant of the Wolffian duct, whereas the appendix testis is a remnant of the müllerian duct. These structures can twist and cause acute testicular pain mimicking testicular torsion. If they are encountered during scrotal surgery, it is common practice to fulgurate the structures to prevent future torsion (see Fig. 64.17).

FIGURE 64.19 Scrotum and spermatic cord.

Blood Supply and Lymphatics

The posterior scrotal artery branches from the perineal artery, described earlier. The anterior scrotal artery is a branch of the external pudendal artery, a branch of the femoral artery. The vessels of the skin of the scrotum run parallel to the rugae and do not tend to cross the raphe. Given the path of the blood supply, transverse and medial incisions along the raphe will tend to have less bleeding (see Fig. 64.15).

The blood supply of the testicle is derived from the testicular artery, originating off the aorta inferior to the ipsilateral renal artery. From here, it descends in the retroperitoneum with the gonadal vein, ultimately meeting with the vas deferens and exiting the retroperitoneum at the internal ring

(Fig. 64.20). The vasal artery is another source of blood supply for the testicle, arising from either the superior or inferior vesicle artery. The spermatic artery, a branch of the inferior epigastric artery, is the final arterial supply of the testicle. Near the tail of the epididymis, these three vessels coalesce to offer a variety of blood flow to the testicle.

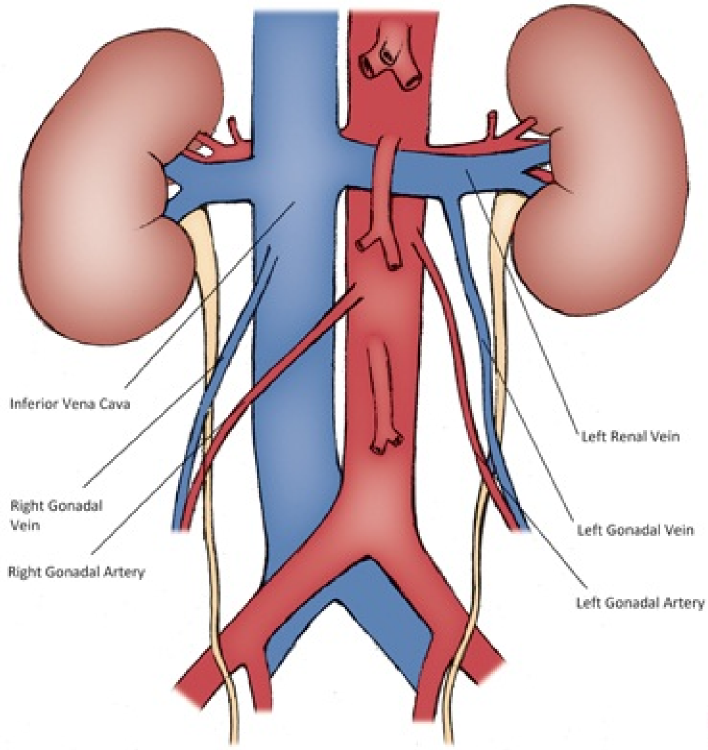

FIGURE 64.20 Arterial supply and venous drainage of the testicle.

The venous drainage of the skin of the scrotum is to the superficial external pudendal vein (see Fig. 64.15). Venous drainage of the testicle is via the pampiniform plexus, a collection of veins that coalesce to form the right or left gonadal vein. The right gonadal vein drains directly into the inferior vena cava, whereas the left gonadal vein drains to the left renal vein (see Fig. 64.20). Dilation of the pampiniform plexus may occur, resulting in a varicocele. Alternatively, compression or occlusion of the inferior vena cava may result in a more sudden onset varicocele concerning for a retroperitoneal cancer or caval thrombus from a renal tumor.

The lymphatics of the scrotum drain to the superficial inguinal lymph nodes. Unlike penile lymphatics, those of the scrotum do not tend to cross the raphe. The lymphatics of the testicles enter the retroperitoneum and drain to the periaortic and paracaval lymph nodes.

Innervation

The anterior scrotum is innervated by the anterior scrotal nerve, a division of the ilioinguinal nerve and the genital branch of the genitofemoral nerve. The posterior scrotum is supplied by the posterior scrotal nerve, a branch of the superficial perineal nerve. Like the blood supply, the nerves of the scrotum tend run parallel to the rugae and do not cross the raphe. Visceral innervation to the testicle arises from the renal and aortic plexus as well as the pelvic plexus. Nerves originating from the visceral and pelvic plexi travel with the gonadal vessels and vas deferens through the inguinal canal.

CHAPTER 65 PARTIAL AND TOTAL PENECTOMY IN THE MANAGEMENT OF INVASIVE SQUAMOUS CELL CARCINOMA OF THE PENIS

FERNANDO P. SECIN, AGUSTÍN R. ROVEGNO, ANA MARÍA AUTRÁN GÓMEZ, AND RAFAEL SÁNCHEZ-SALAS

Penile cancer is an uncommon malignancy with specific geography-related incidence. Although high incidence rates account for up to 10% to 20% of all malignancies in developing continents, such as Asia, Africa, and South America, its incidence in Europe is low (one case per 100,000 people) (1). In the United States, it is estimated that 1,570 men will be diagnosed and 310 will die from this disease in 2013 (2).

There is an increasing body of literature supporting the association between sexually transmitted viral disease and penile cancer. Human papilloma viruses (HPV), especially types 16, 18, 31, and 33, are the most frequently detected types in penile cancer (3). In a large case series by Dillner et al. (4), HPV DNA was identified in penile neoplastic tissue. The authors found that in penile intraepithelial neoplasia, between 70% and 100% of the lesions were positive for HPV DNA, whereas invasive penile cancer was positive for HPV in only 40% to 50% of the cases (4).

However, the most important risk factor for invasive penile cancer is the presence of an intact foreskin. Penile cancer is rarely seen in Jews or in Igbos, an ethnic group of southeastern Nigeria, who ritually circumcise males on the eighth day of birth. The lowest incidence of penile cancer has been reported in Israeli Jews (0.1/100.000), making an argument in favor of the protective effect of circumcision (5). Schoen et al. (6) observed that the relative risk of invasive penile cancer for uncircumcised to circumcised men was 22:1. In a case-control study, neonatal circumcision was associated with a threefold decreased risk of cancer development, albeit 20% of penile cancer patients had been circumcised neonatally. When compared to men circumcised at birth, the risk for penile cancer was 3.2 times greater among those uncircumcised and 3.0 times greater on those circumcised after the neonatal period (7).

It appears that, enclosed preputial environment, associated with poor genital hygiene of the foreskin, chronic irritation, and exposure to certain etiologic agents, such as viruses, smegma, and hydrocarbons, may also play a causative role in the development of this tumor (8). A retrospective review of approximately 15,000 surgical specimens collected from the Igbos of Nigeria, over a period of 13 years, revealed four cases of penile carcinoma. One tumor arose at the glans penis. This localization pattern suggests that, in circumcised males, smegma-induced squamous carcinoma of the glans can be virtually abolished but not the ordinary squamous carcinoma that can develop by chance on the rest of the penis (9).

Other risk factors identified by case-control studies included chronic inflammatory conditions, such as balanoposthitis and lichen sclerosus, and PUVA treatment. PUVA is psoralen and ultraviolet A (UVA) photochemotherapy, traditionally used to treat psoriasis, vitiligo, atopic dermatitis, or alopecia areata. A consistent association was found between penile cancer and smoking, a dose-dependent association not explained by investigated confounding factors such as sexual history. Cervical cancer in the wife was not consistently associated with cancer of the penis in the husband (4).

Preventive measures that could be considered to reduce the risk of penile cancer include prevention of phimosis, local hygiene, treatment of chronic inflammatory conditions, limiting PUVA treatment, smoking cessation, and prevention of HPV infection (4).

Around 95% of penile cancers are squamous cell carcinoma (SCC) originating in the epithelium covering the glans, coronal sulcus, and/or foreskin. Several histologic subtypes have been described, each with distinctive clinicopathologic and outcome characteristics. The most common subtype is the SCC, representing 48% to 65% of penile carcinomas. Penile verruciform tumors encompass verrucous, warty (condylomatous), and papillary, not otherwise specified carcinomas. As a group, verruciform tumors are low-grade, with low metastatic and mortality rates. In contrast, basaloid and sarcomatoid carcinomas are among the most aggressive penile tumors. Other SCC variants, such as carcinoma cuniculatum and pseudohyperplastic, adenosquamous, and acantholytic carcinomas, are rare (10).

Penile cancer has a predictable natural history. In brief, it initially involves the glans in almost half of patients, followed by prepuce and/or penile shaft locations. Buck fascia and tunica albuginea penetration allows for infiltration of the corpus cavernosum, permeating the lymphatic system. Lymphatic spread is the rule. Tumor initially spreads to the superficial inguinal lymph nodes to continue into the deep inguinal and pelvic nodes. “Skip” lymphatic drainage is rare. If untreated, the inguinal metastases will enlarge, ulcerate through the skin (causing infection), or grow into the femoral vessels, producing potentially dangerous hemorrhage. Untreated patients with penile SCC usually die within 2 years of diagnosis due to uncontrollable locoregional growth or distant metastases. Hematologic metastases, spread to distant sites (e.g., lungs, liver, bone, and brain), are less common (1% to 10% in most large series) and usually occur late in the disease course. Distant metastases in the absence of regional node metastases are unusual (8).

Effective surgical intervention plays an essential role, in both the diagnosis and management of the primary disease, and is crucial for accurate staging and treatment of regional inguinal and pelvic lymph nodes. Goals of surgical treatment for the primary tumor are excision with adequate margins and preservation of as much functional penis as possible for upright voiding and erectile function (11).

Recent advances in the primary management of penile cancer have highlighted that penile-preserving approaches can be employed in select patients, whereby offering the potential of improved quality of life and erectile function preservation. Several clinical variables must be evaluated before considering penile-preserving approaches, including the primary tumor stage, grade, location of the lesion, and ability to maintain a “functional” penis. Complete tumor excision with negative surgical margins at the primary tumor site must never be compromised in order to eliminate the nidus for cancer dissemination as well as a potential site of local symptomatic recurrence. As we incorporate new surgical techniques to our armamentarium, we must ensure that cancer-specific outcomes of these approaches meet the established survival offered by the standard surgical treatment (12).

Delayed or incomplete surgical resections can have significant negative impact on patient survival, a situation made worse by the absence of effective systemic chemotherapy once metastatic disease occurs. Regional inguinal and pelvic lymph node dissection (PLND) remains an integral component of the treatment of invasive penile cancer with evidence mounting that a survival advantage exists for patients undergoing early prophylactic as opposed to therapeutic groin dissection (13). The management of lymph node involvement is described in Chapter 63.

DIAGNOSIS

The primary tumor may present as a nonhealing ulcer (Fig. 65.1), papule, indurated mass, or exophytic growth (Fig. 65.2). It may be associated with penile bleeding or purulent discharge. Physical examination of the primary penile lesion should evaluate and document the number of lesions, tumor dimensions (size), sites involved (foreskin, glans, shaft), color, morphology (flat, papillary, nodular, ulcerating, fungating), relationship with other structures (corpus spongiosum, corpora cavernosa, urethra), and boundaries (edges) (11) (Fig. 65.3).

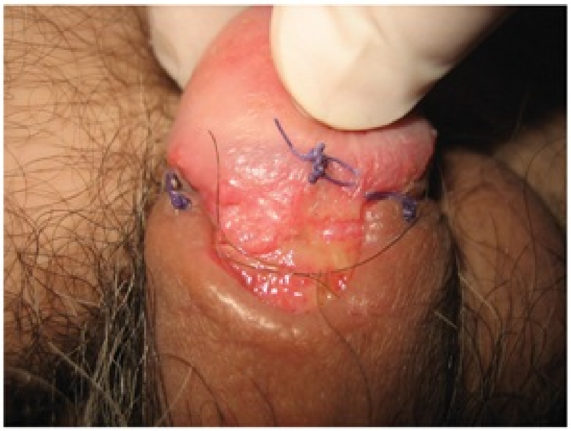

FIGURE 65.1 A nonhealing ulcer following circumcision.

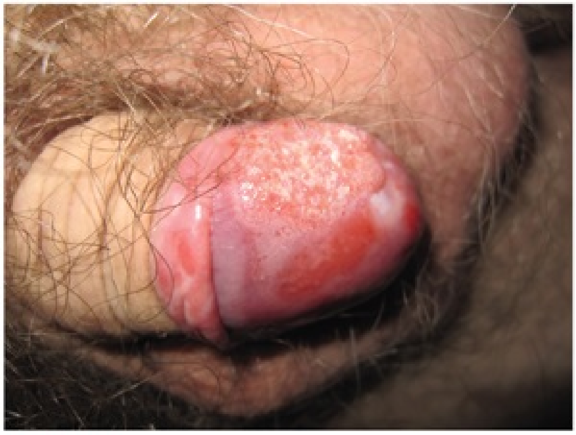

FIGURE 65.2 Erythematous elevated and indurated lesion in glans.

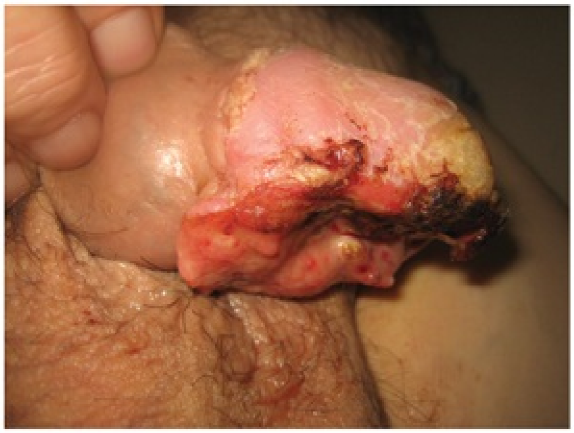

FIGURE 65.3 Ulcerated penile tumor compromising the urethra.

Clinical staging of the primary tumor can be incorrect in 26% of patients (Table 65.1). Understaging results from histologic infiltration not clinically evident and overstaging of absent infiltration may result from edema and infection (14).

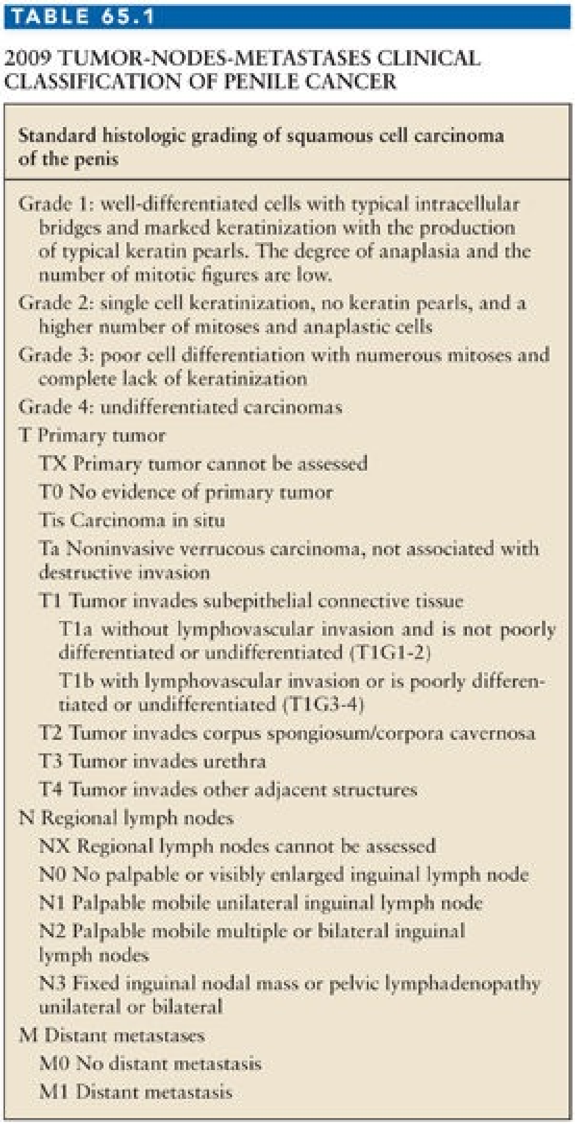

TABLE 65.1

2009 TUMOR-NODES-METASTASES CLINICAL CLASSIFICATION OF PENILE CANCER

Standard histologic grading of squamous cell carcinoma of the penis
Grade 1: well-differentiated cells with typical intracellular bridges and marked keratinization with the production of typical keratin pearls. The degree of anaplasia and the number of mitotic figures are low.
Grade 2: single cell keratinization, no keratin pearls, and a higher number of mitoses and anaplastic cells
Grade 3: poor cell differentiation with numerous mitoses and complete lack of keratinization
Grade 4: undifferentiated carcinomas
T Primary tumor
TX Primary tumor cannot be assessed
T0 No evidence of primary tumor
Tis Carcinoma in situ
Ta Noninvasive verrucous carcinoma, not associated with destructive invasion
T1 Tumor invades subepithelial connective tissue
T1a without lymphovascular invasion and is not poorly differentiated or undifferentiated (T1G1-2)
T1b with lymphovascular invasion or is poorly differentiated or undifferentiated (T1G3-4)
T2 Tumor invades corpus spongiosum/corpora cavernosa
T3 Tumor invades urethra
T4 Tumor invades other adjacent structures
N Regional lymph nodes
NX Regional lymph nodes cannot be assessed
N0 No palpable or visibly enlarged inguinal lymph node
N1 Palpable mobile unilateral inguinal lymph node
N2 Palpable mobile multiple or bilateral inguinal lymph nodes
N3 Fixed inguinal nodal mass or pelvic lymphadenopathy unilateral or bilateral
M Distant metastases
M0 No distant metastasis
M1 Distant metastasis

All penile lesions that appear suspicious for malignancy should undergo histologic evaluation, using one of the following methods: incisional biopsy, tissue core biopsy, fine needle aspiration cytology, brush biopsy, or excisional biopsy (14).

For small discrete lesions, the biopsy procedure can be, at the same time, diagnostic and therapeutic. The biopsy specimen, regardless of location, must contain adequate underlying tissue to allow the pathologist to determine the depth of tumor invasion, an important predictor of local tumor recurrence and regional nodal metastases (15,16).

Some lesions are considered premalignant in SCC of the penis. Lesions sporadically associated with SCC of the penis are cutaneous horns and bowenoid papulosis. Lesions at intermediate risk of developing SCC include lichen sclerosus/balanitis xerotica obliterans (Fig. 65.4). Up to one-third of penile erythroplasia of Queyrat or Bowen disease will transform to invasive SCC and are thus considered high risk of developing SCC of the penis (17).

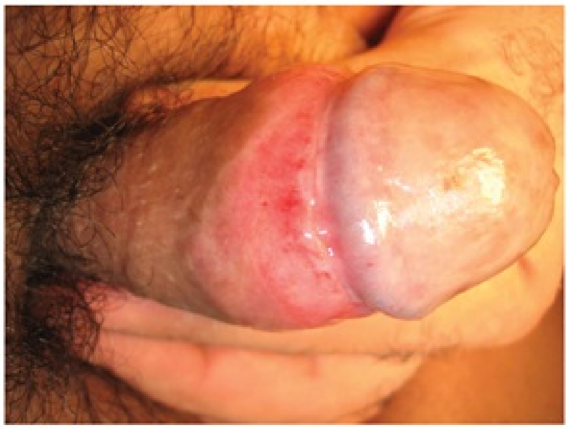

FIGURE 65.4 Balanitis xerotica obliterans, a premalignant condition.

For tumors involving only the prepuce, circumcision can be both diagnostic and therapeutic. Tumors involving the glans, glans and prepuce, coronal sulcus, or shaft are best approached with an initial excisional biopsy that includes ample underlying soft tissue to accurately determine the depth of invasion (11).

When deciding for a diagnostic biopsy only, an incision biopsy is the preferable option, taking a wedge of tissue that includes the tumor and adjacent normal tissue to improve histologic diagnosis. However, the histologic type and grade can be misinterpreted in 30%, the depth of invasion has been undetermined in 91%, and vascular invasion can be missed in 88% of cases (18).

Physical examination of the inguinal and pelvic areas to assess the lymph nodes is mandatory. Between 30% and 60% of patients presenting with SCC of the penis have enlarged lymph nodes in the groin (11). Ultrasound-guided fine needle aspiration cytology is indicated for both palpable and nonpalpable inguinal nodes because complete inguinal lymp node dissection (LND) is indicated in patients with regional node positivity (Fig. 65.5). Antibiotic treatment for 3 to 6 weeks before inguinal LND in patients with palpable inguinal nodes is recommended. Pelvic computerized tomography (CT) and magnetic resonance imaging (MRI) are not useful in patients with nonpalpable nodes. However, they are indicated in those with large, palpable inguinal nodes or in patients with confirmed inguinal lymph node metastasis (LNM) to detect iliac LNMs (Fig. 65.6). Abdominal CT and chest radiography or CT are advisable if the pelvic CT findings are positive to rule out distant metastasis (14,19) (Fig. 65.7). Positron emission tomography/CT is a promising method for detection of distant metastatic lesions and therapeutic strategy planning in penile cancer. However, few studies support its use possible due to its low incidence (20).

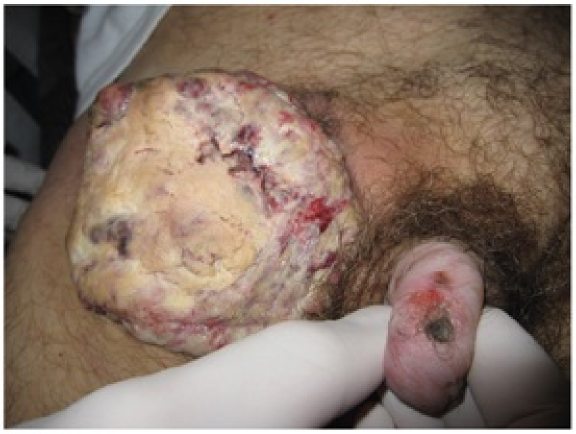

FIGURE 65.5 Ulcerated right inguinal nodes with a relatively small penile lesion.

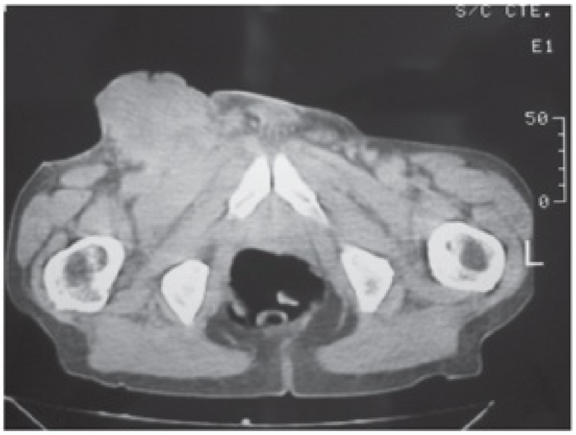

FIGURE 65.6 Pelvic CT to evaluate lymph node extension.

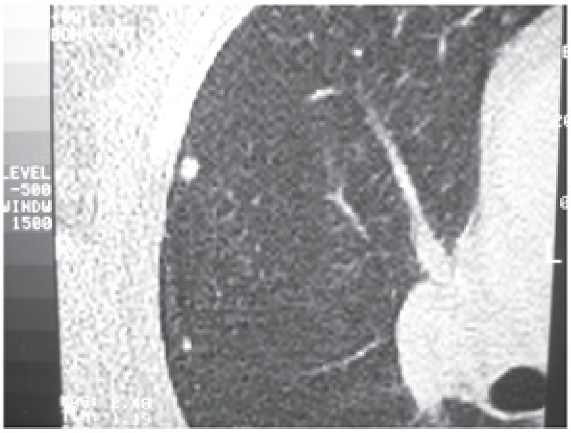

FIGURE 65.7 Chest CT scan show images consistent with lung metastasis.

A full discussion with the patient concerning the degree of penile resection required, the anticipated functional deficit, and the necessary reconstruction required is needed. Occasionally, plastic surgical consultation is requested if a wide local excision with complex rotational flap coverage is contemplated. If total penectomy is planned, a psychiatric consultation is recommended to be certain the patient has the emotional capacity to tolerate such a procedure (11).

The extent of the negative margin required is controversial in penile cancer. Although a 2-cm surgical margin has been traditionally proposed, more recent data suggest that for low-risk tumors a 1-cm clearance is adequate for grade 1 and 2 lesions, and 1.5 cm for grade 2 tumors (21). Nonetheless, experts recommend sending a frozen section of the proximal margin at the time of tumor resection to assure a microscopically negative margin (11).

Molecular markers are not of clinical use in SCC of the penis. SCC antigen is not sensitive in small tumor burden and has little prognostic significance for survival after surgery (22). Lymph node metastases are also correlated with the expression of p53, Ki-67, and E-cadherin, but these markers are not useful in clinical practice (23).

SURGICAL INDICATIONS (24,25)

Stage Ta-Tis

Treatment options for patients with Stage Ta-Tis penile cancer include 5% 5-fluorouracil (5-FU), 5% imiquimod cream; wide local excision including circumcision, cryotherapy, glansectomy, or laser treatment. The advantages of topical chemotherapy include simple application, low rates of toxicity, and adverse events. The disadvantages include risk of prolonged therapy (average duration of treatment of 4 to 6 weeks with estimated healing time of 4 to 8 weeks), local recurrence, and poor therapeutic efficacy in immunocompromised patients (26).

Laser therapy, either carbon dioxide (CO_2) or neodymium-yttrium-aluminum-garnet (Nd:YAG), has been successfully used as a first-line therapy for premalignant lesions and early stages of penile cancer since the 1980s. The CO_2 laser has a tissue penetration of 0.1 mm, whereas Nd:YAG laser penetrates to a depth of 4.2 mm. That is why laser is contraindicated in tumors with >6 mm depth invasion, T2 tumors and in patients not compliant to close follow-up due to its high recurrence rate (27).

The advantages of laser therapy include good functional and cosmetic outcomes and avoidance of surgery, assuming that oncologic outcome and survival are not affected by local recurrence. The disadvantages of laser therapy include its high recurrence rates, reported to be between 3.1% and 48%. The Nd:YAG laser can cause significant tissue coagulation and prevent accurate histologic diagnosis, resulting in understaging of the disease. Although the CO_2 laser does not cause significant tissue coagulation, it is limited by its lower tissue penetration compared with the Nd:YAG laser (28,29).

Cryotherapy is more commonly used in the treatment of genital warts and premalignant lesions than in penile cancer. A study comparing cryotherapy and topical 5-FU in the treatment of Bowen disease showed that the risk of recurrence after cryotherapy (13.4%) was greater than after 5-FU treatment (9%) (26,30).

Although cryotherapy and laser therapy can effectively treat selected patients with small superficial lesions, their effectiveness for overtly invasive penile cancers is uncertain and their use should not be considered an alternative to standard resection.

Stage T1G1-3 of the Foreskin

For patients with an invasive tumor confined to the prepuce, a penile-preserving strategy using circumcision is strongly recommended. Careful assessment of the glans is required to exclude dysplasia or carcinoma in situ. Alone, circumcision is curative for low-grade, low-stage preputial disease. The disadvantage of circumcision is the reported recurrence rate of 50% at 2 years, indicating the need for regular close surveillance (31).

Stage T1G1-3 of Glans

For patients with stage T1G1-3 of the glans, who can guarantee regular follow-up examinations, a penile-preserving strategy is strongly recommended. Choice of the treatment will be influenced by the size and location of the tumor and the possible side effects. Meticulous follow-up and/or self-examination are advisable in order to detect and rapidly treat local recurrence.

Treatment options include the following:

1. *Wide local excision* (*WLE*) with wide negative margins, with or without split or full-thickness skin graft, can be performed for precancerous lesions, discrete lesions, extensive preputial disease (where circumcision alone is not curative), and T1 low-grade tumors of the shaft. A 1- to 1.5-cm negative margin may adequate for low-risk tumors (21). Contraindications to WLE include tumor in close proximity to the urethra, urethral involvement, or lesions extending more than half of the glans penis. The disadvantages may include potential tumor recurrence and significant deformity or deviation of the penis during erections (32).

    Mohs micrographic surgery could be used with concurrent microscopic evaluation to ensure that a tumor-free plane is obtained. The indications for performing penile Mohs surgery are carcinoma in situ or verrucous carcinoma (which are of low to intermediate grade and have an exophytic growth pattern); lesions of the distal penis or glans penis, otherwise amenable to partial penectomy; and the desire for penile-preserving surgery in compliant patients. Higher than 85% 5-year survival rates have been reported with this procedure. The success rate is shown to be stage-dependent. The advantages of the Mohs technique include proper tumor mapping and excision of the tumor with no positive margins, and preservation of uninvolved penile tissue, with improved cosmetic or functional outcome. The disadvantage of the Mohs technique is its poorer local control as evidenced by the high rates (30%) of local recurrence after one procedure (33,34). However, most recurrences were suitable for further Mohs surgery. Contraindications to Mohs surgery include advanced tumor stage amenable to partial penectomy and, in instances where the involvement of the urethra, or the size of the defect, outweighs potential cosmetic or functional results. Complications, such as meatal stenosis or glans disfigurement, have been reported (26).
2. *Glansectomy* can be partial or complete. Recent studies have shown that a margin of 0.5 cm may be oncologically safe (35). Depending on the size of the defect, reconstruction can follow three techniques: (a) primary closure, (b) preputial or scrotal skin flap, or (c) skin grafting. Potential disadvantage of glansectomy is cancer recurrence in the remaining glans. Complications associated to reconstruction of the glans include loss, or graft contraction, graft overgrowth over the external urethral meatus, penile tethering by flaps, loss of penile length, and decreased penile sensitivity (36,37).
3. *Partial penectomy* remains the standard care for men with distal penile cancer and is particularly indicated when it is necessary to dissect the corpora cavernosa to achieve a negative margin. Extension into the urethra or corporal bodies and/or local recurrence of disease after previous conservative treatment are formal indications for partial penectomy. At least a 1-cm margin of resection is recommended (11). Leijte et al. (38) recently compared laser therapy, WLE, and radiotherapy to partial or total penectomy and showed that local disease recurrence rates were 5 to 6 times lower with the latter treatments, albeit there was no significant difference in overall disease survival (38). The presence of local recurrence after partial penectomy carries a poor prognosis. Partial penectomy offers excellent local control with low recurrence rates (<10%) and allows for preservation of urinary function and possible sexual function in most cases. The most common complication is neourethral meatal stenosis (39). Intraoperative frozen sections to achieve negative

surgical margins are always recommended in all aforementioned options.

Stage T2 of Glans

For patients with stage T2 disease of the glans, a conservative strategy of total glansectomy with or without resurfacing of the corporeal heads is recommended. An alternative treatment for very carefully selected patients is partial glansectomy of tumors involving less than 50% of the glans, provided close monitoring is possible. The traditional 2-cm macroscopic clear margin has been questioned by the international panel.

Stage T2 of Corpora and Stage T3

For patients with stage T2 or T3 disease, partial or radical amputation has been considered standard treatment. For lesions extending proximally, to a location that, partial penectomy would not achieve a functional penile remnant, total penectomy is advised (26).

Current guidelines also consider primary radiotherapy (external beam radiation therapy [EBRT]) as a treatment alternative in T1-2 N0 as penile-preserving strategy in highly selected patients. The National Comprehensive Cancer Network guidelines propose circumcision followed by either brachytherapy (BT) alone or EBRT with or without chemotherapy in patients with tumors less than 4 cm. The recommended radiation dose is 65 to 70 Gy with conventional fractionation, using appropriate bolus to primary penile lesion with 2-cm margins.

BT consists of implantation of a radioactive iridium (Ir 192) seed into the penis, and this is removed when the predetermined dose has been delivered. Circumcision should be performed before radiotherapy with glans tumor to reduce radiation-induced complications. BT offers good success rates particularly for low-stage disease and in general is more successful than EBRT. The 5-year rate of penile preservation after BT ranges from 70% to 88%, which is higher than the corresponding 36% to 66% rates for EBRT (26,40).

When opting for radiotherapy for tumors larger than 4 cm, circumcision is followed by EBRT with chemotherapy. In this case, 45 to 50.4 Gy are administered to a portion of or whole penile shaft, depending on the extent of the lesion, plus pelvis/inguinal nodes administration. This is followed by a boost on the primary lesion, with a 2-cm margin, for a total dose of 60 to 70 Gy. BT should be used very selectively in larger tumors and be also restricted to patients compliant to close follow-up.

In T3-4 patients or N-positive patients not suitable for surgical treatment, 45 to 50.4 Gy are administered to the whole penile shaft, pelvic lymph nodes, and bilateral inguinal lymph nodes, to then boost the primary lesion, with a 2-cm margin, and gross lymph nodes, for a total dose of 60 to 70 Gy.

The preferred radiosensitizing agent is cisplatin alone or in combination with 5-FU. Paclitaxel, ifosfamide, and cisplatin (TIP) is the first-line combination chemotherapy of choice. 5-FU in combination with cisplatin can be considered as an alternative to TIP (25).

The advantages for radiotherapy include good long-term cosmesis and excellent rate of penile preservation. However, local failure rates after radiotherapy are higher than after partial penectomy. Most frequently reported complications are urethral stenosis, 10% to 45% at 3 years; glans necrosis or ulceration, 10% to 20% at 7 and 18 months after treatment, requiring debridement or amputation of penile tissue; and late fibrosis of the corpora (41). Skin pigmentation, telangiectasia, long treatment duration, and healing time (up to 3 months) are other disadvantages of radiotherapy (40,42,43).

No scientifically supported recommendations can be given regarding surgical procedures versus radiotherapy. Institutional experience and possibilities play an important role in decision making (17).

SURGICAL TECHNIQUE

Partial Penectomy

The operation should be designed, if possible, to allow the patient to void in the upright position and without the need to push away the scrotum; otherwise, a perineal urethrostomy should be considered. After proper anesthesia, the patient is placed in supine position. The lesion and urine should be cultured preoperatively and appropriate parenteral antibiotics started prior to the surgical procedure (Fig. 65.8). The penis is prepared with a povidone-iodine solution, and the tumor isolated using a sterile condom or glove that is sutured in place using 3-0 silk sutures to avoid spillage of cells during penile manipulation. It is recommended to outline the planned incision with a marking pen, providing an adequate minimum 1-cm margin (Fig. 65.9). A tourniquet is placed around the base of the penis to minimize blood loss, especially during sectioning of the cavernous bodies (Fig. 65.10). The incision is circumferentially carried through the skin, dartos (superficial fascia), and Buck fascia (deep fascia) to the tunica albuginea. On the dorsum of the penis, the dorsal neurovascular bundle is individually ligated and sectioned with absorbable sutures (see Fig. 65.10). As the resection is carried ventrally, a 1-cm stump of the urethra is created (Fig. 65.11). The corpora cavernosa are sharply divided down to the urethra and the central cavernosal arteries ligated on each side (Figs. 65.12 and 65.13). The corporal ends are closed with 2-0 absorbable sutures, incorporating Buck fascia and tunica albuginea (Fig. 65.14). The penile base tourniquet is then released, and all minor vessels are fulgurated or ligated until adequate hemostasis is obtained. The urethra is spatulated to prevent stenosis of the neomeatus (Fig. 65.15) and sutured to the ventral penile skin (Fig. 65.16). A 16Fr Foley catheter is left indwelling for 48 hours (11).

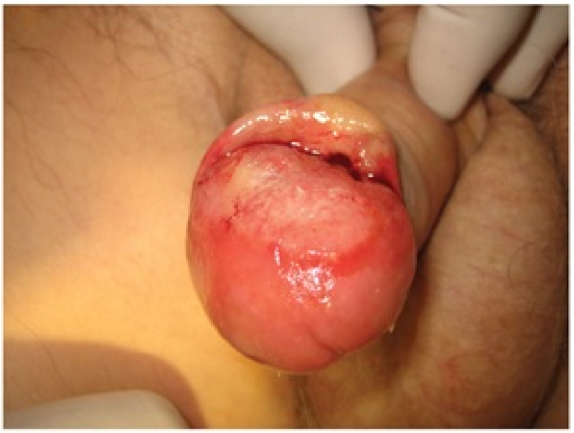

FIGURE 65.8 Ulcerated lesion of the glans and sulcus requiring partial penectomy.

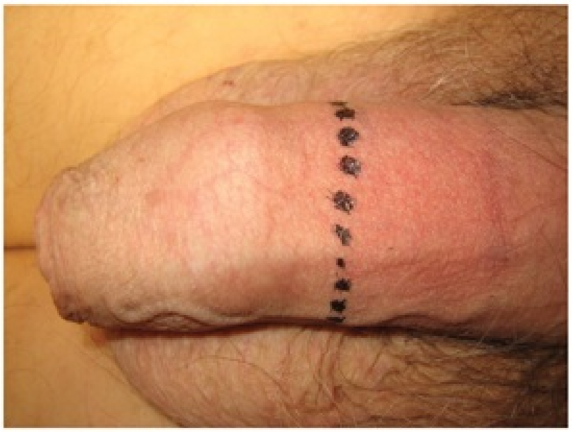

FIGURE 65.9 The incision is outlined with a marking pen, providing an adequate minimum 1-cm margin.

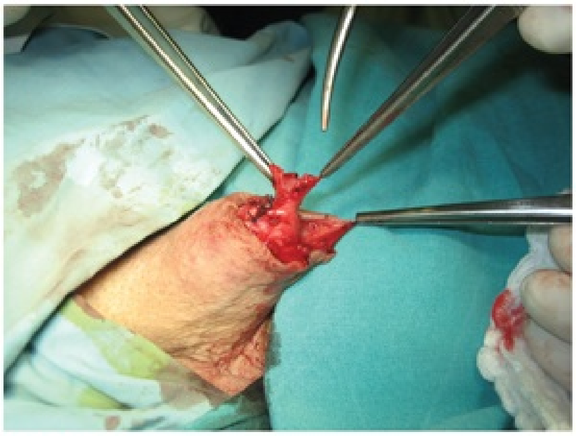

FIGURE 65.15 The urethra is spatulated to prevent stenosis of the neourethra.

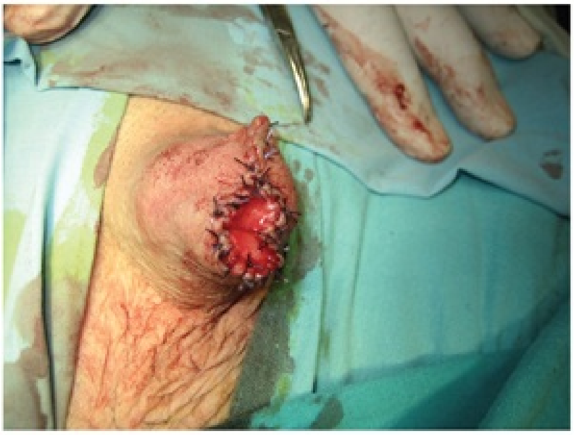

FIGURE 65.16 The urethra is sutured to the ventral penile skin.

Total Penectomy

Total penectomy is indicated for proximal tumors that are locally advanced and sometimes associated with painful local symptoms. Contrary to partial penectomy, the patient is placed in low lithotomy position. The lesion is prepared and covered in a similar fashion to the partial penile resection. Again, antibiotics are tailored to preoperative urine and penile tumor cultures. During total penectomy, an incision is carried out circumferentially at the base of the penis with extension into the median raphe of the scrotum (Fig. 65.17). The suspensory ligament of the penis is identified and divided at the base of the penis. The dorsal vein and penile arteries are ligated and divided. The penis is then reflected cephalad, the Buck fascia is opened ventrally (see Fig. 65.17), and the urethra is dissected free from the corpora cavernosa (Fig. 65.18). The urethra and corpus spongiosum are mobilized from the corpora between clamps and divided (Fig. 65.19). At the distal bulbar region, the urethra is divided, preserving enough length for construction of a perineal urethrostomy. The urethral remnant is passed through the scrotum to the midline perineum and the urethrostomy is performed. The corpora cavernosa are dissected up to the ischiopubic rami, clamped, sectioned, and sutured (11) (Figs. 65.20 and 65.21).

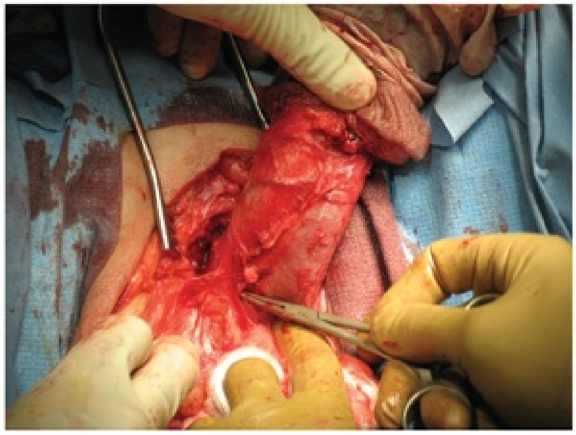

FIGURE 65.17 The penis is then reflected cephalad, the Buck fascia is opened ventrally. Note the extent of the incision.

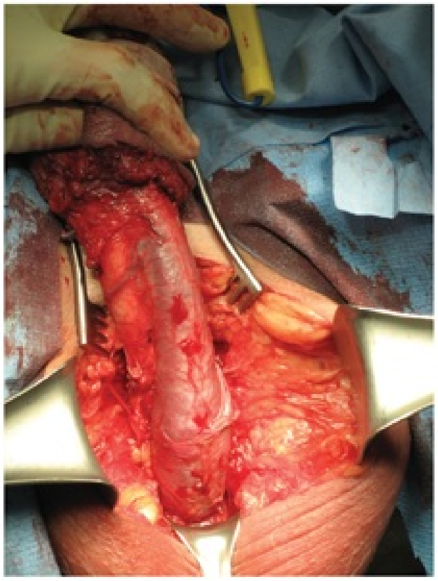

FIGURE 65.18 The urethra is dissected free from the corpora cavernosa. Again, note the extent of the incision.

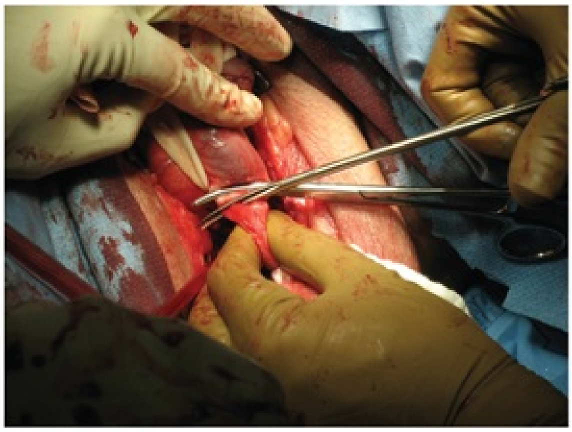

FIGURE 65.19 The urethra and corpora spongiosum are mobilized from the corpora between clamps and divided.

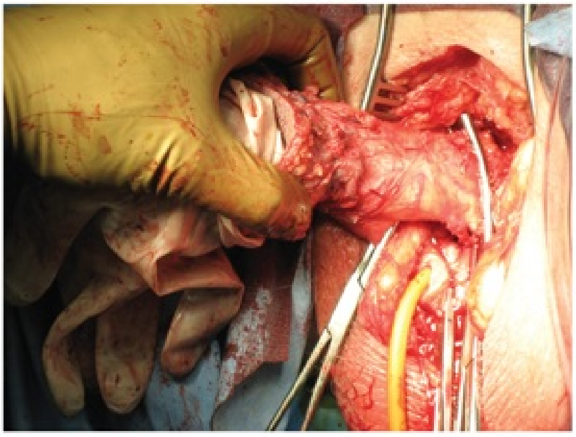

FIGURE 65.20 The corpora cavernosa are dissected up to the ischiopubic rami, clamped, and sectioned.

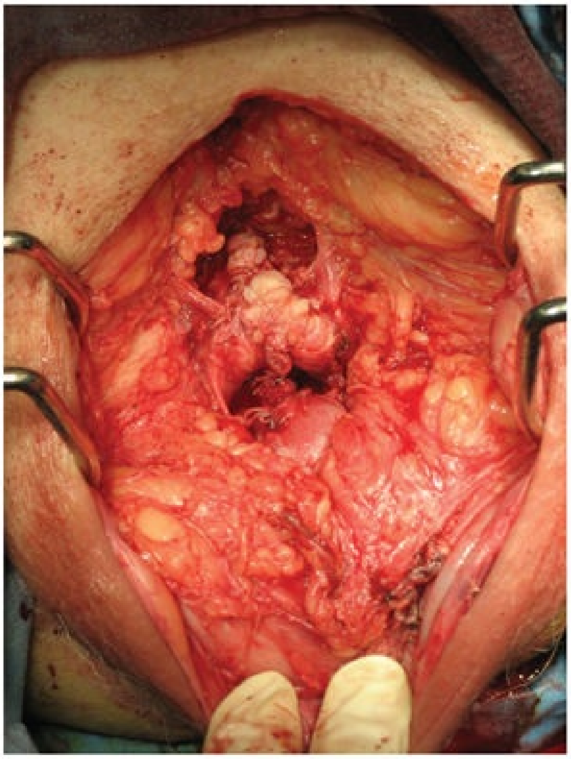

FIGURE 65.21 The corpora cavernosa are sutured.

The perineal urethrostomy is constructed by removing a 1-cm ellipse of skin and subcutaneous tissues from the midperineum, equidistant from the anus and scrotum (Fig. 65.22). Urethral angulations are to be avoided when the urethra is drawn into the perineal incision. The urethra is then spatulated dorsally, and a V-inlay of skin can be created and sutured watertight to the urethra using 3-0 absorbable sutures. An 18Fr Foley catheter is inserted, and drains are left to drain each side of the scrotum. The scrotal incision is closed transversally to allow elevation of the scrotum away from the perineal urethrostomy using 3-0 absorbable sutures (Fig. 65.23). The Foley catheter is left indwelling for at least 5 days and drains removed within 48 hours (11) (Fig. 65.24).

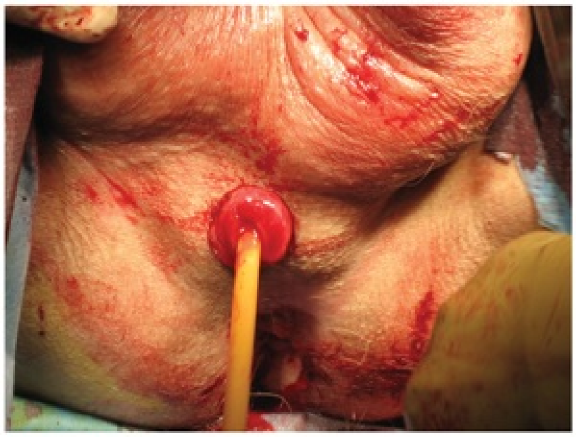

FIGURE 65.22 Construction of the perineal urethrostomy equidistant from the anus and scrotum.

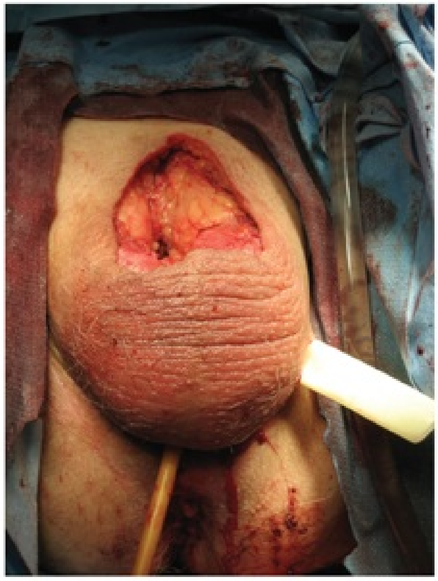

FIGURE 65.23 The scrotal incision will be closed transversally to allow elevation of the scrotum away from the perineal urethrostomy.

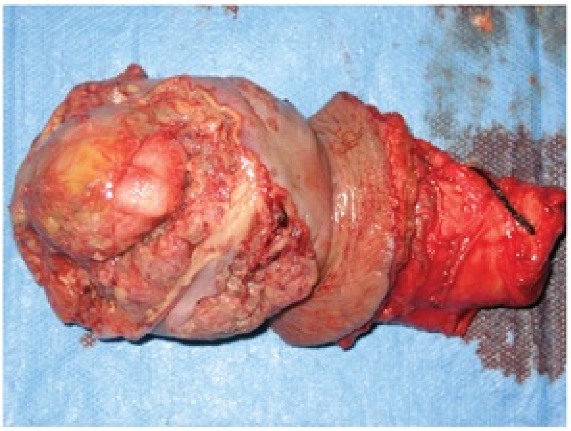

FIGURE 65.24 Resected specimen.

In rare cases, the site of attachment of the corpus cavernosum to the pubic bone may need to be resected in order to achieve a clear margin. Additionally, lesions involving the perineum and anterior abdominal wall may need total emasculation, and the defect covered with a myocutaneous flap (44). Total phallic reconstruction after total penectomy is an option for motivated patients after a psychological evaluation and proper counseling, for it carries a high rate of complications (24,25).

POSTOPERATIVE MANAGEMENT AND COMPLICATIONS

Early complications after partial or total penectomy include wound infection, hematoma, and stricture of the neomeatus. The most common complication of partial and total penectomy is meatal stenosis (Fig. 65.25). The V-inlay technique has been used to decrease the stenosis at the urethral opening. Adequate irrigation of the urethral stump at the time of neomeatus reconstruction is key to avoid ischemic complications. Stricture of the neomeatus can be managed by simple (self) dilatation or meatotomy, whereas recurrent strictures may need some form of meatoplasty.

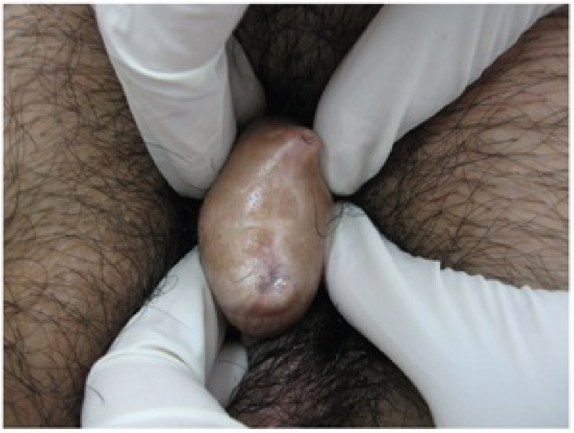

FIGURE 65.25 Meatal stenosis after partial penectomy. Purulent discharge is noted.

As mentioned earlier, patients with partial and total penectomy suffer psychological and physical trauma that can adversely affect their quality of life; however, there is little published on this subject. For previously potent men, erectile function is usually preserved and a normal sense of orgasm and ejaculation can persist after partial penectomy. Patients with total penectomy can sometimes reach orgasm if the sensitive areas around the scrotum are stimulated (11,39).

MANAGEMENT OF REGIONAL LYMPH NODES

General Considerations

The single most important prognostic factor for cancer-specific survival is the presence of nodal metastases (46). Nevertheless, patients with a low number of positive nodes can still be cured with an adequate surgical approach (47). In pN1 (intranodal metastasis in a single inguinal lymph node) patients with surgically resected inguinal lymph nodes, 5-year survival rates are around 62% (48).

Like all SCCs, penile cancer has a propensity for locoregional dissemination, whereas hematogenous dissemination in the absence of lymphatic invasion is very uncommon. Metastases in penile carcinoma occur in a sequential manner, with tumor cells embolizing through first-echelon superficial regional inguinal nodes and then on to second-echelon deep pelvic nodes (11).

The statistical probability of inguinal micrometastases can be estimated using risk group stratification or a risk calculation nomogram (19). However, patients with no evidence of tumor on preoperative physical examination, ultrasound or fine needle aspiration cytology are estimated to have an approximately 20% chance of harboring occult metastases, and unfortunately, contemporary imaging with CT scan or MRI are not able to reliably detect minimal metastatic disease (11,49). Therefore, early detection and treatment of metastases may be of great importance in selected patients.

Founded on original studies by Ramón Cabañas (50) at Memorial Sloan Kettering Cancer Center, the detection of these metastases in patients with cN0 disease has changed in the last 20 years since the introduction of dynamic sentinel node biopsy (DSNB) for cN0 cases (51). This evolving technique has the potential to identify early metastatic disease and at the same time spare the side effects of groin dissection in patients who are node-negative. Unlike other genitourinary tumors (renal, upper tract urothelial), in which nodal involvement is often synonymous with incurable disease, nodal metastases in penile cancer are potentially curable, even in patients with locally advanced lymphatic involvement (11).

The management of cN0 cases has shifted from observation to risk adapted inguinal LND and DSNB instead of prophylactic inguinal LND (52).

Since DSNB introduction in 1994, improvement of cancer-specific survival has been observed in cN0 cases of SCC of the penis after adjusting for pathologic T stage and grade, with the most probable reason being the introduction of DSNB and early treatment of microscopic disease (48). However, the probability of false-negative results underlines a strict follow-up scheme in node-negative patients after DSNB. Patients who cannot comply with a strict follow-up should not be submitted to DSNB.

According to the recommendations formulated and discussed at the first International Consultation on Penile Cancer, ultrasound-guided fine needle aspiration cytology is indicated for both palpable and nonpalpable inguinal nodes. If the findings confirm LNM, complete inguinal LND is indicated in the absence of distant spread. In patients with nonpalpable inguinal nodes, if the ultrasound-guided fine needle aspiration cytology findings are negative for tumor, DSNB with lymphoscintigraphic and blue dye localization can be performed if the equipment and technical expertise are available (19) (Figs. 65.26 to 65.28). In the absence of DSNB expertise, sentinel node biopsy based on the anatomic position can be performed, provided the patient is willing to accept the potential false-negative rate of 25% (50).

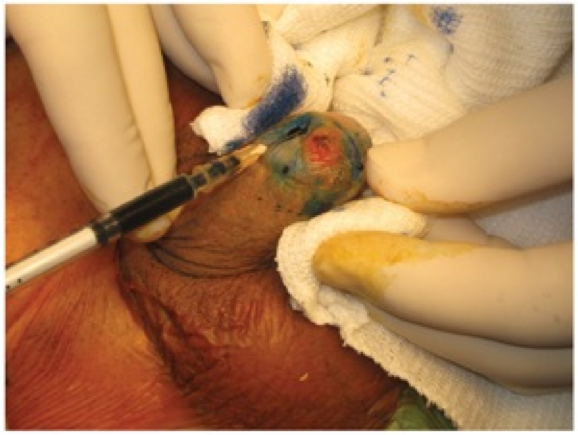

FIGURE 65.26 Perilesional injection of blue dye during DSNB.

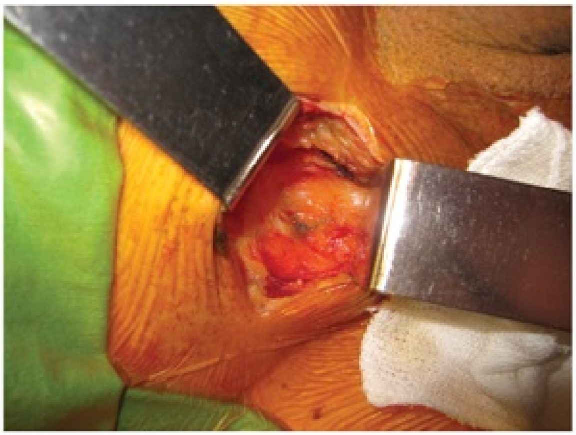

FIGURE 65.27 Tracing of blue dye into first echelon right groin lymphatics.

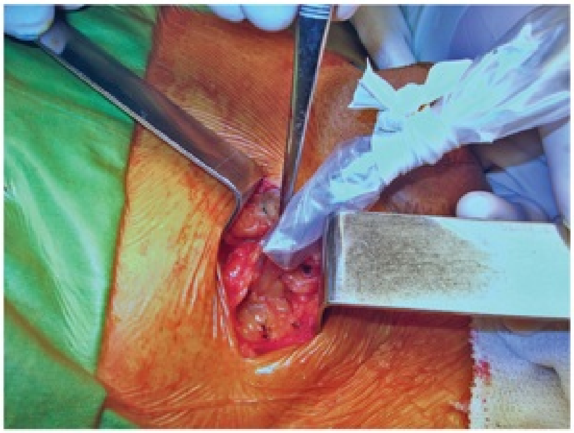

FIGURE 65.28 Lymphoscintigraphic (portable gamma probe) and blue dye localization of sentinel node during DSNB.

DSNB is usually performed at the time of the penile tumor removal. Frozen section histologic examination can be used during sentinel node biopsy or limited inguinal LND. If the results are positive, complete inguinal LND can be performed immediately. Although some surgeons advocate inguinal LND at the time of penectomy, others advocate avoiding immediate groin dissection wishing not to inflict its potential morbidity (cellulitis, flap necrosis, lymph edema) without the certainty of a therapeutic effect (19).

In patients with cytologically or histologically proven inguinal metastases, complete inguinal LND should be performed ipsilaterally. Because there is a 60% rate of bilateral disease because of the rich lymphatic communications at the base of the penis, patients with histologically confirmed inguinal metastases involving two or more nodes on one side, contralateral limited inguinal LND is recommended. Frozen-section analysis can be performed, with complete inguinal LND if the frozen-section analysis findings are positive (19).

PLND is recommended if two or more proven inguinal metastases, grade 3 tumor in the lymph nodes, extranodal extension, or large (2 to 4 cm) inguinal nodes are present, or if the femoral (Cloquet) node is involved. Performing inguinal LND before PLND is preferable because PLND can be avoided in patients with minimal inguinal metastases, thus avoiding the greater risk of chronic lymphedema (19). It is very unusual for metastatic cells to skip inguinal nodes into pelvic or other node stages (11).

The statistical probability of inguinal micrometastases can also be estimated using risk group stratification or a risk calculation nomogram. Surveillance is recommended if the nomogram probability of positive nodes is <10%. Surveillance is also recommended if the primary lesion is grade 1, pTis, pTa (verrucous carcinoma), or pT1, with no lymphovascular invasion, and clinically nonpalpable inguinal nodes, but only provided the patient is willing to comply with regular follow-up. In the presence of factors that impede reliable surveillance (social reasons, obesity, previous inguinal surgery, or radiotherapy) prophylactic inguinal LND might be a preferable option.

In the intermediate-risk group (nomogram probability 10% to 50%, primary tumor grade 1-2, T1-T2, cN0, no lymphovascular invasion), surveillance is acceptable, provided the patient is informed of the risks and is willing and able to comply. If not, DSNB or limited (modified) inguinal LND should be performed.

In the high-risk group (nomogram probability >50% or primary tumor grade 2-3 or T2-T4 or cN1-N2, or with lymphovascular invasion), bilateral inguinal LND should be performed (13).

The fact that there are no curative chemotherapy regimens currently available for the treatment of disseminated disease enhances the appeal of a preemptive surgical approach to patients at risk for metastatic penile cancer. Although the argument for early groin dissection is based on a relatively limited number of patients from retrospective studies, it makes intuitive sense that the early intervention of minimal metastatic disease would lead to an improved probability of survival.

Patients with grossly enlarged iliac nodes in CT or MRI, or patients with fixed or recurrent inguinal nodes are candidates for neoadjuvant chemotherapy and the response assessed before proceeding with pelvic and/or inguinal LND (17,19).

Inguinal Lymph Node Dissection Technique

As described by Dr. Willet Whitmore at Memorial Sloan Kettering Cancer Center, the inguinal LND is characterized by generation of thick skin flaps to reduce the perioperative morbidity of leg lymphedema (11).

The blood supply to the skin of the inguinal region derives from branches of the common femoral artery—the superficial external pudendal, superficial circumflex iliac, and superficial epigastric arteries. Complete inguinal dissection necessitates ligation of these branches. Viability of the skin flaps raised during the dissection depends on anastomotic vessels in the superficial fatty layer of Camper fascia that course lateral to medial along the natural skin lines. Because lymphatic drainage of the penis to the groin runs beneath Camper fascia, this layer can be preserved and left attached to the overlying skin when the superior and inferior skin flaps are fashioned. On the basis of this anatomy, a transverse skin incision least compromises this blood supply, and skin flaps are developed in the plane just beneath Scarpa fascia.

The patient is positioned supine in the frog leg position. Although a variety of incisions have been described, an oblique incision is made three fingerbreadths below the inguinal ligament (Fig. 65.29). As mentioned, thick skin flaps are developed. The boundaries of the dissection are superiorly, the inguinal ligament; laterally, the Sartorius muscle; inferiorly, the base of the femoral triangle; and medially, to the adductor longus muscle (Fig. 65.30). The saphenous vein is identified at the base of the femoral triangle, ligated, and divided. Small branches of the femoral artery and vein as well as lymphatic vessels are meticulously tied and clipped as the dissection proceeds toward the saphenofemoral junction and the fossa ovalis. The undersurface of the inguinal ligament is dissected. There is no need to dissect beneath the femoral vessels because all nodal tissue rests above. The node package is usually delivered when the saphenous vein is ligated as it enters the femoral vein. The Sartorius muscle is sharply divided from its attachment at the anterior iliac spine, mobilized on its fascial pedicle, rotated and sutured to Cooper ligament in order to cover the femoral vessels. Closed suction drain is placed above the Sartorius muscle and brought out through a separate stab wound. Compression stockings and/or intermittent pneumatic compression devices are routinely used in the perioperative period. Early ambulation with strict orders to avoid the sitting position is recommended

(11).

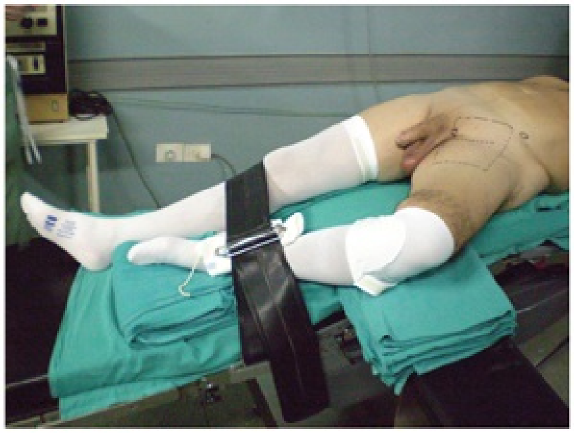

FIGURE 65.29 The patient is positioned supine in the frog leg position with compressive stockings. A curved transverse incision is made three fingerbreadths below the inguinal ligament.

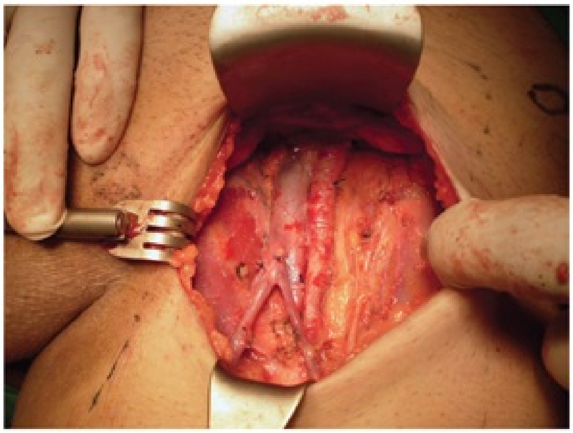

FIGURE 65.30 The boundaries of the dissection are superiorly, the inguinal ligament; laterally, the sartorius muscle; and inferiorly, the base of the femoral triangle and medially, to the adductor longus muscle. In this case, the saphenous vein was preserved.

Catalona (53) has described a modified groin dissection with a shorter skin incision, with the aim of decreasing postoperative complications in patients with clinically negative inguinal lymph nodes. The author originally described the technique in six patients, in whom the lateral and caudal extents of nodal excision were reduced, and the saphenous veins preserved. Nine years later, a follow-up study of the technique in a total of nine patients was presented, with none of them having disease recurrence despite three of them had positive nodes. Two patients developed skin flap necrosis, one had prolonged lymphatic drainage, and one a delayed groin lymphocele and cellulitis (54). Some authors have questioned the reliability of this technique, on the grounds that understaging may occur. Lopes et al. (55) reported two inguinal lymph nodes recurrences within the operative field in 13 patients with clinically negative inguinal nodes who underwent the modified technique.

Therefore, the lymph node packet can be analyzed by frozen section, and if it confirms metastatic disease, then a complete inguinal lymphadenectomy can be performed. A single photon emission CT study has shown that all sentinel nodes were located in the superior and central inguinal zones, with most found in the medial superior zone. No lymphatic drainage was observed from the penis to the two inferior regions of the groin, and no direct drainage to the pelvic nodes was visualized (56). With the advent of DSNB, the future of this modified groin dissection seems to be limited to centers without such technology (11).

There is a high incidence of complications after inguinal LND. The most common complications are wound infection (10% to 20%), skin necrosis with or without wound dehiscence (14% to 65%), lymphocele/seroma (19% to 45%), and lymph edema (2% to 100%) (Fig. 65.31). That is why wound should be closely monitored with early therapeutic antibiotics prescribed in case of wound cellulitis (11).

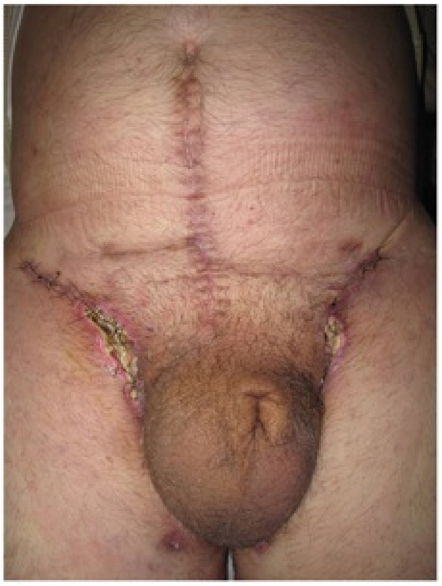

FIGURE 65.31 Wound dehiscence and infection in a patient with simultaneous bilateral inguinal LND.

With the objective of decreasing cumbersome complications, different centers started to develop a minimally invasive inguinal LND (57–59). Mathevet et al. (60) have presented an interesting experience with a gasless endoscopic approach for the inguinal dissection in vulvar and distal vaginal carcinoma. This is probably the most extensive experience for the inguinal endoscopic approach, and they reported low morbidity outcomes with a single operative vascular lesion. They verified 25% of perioperative complications, represented by lymphoceles observed in seven patients.

In the urologic field, Bishoff et al. (61) presented the initial experience with inguinal endoscopic dissection for penile carcinoma; they described a subcutaneous modified inguinal lymphadenectomy in two cadaveric models and one patient with stage T3N1M0 penile carcinoma. This initial experience was not completed due to the presence of a large lymph node that precluded the dissection.

Tobias-Machado et al. (62) reported a clinical experience with their video endoscopic inguinal lymphadenectomy (VEIL) technique in 10 patients with clinically negative inguinal nodes. Based on risk factors for lymph node metastasis, the authors performed the standard open surgery in one groin and a video-assisted surgery in the contralateral side. Despite the small number of patients, the authors noted a significant decrease in cutaneous complications and overall morbidity with VEIL. The mean number of retrieved and positive lymph nodes was similar for the two techniques. At a mean follow-up of 18.7 months, no signs of recurrence or disease progression were noted (62).

One year later, Sotelo et al. (58) described a standardized technique of endoscopic groin dissection for penile carcinoma with a preoperative Doppler ultrasound mapping of the inguinal region (60). More recently, Josephson et al. (63) reported a robotic-assisted endoscopic inguinal LND in a 37-year-old patient with palpable inguinal nodes despite oral antibiotics, arguing how robotic technology potentially allowed for an ergonomic platform and dexterity.

Matin et al. (64) prospectively determined the oncologic adequacy of robotic assisted VEIL by having an independent surgeon perform a separate open incision at the conclusion of the robotic assisted VEIL in 19 groins. The verifying surgeon confirmed that 18 of 19 inguinal fields had an adequate inguinal LND.

In summary, minimally invasive inguinal LND seems to be less morbid and early oncologic results are encouraging. However, clinical experience is still limited (65).

FOLLOW-UP

Recommendations for follow-up are tailored to primary tumor and lymph node status characteristics. Patients with penile-preserving treatment are recommended to be followed every 3 months for the first 2 years and every 6 months until year 5, with regular physician or self-examination. This frequency decreases to every 6 months during the first 2 years and yearly up to year 5 in patients with penile amputation.

Patients whose inguinal lymph nodes were observed or those whose nodes were positive are recommended to be followed every 3 months for the first 2 years and every 6 months until year 5 with regular physician or self-examination and groin ultrasound with fine needle aspiration biopsy. In those with pN0, the follow-up frequency decreases to every 6 months during the first 2 years, and yearly up to year 5, again, with regular physician or self-examination and groin ultrasound with fine needle aspiration biopsy (17).

CONCLUSIONS

Risk factors for penile cancer are known, and prophylactic measures should be taken. Early surgery is essential in the diagnosis and treatment of the penile lesion and the management of the inguinal and/or pelvic nodes. Effective local control of carcinoma in situ or Ta tumors can be achieved by excision, local ablation therapies, and Mohs microsurgery. As the T stage increases, surgical resection with circumcision, partial penectomy, or total penectomy plays an increasingly important role in the management of penile cancer. Regional lymph nodes can be enlarged because of inflammation or early metastatic disease. Lymphadenectomy is an integral part of the management of penile cancer because early dissection of involved lymph nodes improves survival. Therefore, a strong argument for aggressive diagnosis with aspiration cytology, DSNB, or prophylactic groin dissection can be made for patients with high-grade invasive primary tumors as opposed to the protracted administration of antibiotics and surveillance approach. Careful follow-up is necessary and should be tailed to patient and tumor characteristics. For patients with bulky groin metastases, neoadjuvant chemotherapy might be playing an increasing role. Surgical intervention plays no role in the treatment of distant metastases from penile cancer.

CHAPTER 66 ■ INGUINAL LYMPHADENECTOMY FOR PENILE CARCINOMA

JACK W. LAMBERT AND MICHAEL B. WILLIAMS

Penile carcinoma is a rare malignancy in the modern Western world, with an incidence reported between 0.1 and 0.9 new cases per 100,000 males per year (1). For all patients presenting with squamous cell carcinoma (SCC) of the penis, approximately 50% have lymphatic involvement at the time of diagnosis. As with other SCCs, penile cancer typically spreads in a predictable manner to regional lymph nodes before distant metastases occur. Furthermore, lymph node involvement directly correlates with the grade, T stage, and lymphovascular invasion of the primary tumor (2). The progression of lymph node involvement is stepwise, with the superficial inguinal lymph nodes (ILNs) being the first site of metastasis, followed by the deep ILNs below the fascia lata and finally the pelvic lymph nodes (most commonly the obturator and external iliac nodes). Because the penile lymphatic drainage is bilateral, the minimal dissection should be a bilateral superficial lymphadenectomy, although there are rare exceptions to this rule. Based on intraoperative frozen sections, a more extensive lymphadenectomy may be required if the superficial ILNs are positive for metastases, and this may include deep ILNs and pelvic LNs.

The most important prognostic factors for invasive penile SCC remain the presence and extent of lymph node metastases (3). The TNM staging was updated in 2010 (Table 66.1) by the American Joint Committee on Cancer (AJCC), and there were significant changes made in nodal staging including extranodal extension (ENE) conferring N3 disease (4). Regional lymph node metastases undoubtedly confer a worse prognosis, although long-term survival can approach 60% with aggressive surgical extirpation. However, if the pelvic nodes are involved with SCC of the penis, 5-year survival rates are dismal and some report this rate as low as 0% (5). For patients with fixed or bulky lymphadenopathy, neoadjuvant chemotherapy regimens such as paclitaxel + cisplatin + 5FU or paclitaxel + ifosfamide + cisplatin have been used in recent trials (6,7). One recent study in men with N2 and N3 disease without distant metastasis completed four cycles of neoadjuvant chemotherapy, allowing 73% to undergo surgical extirpation and 30% remained alive and free of recurrence at a median follow-up of 34 months (8).

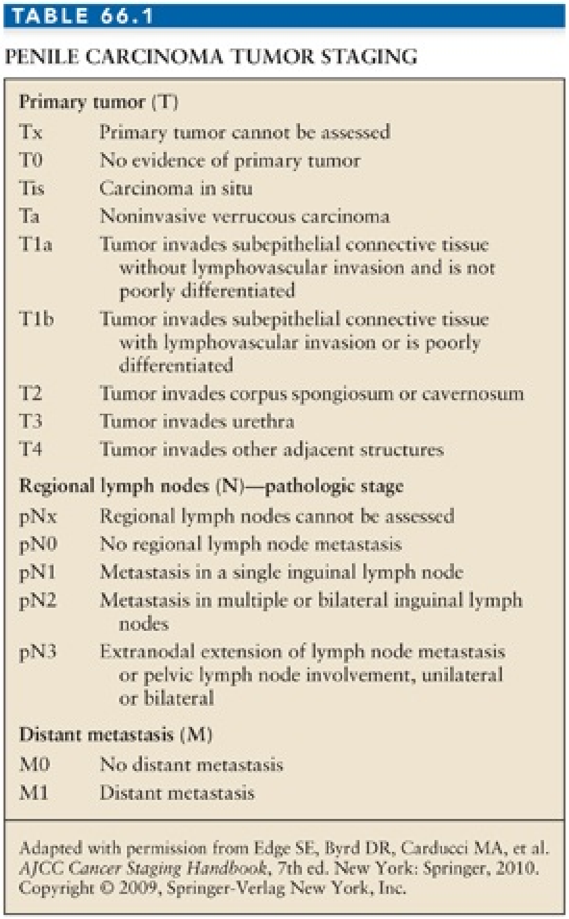

TABLE 66.1

PENILE CARCINOMA TUMOR STAGING

Primary tumor (T)	
Tx	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
Ta	Noninvasive verrucous carcinoma
T1a	Tumor invades subepithelial connective tissue without lymphovascular invasion and is not poorly differentiated
T1b	Tumor invades subepithelial connective tissue with lymphovascular invasion or is poorly differentiated
T2	Tumor invades corpus spongiosum or cavernosum
T3	Tumor invades urethra
T4	Tumor invades other adjacent structures
Regional lymph nodes (N)—**pathologic stage**	
pNx	Regional lymph nodes cannot be assessed
pN0	No regional lymph node metastasis
pN1	Metastasis in a single inguinal lymph node
pN2	Metastasis in multiple or bilateral inguinal lymph nodes
pN3	Extranodal extension of lymph node metastasis or pelvic lymph node involvement, unilateral or bilateral
Distant metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis

DIAGNOSIS AND CLINICAL STAGING

Although penile carcinoma is diagnosed by clinical exam, there are several adjunctive tools that have evolved to assist with staging and improve ultimate management for patients. These include computerized tomography (CT), magnetic resonance imaging (MRI), fluoride positron emission tomography (PET) scans, lymphangiography, and sentinel node biopsies. Lymphangiograms, however, have fallen out of favor with the recent advances in imaging and are now rarely used.

A proper clinical exam is crucial in identifying inguinal lymphadenopathy. When assessing the inguinal nodes, the patient should be in the “frog-leg” position, and the examiner stands on the ipsilateral side of the groin being examined. A manual exam should denote the location of any lymphadenopathy found and its relation to the femoral vessels. Palpable nodes are often documented as “shoddy,” “mobile,” “bulky,” or “fixed.” The most important delineation is whether or not the lymph nodes are amenable to surgical resection (i.e., are they fixed?). Obesity is commonly a limiting factor when performing an inguinal exam, and imaging is mandatory to accurately assess these patients. Approximately 25% of patients with clinically negative nodes will harbor metastatic disease at the time of inguinal lymph node dissection (ILND), whereas up to 70% with palpable lymphadenopathy (LAD) will have metastatic nodes (9).

Although CT and MRI have been used routinely to better stage the depth of invasion and assess for lymphadenopathy, newer imaging studies have improved on this task. (18)-Fluoride PET/CT has demonstrated a sensitivity of 80% and specificity of 100% for detecting lymph node metastasis. However, as with other imaging modalities, the major limitation is with identifying micrometastases, which are often missed. When used in conjunction with lymphotrophic nanoparticles, MRI has demonstrated a sensitivity and specificity for diagnosing positive lymph nodes in up to 100% and 97%, respectively (10).

Biopsy of the first order lymph node draining the penis, known as the sentinel lymph node, has long been sought after for identifying the extent of disease in penile carcinoma. Various modalities have been used over the last two decades including blue dye and nuclear scintigraphy. Recently, there has been a resurgence of dynamic sentinel node biopsies (DSNB), as it currently has improved accuracy in diagnosing metastatic inguinal lymph nodes. In a recent article, 264 patients who were all clinically node negative (cN0) had ultrasound-guided DSNBs, which was 95% sensitive for detecting metastatic penile carcinoma. This was done by injecting technetium-99m 4 hours prior to surgery and then injecting 1 mL of patent blue dye intradermally into the proximal penile shaft 1 hour prior to surgery. A gamma camera was then used to detect the highest amount of active radiotracer in the inguinal basins and this sentinel node was then excised (11). Negative ILNDs have been reported as high as 77% in patients with invasive SCC of the penis, and the use of DSNB may obviate unnecessary surgery in appropriately selected patients that are cN0 (12). In a meta-analysis of 18 studies, the highest sensitivity for DSNB was 92%, and this was achieved when using technetium radiotracers and blue dye for sentinel node mapping (13). DSNB can be a labor-intensive evaluation and the best results are in centers that have high volumes of penile carcinoma.

INDICATIONS FOR SURGERY

The primary risk factors for the development of inguinal lymph node metastasis remain tumor grade, depth of invasion (stage), lymphovascular invasion (LVI), and clinically palpable nodes (cN1). One recent study demonstrated that 68% of high-grade tumors, 49% with a depth of invasion >5 mm, 63% with LVI, and 54% who were cN1 had metastatic disease at the time of ILND (2). Others have reported that even grade 1 tumors can have a nearly 30% incidence of metastatic nodal involvement and those with T2 disease or higher can have up to a 60% rate of positive nodes (14,15). Nomograms have also been developed to help predict the risk of metastatic disease using the aforementioned parameters (16).

As a general rule, it is still advised that all patients with penile carcinoma receive 4 to 6 weeks of antibiotic therapy prior to ILND if palpable lymph nodes are identified, as up to 50% of these are reactive, inflammatory nodes at the time of diagnosis (17). Antibiotic therapy, therefore, may help distinguish pathologic from inflammatory nodes, and it also reduces postoperative infectious complications after inguinal node dissections.

The most recent European Association of Urology (EAU) guidelines from 2009 have published several recommendations for the management of regional lymph nodes. All of the recommendations listed are grade B from good clinical studies without randomization. Active surveillance is appropriate for patients with no palpable LAD and Tis, TaG1, and T1G1 disease, although close follow-up and clinical exams should be performed every 2 to 3 months. For those without LAD and T1G2 disease or higher, they advocate performing a DSNB followed by ILND if the DSNB is positive for malignancy. For patients with palpable LAD, either ultrasound-guided fine needle aspiration (FNA) or DSNB can be performed, followed by ILND if positive versus upfront ILND in those deemed to be higher risk. Pelvic LND is recommended for those with extranodal metastasis, node of Cloquet involvement, or two or more inguinal node metastases. Adjuvant chemotherapy is appropriate for patients with pN2 or pN3 disease after ILND, and neoadjuvant chemotherapy is appropriate for patients with fixed or relapsed LAD (6). A workflow outline for the management of penile cancer from Protzel et al. (18) is outlined in Figure 66.1.

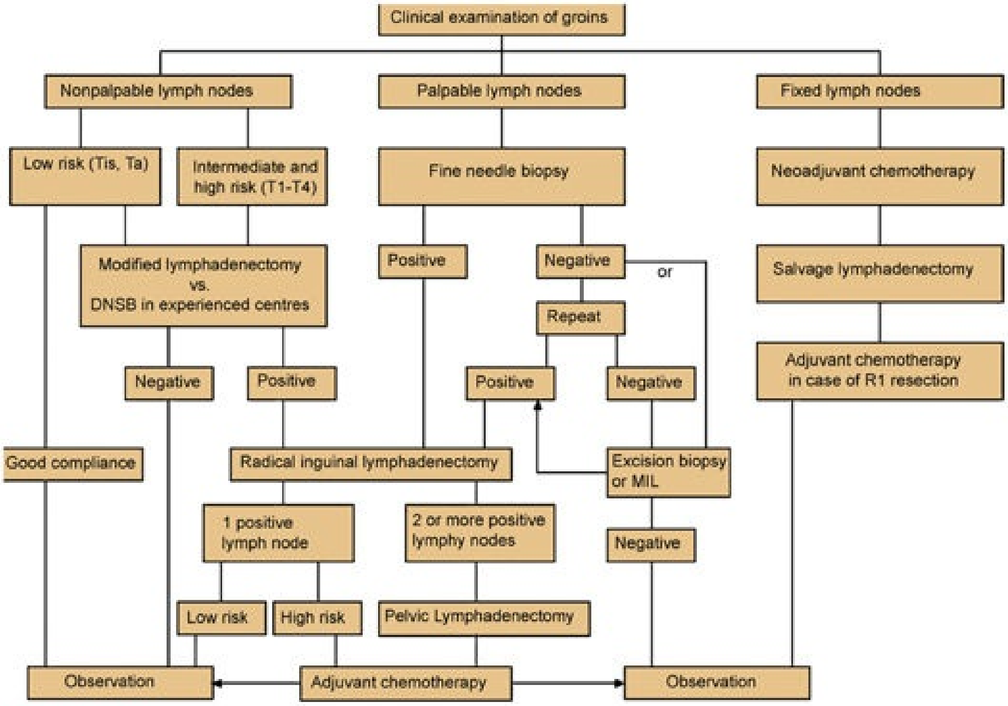

FIGURE 66.1 Workflow for the management of penile cancer patients regarding the inguinal lymph nodes based on this review. MIL, modified inguinal lymphadenectomy. (Reprinted with permission from Protzel C, Alcaraz A, Horenblas S, et al. Lymphadenectomy in the surgical management of penile cancer. *Eur Urol* 2009;55(5):1075–1088. Copyright © 2009, Elsevier. www.europeanurology.com.)

However, there are also some urologists who advocate upfront ILND in patients with high-risk, clinically node-negative disease without performing DSNB first. Due to the pitfalls of limited sampling, as with any biopsy, sentinel node biopsies are not completely accurate. Particularly, it may not detect patients with micrometastatic SCC of the penis that could be potentially cured by ILND. In a retrospective study comparing patients who had cT2-3N0M0 penile carcinoma, those with an upfront ILND had a 3-year overall survival (OS) of 84%, compared to 35% for those who were surveyed until they developed clinically palpable nodes (19).

Chemotherapy in SCC of the penis has only been shown to improve outcomes in the neoadjuvant setting with platinum-based regimens. Employment of this should be in patients with clinical evidence of inguinal node disease >4 cm in size. As mentioned earlier, Pagliaro et al. (8) demonstrated that of patients receiving TIP (paclitaxel, ifosfamide, and cisplatin) for four cycles, over 70% were able to undergo surgical consolidation. In this phase II trial, 50% had a complete or partial response. More importantly, 30% remained alive at a median follow-up of 34 months, which is almost double that of historical data (20). As for patients who are found to have pN2/3 disease post ILND, adjuvant chemotherapy with a similar regimen should be considered. However, this is an extrapolation based on data in the neoadjuvant setting.

PERIOPERATIVE PLANNING AND CARE

1. Metastatic workup should include the following:
    a. CT pelvis or abdomen/pelvis with intravenous (IV) contrast
    b. Chest X-ray (CXR), CT chest if pathologic abdominal findings
    c. Liver function tests
    d. Bone scan if clinically indicated
2. Four to 6 weeks of preoperative antibiotics covering skin flora (e.g., cephalexin)
3. One to 2 g IV cefazolin or 600 to 900 mg IV clindamycin within 1 hour of incision and should be continued for 24 hours perioperatively
4. Adequate hydration
5. Pneumatic compression stockings and 5,000 units of subcutaneous heparin q8 to 12 hours postoperatively
    a. Consider temporary prophylactic Lovenox for a longer duration in higher risk patients (prior deep venous thrombosis [DVT] or immobilization).
6. Continuous suction Jackson-Pratt (JP) drains should be placed in the inguinal beds until minimal output (<30 mL/day) to mitigate the risk of seroma formation, abscess, and wound necrosis.

SURGICAL ANATOMY

The extent of an inguinal lymphadenectomy continues to be of controversy. Although some centers still perform radical ILND in all patients with penile carcinoma, there is compelling data to suggest that a modified ILND may be more appropriate in correctly selected patients, particularly those who are cN0.

The superficial inguinal region is divided into four quadrants with the midpoint at the saphenofemoral junction. These quadrants all contain lymph nodes, which are known as the superomedial, superolateral, inferomedial, and inferolateral nodes (Fig. 66.2) (18). The superolateral nodes are near the superficial circumflex vein, the superomedial nodes are in proximity to the superficial external and superficial epigastric veins, and the inferomedial nodes are centered around the greater saphenous vein. It is crucial when dissecting in these areas that lymphatics and venous structures are meticulously dissected and ligated with permanent suture (e.g., 3-0 silk) to minimize the risk of lymphocele formation. Smaller lymphatics and veins can safely be divided using a LigaSure device or vascular clips.

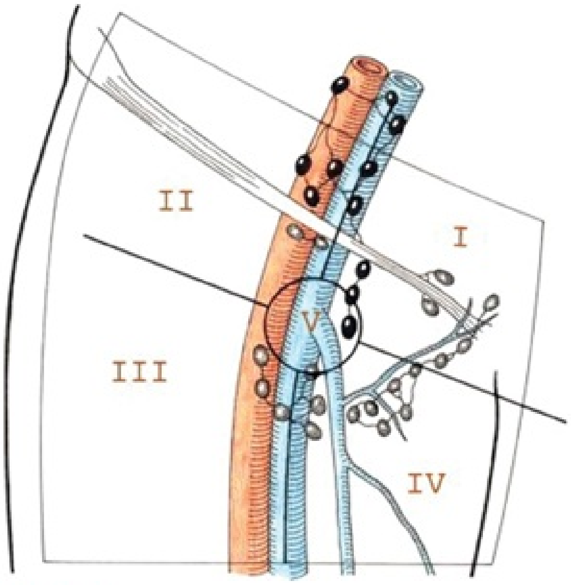

FIGURE 66.2 Lymphatic drainage regions of the inguinal-femoral canal. The region is divided into five zones: one central zone (*V*), superior (*I*) and inferior (*IV*) medial zones, and superior (*II*) and inferior (*III*) lateral zones. (Reprinted with permission from Protzel C, Alcaraz A, Horenblas S, et al. Lymphadenectomy in the surgical management of penile cancer. *Eur Urol* 2009;55(5):1075–1088. Copyright © 2009, Elsevier. www.europeanurology.com.)

Lymph node (LN) yield is quite variable with reported ranges between 4 and 25 LNs, with averages between 8 and 14 depending on the study (21,22). The superomedial quadrant contains the highest distribution of nodes with an average of four (21). It is also important to note that there are also central nodes located around the saphenofemoral junction.

The superficial and deep inguinal lymph nodes are separated by the fascia lata, which lies anterior to the femoral triangle. The femoral triangle is bound by the sartorius muscle laterally, the inguinal ligament superiorly, and the adductor longus muscle medially (Fig. 66.3) (18). The deep inguinal lymph nodes are located medial to the femoral vein with the superior extent of the dissection being the node of Cloquet found adjacent to the lacunar ligament. If any of these LNs reveal metastatic disease, then a pelvic LND is mandatory as the deep inguinal lymph nodes drain directly into the obturator, internal and external iliac lymph node basins.

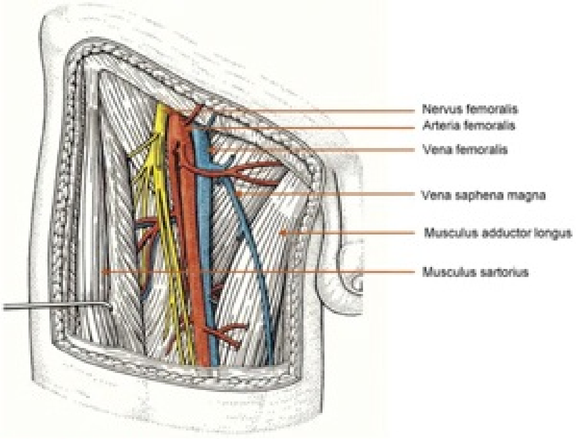

FIGURE 66.3 Surgical anatomy of the inguinofemoral region. (Reprinted with permission from Protzel C, Alcaraz A, Horenblas S, et al. Lymphadenectomy in the surgical management of penile cancer. *Eur Urol* 2009;55(5):1075–1088. Copyright © 2009, Elsevier. www.europeanurology.com.)

Finally, the arterial supply to the groin skin includes the superficial external pudendal, the superficial circumflex iliac, and the superficial epigastric arteries. Because these arteries are divided during an ILND, skin flap integrity relies on the arterial supply above Camper fascia.

Radical Inguinal Lymphadenectomy

The proper positioning for a radical inguinal lymphadenectomy (RIL) is with the patient supine and the ipsilateral lower extremity placed in a frog-leg position. The incision starts medially, two fingerbreadths lateral and inferior to the pubic tubercle. This incision is made in a “Z” shape toward the anterior superior iliac spine (ASIS) in the superolateral direction and extends to the most inferomedial aspect of the node dissection. The limits of an RIL are the inguinal ligament superiorly, extending from the pubic tubercle medially to the ASIS laterally. The lateral border of this dissection is 20 cm inferior from the ASIS and the medial border extends 15 cm below the pubic tubercle. The inferior limit joins the previously described lateral and medial borders along the upper thigh.

The first step of this dissection is to create skin flaps just below Camper fascia. Skin hooks can be used to create these flaps and mobilize the skin and subcutaneous fat off of the underlying Scarpa fascia. Meticulous care has to be taken to avoid making these skin flaps too thin, as this could lead to wound breakdown and necrosis. Army-Navy or Deaver retractors can be used to help elevate the skin flaps, which should be mobilized approximately 6 cm below and above the incision.

Next, dissection continues through Scarpa fascia onto the external oblique aponeurosis. The spermatic cord is then identified emerging from the external inguinal ring and retracted medially. All lymphatics along the spermatic cord and below Camper fascia are separated and ligated carefully to avoid postoperative lymphocele formation. These lymphatic packets are dissected off of the external oblique fascia to the inferior aspect of the inguinal ligament. Here, the femoral vessels can easily be palpated and identified within the femoral sheath. From lateral to medial, the femoral sheath contains the femoral nerve, artery, vein and lymphatics, respectively.

The medial border of the femoral triangle is the adductor longus muscle and the lateral border is the sartorius muscle, which are identified next in the dissection. The fascia lata overlying these muscles is then incised and the muscles are followed to their confluence at the most inferomedial aspect of the femoral triangle. The remainder of the lymphatics within the femoral triangle is then dissected out to complete the lymphadenectomy.

The saphenous vein can be identified medially in the femoral triangle, just medial and inferior to the fossa ovalis. Traditionally during an RIL, this vein was ligated; however, more recently, care has been taken to preserve the saphenous vein in order to minimize postoperative lymphedema. Occasionally, when there is bulky lymphadenopathy, the saphenous vein must be sacrificed in order to completely resect all disease. The femoral sheath overlying the femoral artery and vein is then incised and carried to the node of Cloquet, which is the most cephalad extent of the deep dissection. The sheath is opened inferiorly to the junction of the adductor longus and sartorius muscles. All lymphatic tissue between the femoral artery and vein is then dissected out carefully. Some superficial cutaneous arteries and veins are ligated as they come off the femoral vessels. Care must be taken not to extend the dissection too laterally or posterolaterally, as the femoral nerve and profunda femoris artery are in this location and subject to injury.

Once the dissection is completed, the wound is irrigated copiously and a sartorius flap is then mobilized off of its insertion on the ASIS. It is rotated over the femoral vessels and sutured to the cephalad portion of the inguinal ligament with several interrupted permanent sutures. Care must be taken during mobilization of the sartorius muscle, particularly medially, where its blood supply is derived. The medial aspect of the sartorius muscle can also be reapproximated to the adductor longus muscle for better coverage of the femoral vein. To prevent an inguinal hernia, Cooper ligament can be sutured to Poupart ligament with interrupted 2-0 Prolene. A JP drain is brought out inferior to the incision and then the Scarpa fascia is then sutured together incorporating some of the underlying sartorius muscle to minimize the dead space. The skin is then closed with a running subcuticular 4-0

Monocryl suture. Sterile dressings are placed over the incisions for 48 hours and the patient is allowed to ambulate on postoperative day 1. Additionally, patients should wear antiembolic stockings that extend above the knee for 3 to 6 months postoperatively.

Modified Inguinal Lymphadenectomy

The modified inguinal lymphadenectomy (MIL) was first proposed by Catalona (23) in 1988 that had several benefits which are listed as follows: a shorter 10-cm incision, preservation of saphenous vein to mitigate lymphedema risk, avoiding dissection lateral to the femoral artery, and eliminating the need for a sartorius flap. Patient positioning is the same as that for an RIL, with the thigh abducted and externally rotated and a pillow placed underneath the knee. Again, a 10-cm curvilinear incision about 2 cm below the inguinal groin crease is made extending it toward the ASIS. Skin flaps are developed at a minimum of 6 cm superior and inferior to the incision. They should be covered with saline-soaked gauze and handled gently to prevent necrosis. Rarely, the skin may be fixed and involved when there is bulky lymphadenopathy present and therefore must be excised. A muscle flap can then be rotated into this space for coverage.

The cephalad and medial extent of the MIL is identical to the radical lymphadenectomy, but dissection laterally is limited to the femoral artery as previously alluded to. The sartorius muscle is not exposed during this dissection and the saphenous vein is preserved when removing the superficial nodes. The dissection inferiorly along the fascia lata and femoral sheath extends to the inferior border of the fossa ovalis as opposed to the confluence of the sartorius and adductor longus muscles in the radical lymphadenectomy. Should a deep dissection be mandatory, all lymphatics between the femoral artery and vein are removed as well.

Some important limitations of the modified inguinal lymph node dissection are its reliance on frozen sections, which may dictate whether a deep inguinal dissection is to be performed. Given the rarity of penile carcinoma in the modern Western world, some centers may not have pathologists who have adequate exposure to penile cancer cases. Therefore, low-volume centers may not accurately diagnose patients with metastatic penile carcinoma on frozen sections and subject them to inferior outcomes. It is our belief that penile carcinoma cases should be referred to high-volume centers of excellence in order to optimize surgical outcomes.

Suprainguinal Dissection in Inguinal Lymphadenectomy

Occasionally, penile carcinoma metastases may be found above the inguinal ligament, which dictates a different approach in surgical extirpation. In some cases, the metastases found may be above the inguinal ligament. The incision is made about 2 cm above the inguinal ligament and extends from the pubic tubercle medially to the anterior superior iliac spine laterally. The standard groin dissection as previously described can be performed through a suprainguinal incision, albeit the most inferior aspect of the dissection may be more difficult due to poorer exposure. However, most centers that perform suprainguinal dissections have found that the skin flap viability is comparable or even better than a subinguinal incision due to less retraction of the skin when dissecting around the femoral vessels.

Laparoscopic and Robotic-Assisted Inguinal Lymphadenectomy

Further surgical advancements have been made in recent years and the feasibility of laparoscopic and robotic-assisted approaches to inguinal lymphadenectomy have been realized. In a recent phase 1 prospective trial, the oncologic adequacy of robotic-assisted video-endoscopic inguinal lymphadenectomy (RAVEIL) was tested (24). This study included 10 patients with cT1-3N0 penile carcinoma with a mean of nine lymph nodes removed per groin. Only 2 of the 10 patients had metastatic disease and 95% of the inguinal lymph node dissections performed were inspected and determined free of residual lymphatic tissue requiring excision. The surgical technique includes a 1.5-cm incision made 2 to 3 cm below the apex of the femoral triangle. Once Scarpa fascia is opened, a balloon dilator is inserted and inflated to 800 mL to create adequate working space for the robotic instruments. Only three ports are used for the dissection, a 10-mm camera port and two 8-mm robotic trochars. Operative times ranged from 3 to 4 hours to complete bilateral ILNDs and there were only two minor complications (cellulitis and an inguinal abscess requiring incision and drainage). Thus, morbidity may be decreased by a minimally invasive approach.

Similarly, a standard laparoscopic inguinal approach has been reported by several groups with similar oncologic efficacy to the open ILND (25,26). Typical port placement involves three trochars: one placed at the apex of the femoral triangle, one lateral to the sartorius muscle, and one medial to the adductor longus. In one study involving 32 patients, their mean operative times were 165 minutes and the mean node count was 11 per groin. Complications were minor in nature, with 18% having postoperative wound infections and cellulitis being the attributable cause in the majority of cases.

Flap Reconstruction after Inguinal Lymphadenectomy

After radical inguinal lymphadenectomy, particularly in the case with bulky disease, flap coverage may be required to protect the femoral vessels in addition to split-thickness skin grafting for wound coverage. The goal of both is to mitigate the risk of wound necrosis and also protect the femoral vessels from rupturing, particularly in cases where adjuvant radiation may be necessary. The most commonly described flaps are as follows: fascia lata myocutaneous flap, gracilis flap, abdominal rotational flap, rectus abdominis myocutaneous flap, deep inferior epigastric artery myocutaneous flap, and a thigh rotational flap. The sartorius muscle flap, as previously described, is one of the most common methods used to cover the femoral vessels.

The inferior rectus abdominis myocutaneous flap is another commonly employed technique for vessel and skin coverage in patients with large defects. A flap from the contralateral rectus abdominis is used and tunneled under the subcutaneous tissue and placed anterior to the ipsilateral rectus abdominis muscle. If there is a large inguinal skin defect, an elliptical area of lower abdominal skin can be used with the rectus abdominis flap for coverage. Otherwise, a split-thickness skin graft can be used to bridge skin coverage.

COMPLICATIONS

There are several common complications following inguinal lymph node dissections of which skin edge necrosis is the most common, ranging from 45% to 62% in several studies. This complication has been reduced to nearly 10% in more recent reports by modifying surgical technique (27). Some simple steps to prevent skin necrosis are to use an incision below the inguinal fold, meticulous handling of the skin flaps, avoid tension by reapproximating the skin flaps to the underlying muscle aponeurosis, and to make sufficiently thick flaps that incorporate both Camper and Scarpa fascia. Split-thickness skin grafting may be required if there is significant skin loss.

Lymphedema is the second most common complication reported ranging from 23% to 50% (28,29). As previously stated, this can be prevented by meticulous ligation of lymphatics and preservation of the saphenous vein, but the risk increases significantly when a deep inguinal node dissection is performed. There are several conservative methods of improving lymphedema which include elevation of the affected lower extremity, range of motion exercises, elastic stockings, 24-hour ACE wraps, and diuretics (30).

Wound infection and seroma formation are frequently reported in 10% to 15% of cases. Most infections can be treated conservatively with intravenous antibiotics with good gram-positive bacterial coverage. Also, a chlorhexidine scrub within 24 hours of surgery may help minimize the risk of wound infections. Complex wound infections that require opening the incision can be managed by wound vacuum-assisted closure (VAC) devices to expedite wound closure. Vascular injuries and DVT are rare complications with a reported incidence between 0% and 10%.

SUMMARY

SCC of the penis is a rare malignancy in the Western developed world and, consequently, few controlled studies have been completed to delineate the optimal management of lymphatic dissections. It is crucial to have an accurate pathologic diagnosis, as this ultimately determines the type of treatment a patient will receive. It is important to remember that T stage, lymphovascular invasion, and histologic grade all strongly correlate with the presence of malignant nodal involvement. Of particular note is the new AJCC criteria identifying extranodal extension, which confers a worse prognosis. According to the EAU guidelines, all patients with cT1G2 disease or worse should undergo DSNB followed by ILND, although ILND alone may be more prudent in lower volume centers that have less experience with sentinel node biopsies due the inherent pitfalls in its diagnostic accuracy. Upfront ILND is also appropriate in invasive penile carcinoma even in the absence of clinically positive nodes, as this has been shown to improve overall survival.

For patients with fixed or large lymph node masses, neoadjuvant chemotherapy has been demonstrated to have a 50% response rate with a doubling of overall survival as compared to historical data. A multidisciplinary approach is crucial in providing the best care for patients with metastatic penile carcinoma.

The key surgical tenets of inguinal lymph node dissections are as follows: create sufficiently thick skin flaps, meticulously handle the skin flaps, preserve the saphenous vein to minimize lymphedema, use musculocutaneous flaps appropriately to protect the femoral vessels, and make an incision that avoids the groin crease to prevent wound necrosis and maceration.

CHAPTER 67 SURGICAL TREATMENT OF PEYRONIE’S DISEASE

BROOKE EDWARDS AND RAMÓN VIRASORO

Peyronie's disease (PD) is a scarring disorder of the tunica albuginea leading to penile deformity (Fig. 67.1). PD is a completely clinically established entity; still, its etiology is uncertain. Several theories have been proposed since its first description in the mid-18th century, but none has been confirmed yet (1–3). To the authors' knowledge, the development of PD is related to the unique anatomy of the tunica albuginea and its relationship to the septal fibers. The most accepted etiology seems to be the occurrence, in genetically susceptible individuals, of repetitive minimal trauma during sexual life. Unidentified buckling injuries of the penis will eventually lead to scarring and penile deformity (4). Only a few patients relate the onset of symptoms to a specific penile injury during sexual intercourse.

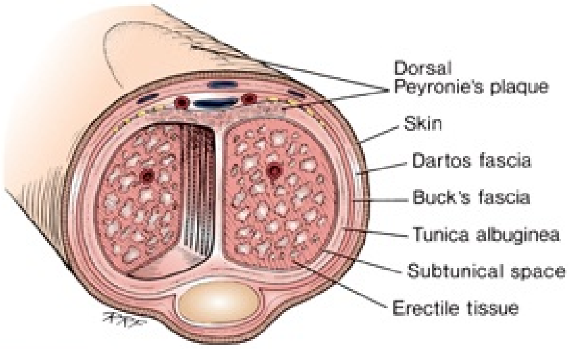

FIGURE 67.1 Cross-sectional penile anatomy with dorsal Peyronie's plaque.

The incidence of PD has recently been estimated at up to 3% or as high as 7% to 9% of the general male population (5,6).

CLINICAL PRESENTATION

The most frequent presentation is the development of penile curvature, but decrease in penile length, indentation, hinge deformity, and erectile dysfunction are very common complaints (Fig. 67.2).

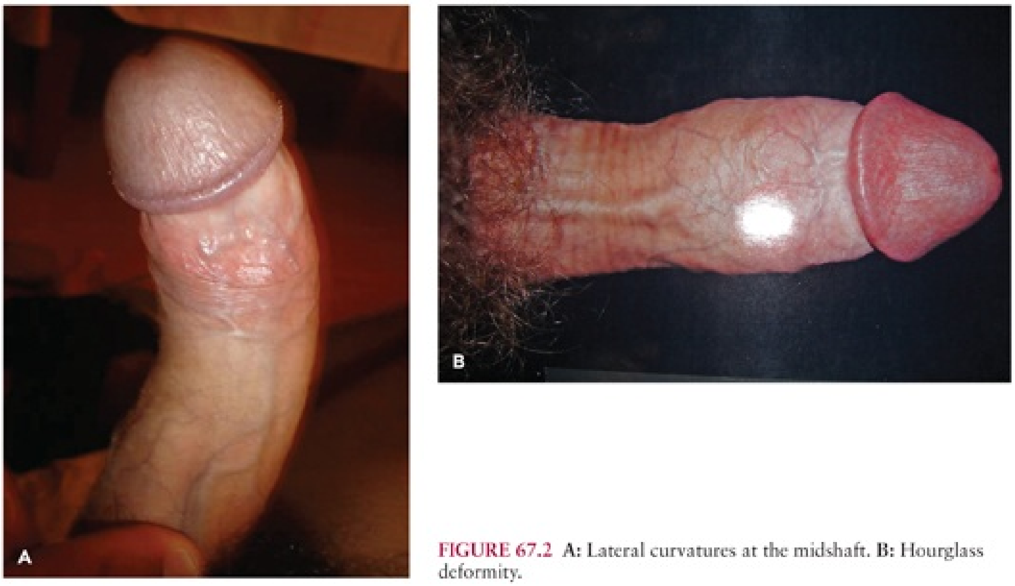

FIGURE 67.2 A: Lateral curvatures at the midshaft. B: Hourglass deformity.

Clinically, PD has two phases. The first, an active phase, is commonly associated with painful erections and changing deformity of the penis. It is followed by a quiescent secondary phase, characterized by deformity stabilization, disappearance of painful erections, if they were present, and, in general, stability of the process. Up to a third of patients, however, present with what appears to be sudden “overnight” development of painless deformity.

DIAGNOSIS

The diagnosis of PD is mainly clinical, based on a detailed history and physical examination. Recollection of onset, duration, and progression of penile deformity is crucial as well as any degree of sexual dysfunction. Erectile dysfunction, if present, is multifactorial because many of these patients have preexistence comorbidities. The psychological impact of the disease plays an important role.

The physical examination should be focused on delineating plaque location, size, and penile sensitivity because many patients complain of hypoesthesia. Decrease in penile sensitivity needs to be established for this is a common postoperative complaint, and basal sensitivity needs to be established. In an attempt to elicit known disease associations such as Dupuytren’s contracture or other elastic tissue fibromatosis, an examination of hands and feet should be made. Objective evaluation of penile curvature with home-taken photographs of the erect penis, we find, is extremely helpful, but other authors have found it most useful to perform an artificial erection with vasoactive substances at the time of office visit. Curvature is then measured using a goniometer or protractor. Plain radiographs are effective in demonstrating plaque calcification (Fig. 67.3). The presence of calcifications, once believed to be a sign of plaque maturity, is now debatable, for recent reports have shown it to be more prevalent and present early in the onset of symptoms (7). Plaque calcification is also easily demonstrated with ultrasonography (8). The plaque can be imaged by both computerized tomography (CT) and magnetic resonance imaging (MRI), both being unnecessary except for the possibility of using MRI to “stage” the phase of disease for research or study protocol purposes, or in a rare patient where the diagnosis is not certain and a concern for a possible malignancy arises (9).

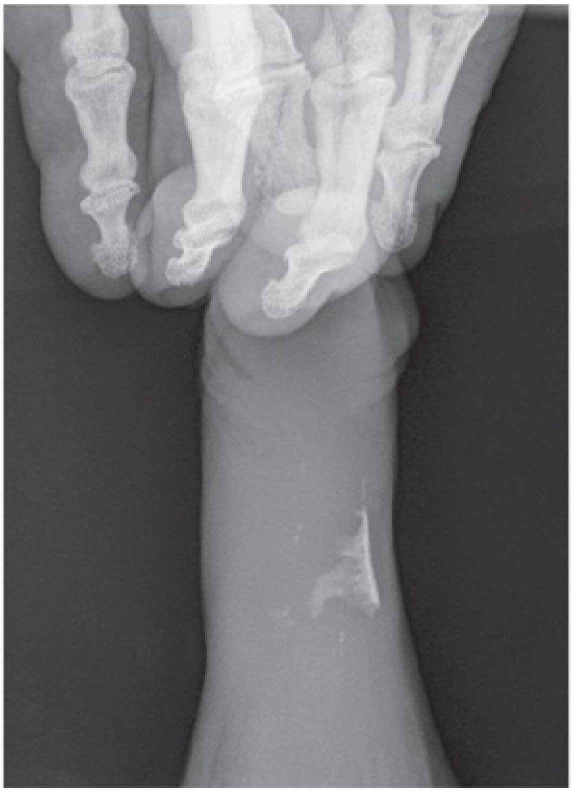

FIGURE 67.3 Prominent calcification of a dorsal plaque.

It is important to evaluate and define the surgical candidate’s preoperative erectile function. Prospective surgical patients, at our center, are evaluated with color duplex ultrasound in the presence of pharmacologically induced erection. Abnormalities in the resistive index and end-diastolic velocity, at our institution, prompt further testing with dynamic infusion cavernosometry/cavernosography. In addition, one must determine if acceptable intercourse can be accomplished by enhancement of erectile rigidity alone. In this scenario, patients may be best served with a pharmacologic erection program as an alternative to surgery.

INDICATIONS FOR SURGERY

A frank discussion of treatment goals with the couple is imperative. The patient should be assured that the process is not malignant or life-threatening. The goal of surgery is to straighten the penis and maintain erectile function so that satisfactory intercourse can be achieved.

Couples must be aware that preexisting penile shortening and erectile dysfunction will not be improved by straightening procedures. Rigidity may be improved by straightening the penis, but truly improved erectile function does not occur. Evaluation with a sex therapist can help patients and partners adjust to these new sexual expectations.

Surgical candidates must have stable and mature disease, which includes resolution of pain and stabilization of curvature or other deformity. Fortunately, only a small proportion of patients with PD have deformity requiring surgical intervention. Surgical intervention should be regarded as palliation of the deformity only and not as cure.

In essence, one can correct the penile curvature by “shortening” the long aspect of the curve or by “lengthening” the short aspect of the curve. Additionally, in those patients with PD and associated severe erectile dysfunction, the option of a penile implant with plaque modeling or incision with or without grafting is valid.

Several surgical techniques have been described to correct penile curvature associated with PD, including plication of the opposite aspect of the lesion and incision/excision of the plaque and grafting. The tissues and materials applied to graft the corporal defect include dermis, tunica vaginalis, cadaveric dura mater, temporalis fascia, veins, cadaveric pericardium, and porcine small intestine submucosa (SIS) (10–16).

SURGICAL TECHNIQUE

Skin Incision

At our institution, we perform all Peyronie’s corrective procedures in supine position and use either a circumcising incision and penile degloving or an optional ventral midline incision for ventral plications. If the patient has been previously circumcised, then the incision should be performed through the circumcision scar. Once the incision has been made, an artificial erection is created with a pressure infuser device or butterfly needle and syringe with injectable 0.9% normal saline. We tend not to employ the use of a tourniquet to control bleeding or maintain an artificial erection because it is unneeded and tends to distort the presence of a proximal curvature. Some authors use vasoactive substances, such as papaverine or PGE, for this purpose.

Corporoplasty or Corporoplication Procedures

Several techniques and modifications have been published that describe methods of plication, or shortening of the convex side of the curvature. The techniques fall into (a) nonincisional plication, (b) incisional plication, or (c) excisional plication categories.

Nonincisional or 16-Dot Technique

Gholami and Lue described a 16-dot plication (17). They initially begin with obtaining an artificial erection with papaverine and ring or incisional block with bupivacaine. If a dorsal curvature is present and circumcision incision is not preferred, then the ventral longitudinal incision is made in the midline over the expected point of plication. Adjacent to the corpus spongiosum, a longitudinal incision is made in Buck’s fascia, exposing the tunica albuginea along the full length of the curvature. With a full erection present, the center of the curvature is marked on the ventral side. About 2 to 3 mm lateral to the corpus spongiosum, four dots are made in longitudinal arrangement to mark entry and exit points for the suture needle, each about 0.5 to 1 cm apart. Each four dots represent a single suture. Typically, two to three sutures are required on each side of the corpus spongiosum, which creates the 16- or 24-dot technique. A 2-0 braided, polyester, nonabsorbable suture is placed in an “in, out, in, out” technique with full-thickness bites of tunica albuginea. Each suture is placed and each serially tied down with a single throw or half knot before clamping with a rubber-shod clamp. After each is clamped, a full erection is again obtained to evaluate for correction of curvature. Each suture can then be adjusted to obtain straightness prior to tying down all sutures.

Ventral curvature can be corrected in a similar manner with the sutures placed between the deep dorsal vein and dorsal arteries on each side. Lateral curvature is corrected by placing the sutures on the lateral convex side, under the neurovascular bundles.

Excisional Technique (Nesbit [18], Pryor–Fitzpatrick [19])

Again, either a longitudinal or circumcising incision can be used. For dorsal curvature, the corpus spongiosum is dissected from the corpora cavernosa and retracted away with a Penrose drain. Beneath the corpus spongiosum, an area is marked exactly the point of greatest concavity. An ellipse of full-thickness Buck’s fascia and tunica albuginea is then excised over this area. The ellipse should be 0.5 cm in width and about one-third the circumference of the corpora cavernosa for a 45-degree deformity. For more severe curvatures, requires a wider ellipse, such as 0.8 cm for a 90-degree deformity. Approximately 1 mm for every 10 degrees of curvature is rule of thumb.

You can also choose to leave the corpus spongiosum in place and an excise an ellipse on each side the corpus spongiosum. A 3-0 nonabsorbable suture can be used in interrupted fashion to close the ellipse longitudinally with the knots buried inward to prevent the patient discomfort. An artificial erection should then be created to access for leaks or remaining curvature. Additional interrupted sutures can be placed to correct for a leak while an additional incision can be made to further correct any curvature. If the corpus spongiosum was dissected, then it can be replaced and anchored with fine suture noting that some redundancy can be expected.

Incisional Technique (Heineke-Mikulicz, Yachia [20])

A similar circumcising or longitudinal incision is made. Once Buck’s fascia is dissected off, a 1-cm longitudinal incision is made in the tunica albuginea. The incision is then closed transversely with interrupted 3-0 synthetic absorbable sutures. This is completed without excision of the tunica. Buck’s fascia is then reapproximated to better cover the sutures.

Prior to making an incision in the tunica albuginea, temporary plication sutures similar to that described in the 16-dot technique can be placed and evaluated with an artificial erection. The incision length or position can then be adjusted to correct the curvature. Once in correct position, fluorescent green dye is used to mark the position before the suture is removed and the incision is made.

Plaque Incision/Excision and Grafting

Depending on the technique to be used and the location of the plaque, the incision is planned. Most patients presents with a dorsal plaque because ventral location is very rare. We do not recommend ventral grafting because it has shown poor results on previous series. Dorsal plaques are most effectively approached using a subcoronal circumferential incision. In previously circumcised patients, the incision should be placed through the original circumcision scar to avoid possible future distal shaft and/or glans lymphedema.

Once the superficial Buck’s fascia has been achieved, the penis is degloved to its base, following a “webbed” avascular plane. Small perforators are controlled with a fine-tipped bipolar electrocautery (Fig. 67.4).

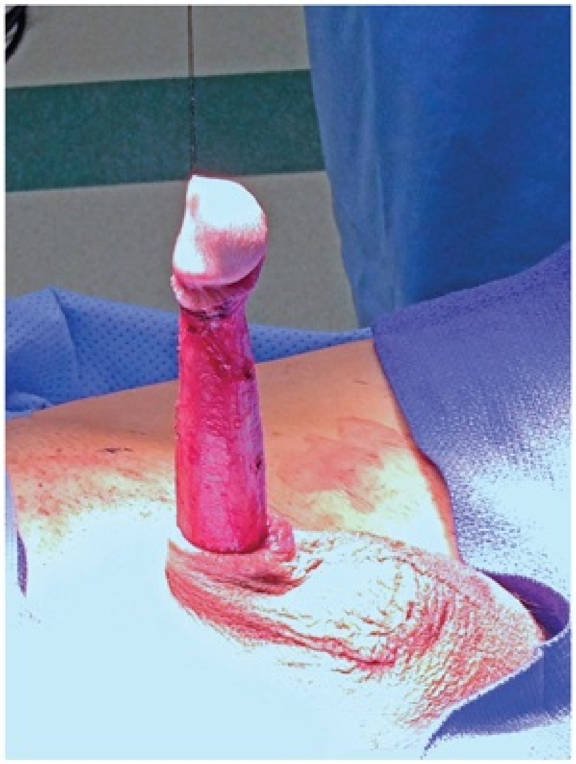

FIGURE 67.4 Aspect of the penis after penile degloving.

For dorsal plaques, the neurovascular bundle is then elevated in concert with Buck’s fascia. This can be accomplished mainly by two approaches. Lateral incisions to the corpus spongiosum are made, with Buck’s fascia and the dorsal neurovascular bundle dissected off the lateral and dorsal aspects of the corpora cavernosa. Alternatively, we currently approach dorsal plaques by dissecting sharply through the bed of the deep dorsal vein and perform a modified vein dissection (Fig. 67.5). We extend proximally to the penopubic junction and distally to the arborizations of the dorsal vein at the corona of the glans penis. Again, circumflex veins are controlled with the bipolar electrocautery.

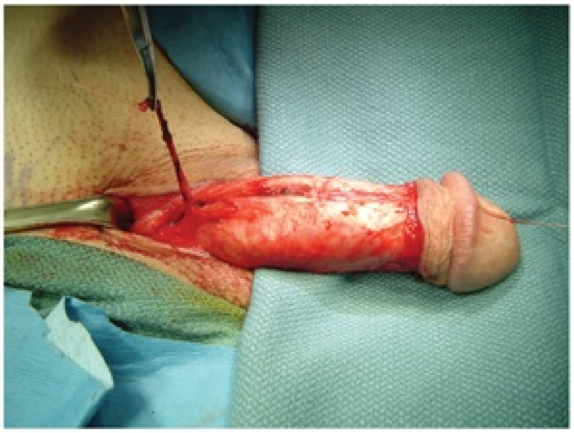

FIGURE 67.5 Deep dorsal vein dissection and ligation.

After dorsal exposure of the tunica albuginea, an artificial erection is performed to determine the extent of the plaque, and the point of maximal curvature is marked with a Prolene suture. In experienced hands, the inelasticity of the plaque can be evident by palpation, and feeling the surface of the tunica albuginea can delineate its extent. We place Prolene stay sutures in the midline, proximal and distal to the plaque, and lateral to the plaque, and then mark the planned incisions (Fig. 67.6). As we mention before, we do not favor the use of a tourniquet for either control of bleeding or induction of an artificial erection, as tourniquets can conceal proximal curvatures.

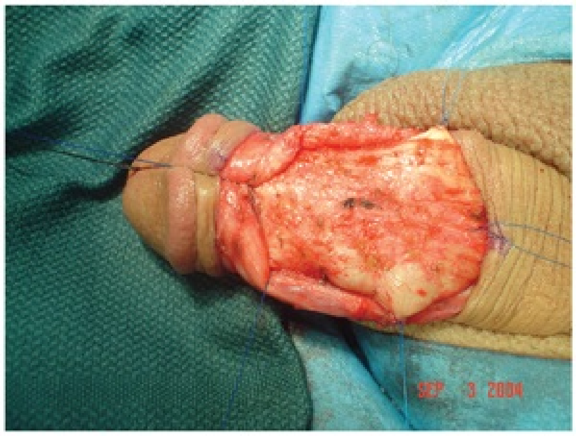

FIGURE 67.6 Tacking sutures exposing the dorsal plaque; the dorsal neurovascular structures were displaced laterally.

At this point, an H-shaped incision is created in the tunica albuginea (Fig. 67.7). The tunical flaps are elevated using sharp scissors or knife, allowing them to slide over the underlined erectile tissue (Fig. 67.8), and then are sutured leaving an approximately square defect (Fig. 67.9). Since 2001, we modified the sliding H incision. At the point of maximal curvature, which can be very accurately identified during artificial erection, a strip of tunica albuginea is excised (Fig. 67.10). This indeed does create a larger corporotomy defect; however, the defect remains approximately square and the graft inlay can be placed without difficulty. After either H incision or incision/excision is created, the sliding flaps are sutured. If there is indentation, the flaps are darted, allowing for expansion.

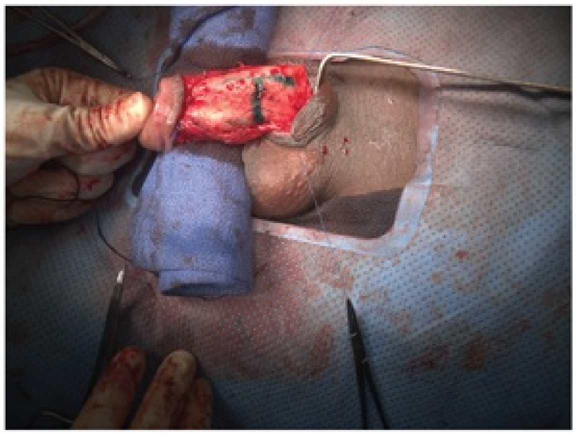

FIGURE 67.7 An H-shaped incision marked at the point of maximal deformity; the stitch marks that point.

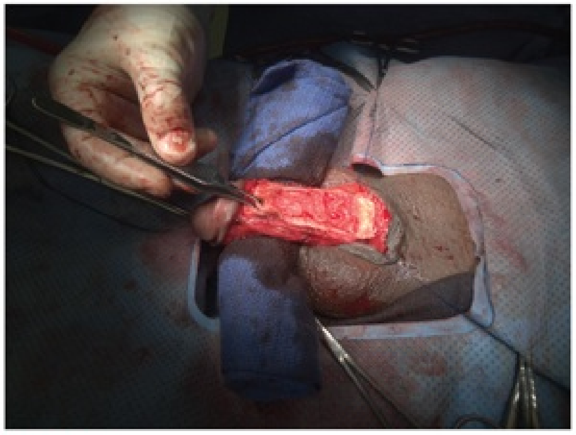

FIGURE 67.8 Incision of the tunica albuginea. Flaps are created to allow tissue sliding and elongation.

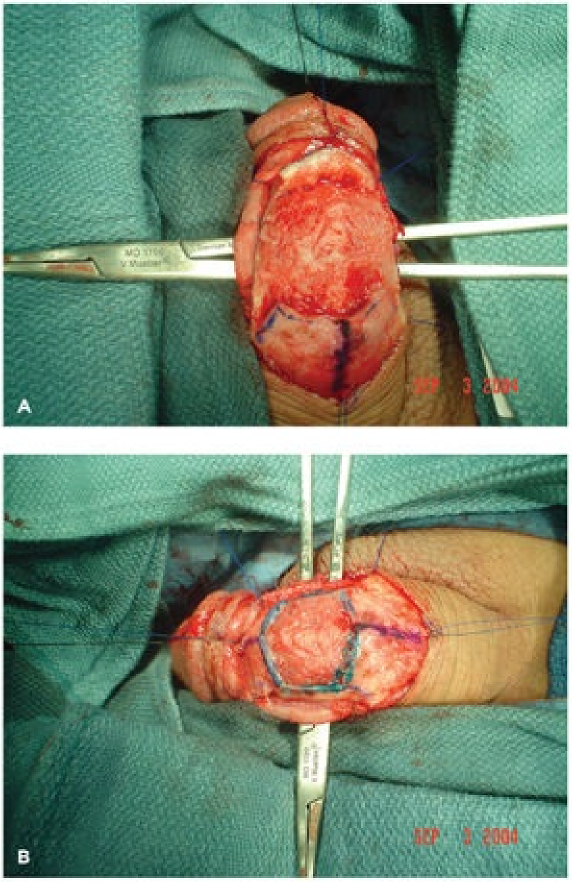

FIGURE 67.9 **A:** The defect after sliding flaps; this maneuver is extremely important in achieving straightening with this technique. Note the expansion of the corporotomy defect. **B:** Creation of a square defect in the tunica albuginea.

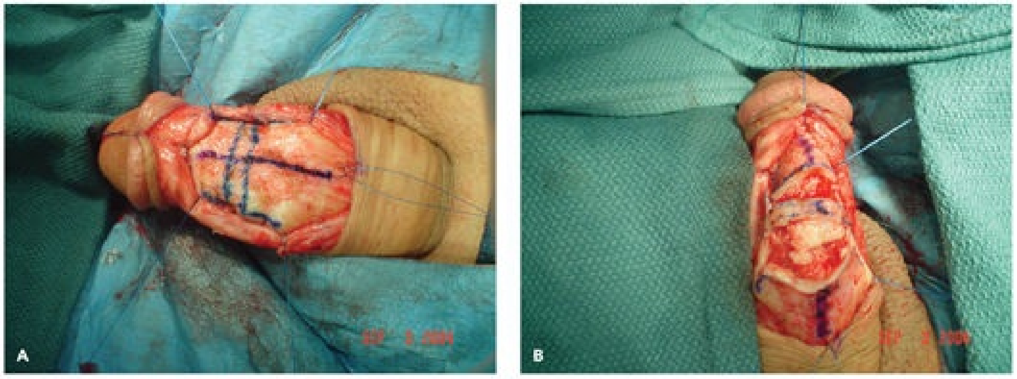

FIGURE 67.10 A and B: Modification of the sliding H technique in which a small strip is excised at the point of maximal curvature; the stitch marks that point.

It is clear that the penis can be effectively straightened with the incision and graft technique alone in about 70% of patients. The addition of the small strip excision allows for straightening in almost all patients. Only about 5% of patients will require touch-up plication, and generally that is for persistent tilt of the glans.

Once the plaque has been incised or excised, depending on the technique selected, we measure the defect, stretching the penis to ensure accurate coverage.

Dermal Graft

Since its first description by Devine in the early 70s (10), at our institution, we have used the dermal graft as the preferred method, although in recent years, the tendency has shifted toward the use of off-the-shelf grafts, specifically the SIS (porcine jejunal submucosa). The dermal graft is outlined on the donor site, considering that the graft, when released from the inherent tissue tension at the donor site, “contracts” about 30%. This should not be confused with graft contraction during “take.” We prefer to use the skin of the abdomen just above the iliac crest, lateral to the hairline as the donor site for the dermal graft. The donor site is closed per primam with subcuticular sutures, using either a pullout or the newer absorbable long-acting monofilament suture (Fig. 67.11).

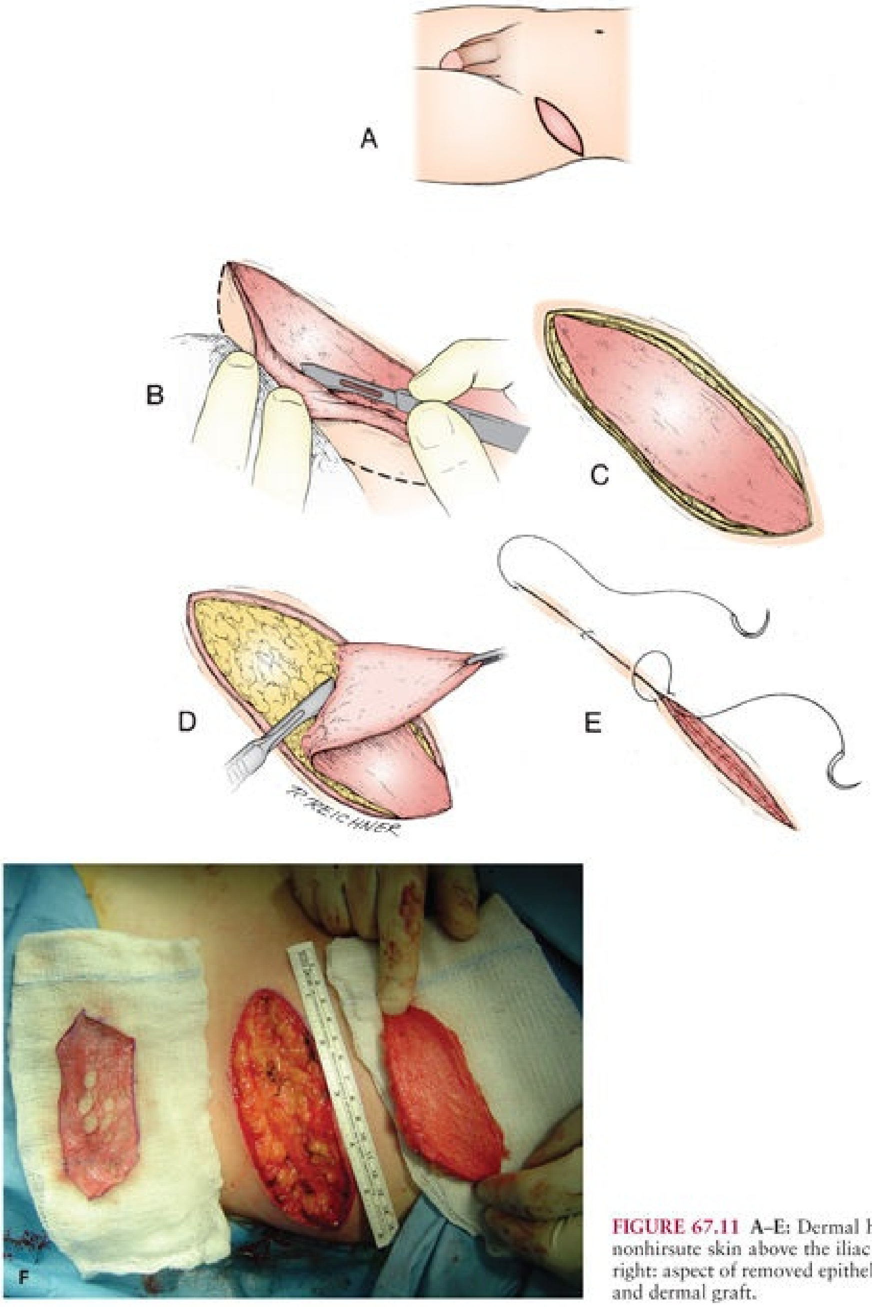

FIGURE 67.11 **A–E:** Dermal harvest from the nonhirsute skin above the iliac crest. **F:** Left to right: aspect of removed epithelium, donor site, and dermal graft.

We then carefully tailor the graft to measure approximately 30% larger in all dimensions than the corporotomy defect and place it into the defect (Fig. 67.12). After completing the graft inlay using 4-0 polydioxanone suture (PDS), we perform another artificial erection to demonstrate that the penis is straight and the suture lines are watertight (Fig. 67.13). If there are leaks, they are oversewn. If the penis is not straight during surgery, it will not be straight postoperatively. If curvature persists, therefore, further modification by means of incisions and grafting or “touch-up” plications is necessary.

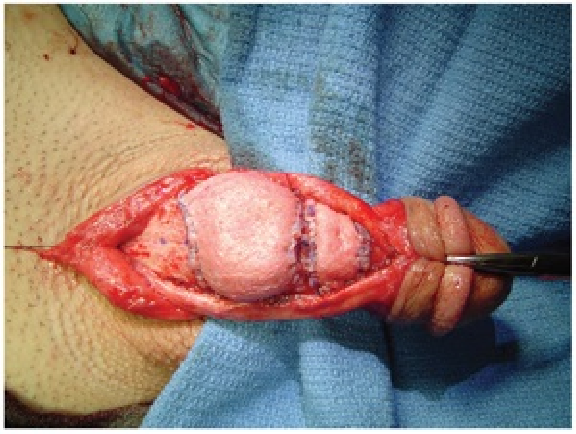

FIGURE 67.12 Watertight closure of the corporotomy after dermal graft.

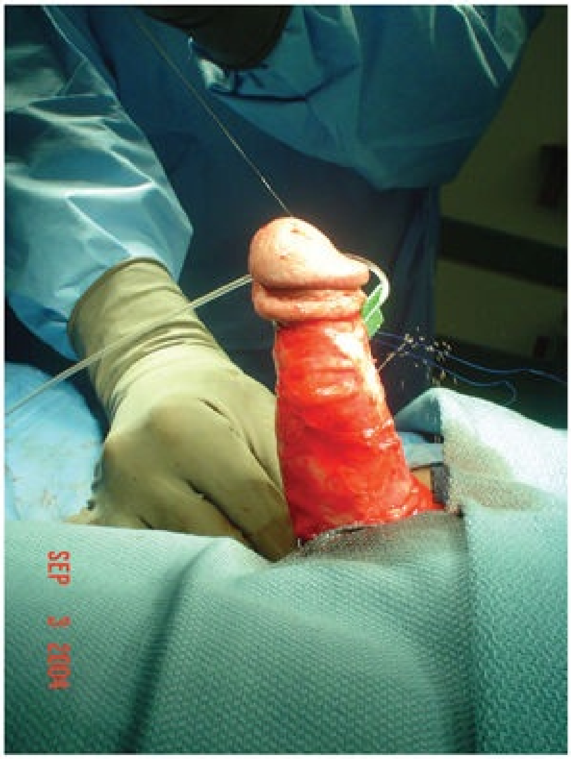

FIGURE 67.13 Artificial erection confirms penile straightening.

After completion of the dermal graft inlays, we anatomically close the penis. Buck's fascia is reapposed using PDS, and two small suction drains are placed superficial to Buck's fascia but deep to the dartos layer. We close the skin incisions using either chromic or small Vicryl sutures. If a ventral midline incision was created that crosses the penoscrotal junction, a Z-plasty should be used to prevent penoscrotal tethering.

Small Intestine Submucosa Graft (Surgisis Biodesign, Cook Medical Inc, Bloomington, IN)

Since early 2002, we have been using more frequently SIS graft than dermal graft. Recent comparative reports (21,22) have shown to be at least equivalent to the dermal graft. In this case, lyophilized (freeze dried) porcine jejunal submucosa (SIS) is immersed in normal saline and then appropriately tailored to oversize 30% of the tunical defect. The graft is sutured with watertight running 4-0 polyglycolic suture (Fig. 67.14). Another artificial erection confirmed the penile straightness (see Fig. 67.13).

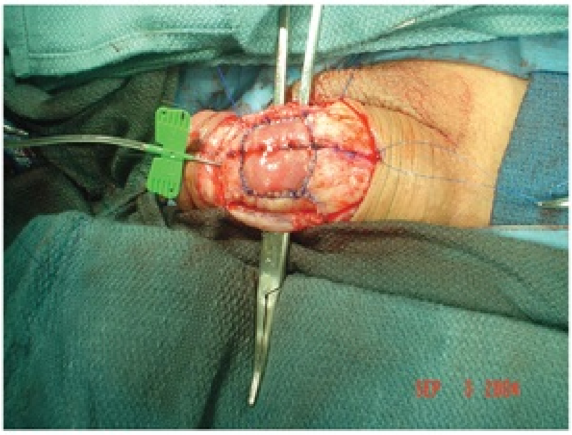

FIGURE 67.14 Watertight closure of the corporotomy after SIS graft.

Wound is closed in layers, leaving a 10Fr subfascial drainage for 24 hours. The penis is dressed with a Bioclusive dressing, loosely applied and extending from the base of the penis to the level of the mid glans to avoid sliding. A mildly compressing Kling dressing is wrapped over the Bioclusive dressing to limit edema and allow better collapse of the surgical spaces around the suction drains. The Kling dressing is left in place for 4 hours, during which the glans is checked every 30 minutes. A 14Fr Foley catheter is left until the patient ambulates on the morning after surgery. The suction drains are removed on the first postoperative day, and usually, the patient is discharged on that day. We suppress erections with diazepam and amyl nitrite and instruct patients to avoid them for about 2 weeks.

Dermal grafts mature in the same manner as other grafts: first nourished by imbibition of tissue fluids the first 48 hours, whereas inosculation occurs from adjacent blood vessels after the second day. Remodeling takes place during the late phase of maturation, with the graft tending to first contract and then become compliant. In the first 3 months, the graft may contract enough to re-create some of the curvature, but, as the graft softens, straightening occurs. Patients should be forewarned of this sequence of events to avoid undue anxiety.

After the first 2 weeks, we encourage patients to have erections but discourage them from intercourse for about 10 to 12 weeks. During this time, it is desirable for the penis to be manipulated so that the skin does not adhere to the deeper layers of the penis. In addition, erections stretch the graft and aid in the maturation phases of graft take. In some patients, we encourage the use of the vacuum erection device without the constriction ring as a means of distending and stretching the graft.

Penile Prosthesis in Peyronie’s Disease

The consensus committee on PD at the World Health Organization’s Second International Consultation on Sexual Dysfunctions states that penile prosthesis is a reliable option for the older man with vascular impairment, erectile dysfunction, and acquired deformity of the penis (23). It is not the only treatment in PD but rather prudent treatment for the patient with significant erectile dysfunction in association with their PD. Hydraulic prostheses are preferred, and those prostheses that have true controlled expansion cylinders have been shown to provide better results.

The technique of penile prosthesis implantation is covered elsewhere in this book.

CHAPTER 68 ■ PRIAPISM

ARTHUR L. BURNETT II AND NATE READAL

Priapism refers to an erectile disorder in which an erection persists uncontrollably without sexual purpose. The general timeframe is any erection persisting beyond 4 hours. It is a medical emergency that requires prompt diagnosis and immediate treatment to prevent long-term sequelae, and a urologist should be involved early in the care of priapism patients. The disorder is a result of disturbances in the mechanisms governing erectile physiology as it relates to regulatory control of penile detumescence and initiation and maintenance of penile flaccidity. Priapism represents one of the greatest challenges in therapeutic management of erectile disorders, and although relatively rare, knowledge of proper management is required from urologists, emergency room personnel, and hematologists.

During an episode of ischemic priapism, blood fails to drain from the corporal sinusoids of the penis resulting in a prolonged, painful erection. Pain with priapism is believed to be a consequence of tissue ischemia and increased pressure within the corporal bodies that results from failure of blood egress. When prolonged, ischemic priapism leads to erectile dysfunction (ED) and prompt recognition, and diagnosis and management are necessary to minimize this risk. However, all patients should be aware that permanent ED is a possibility following a priapic episode, particularly if the duration of priapism is prolonged. Global penile fibrosis and impaired erectile mechanisms are the end result of untreated ischemic priapism and the overall rate of ED can be as high as 59% (1–3).

Priapism can be classified into two types, *ischemic (or low flow*, *venous) priapism* and *nonischemic (or high flow*, *arterial) priapism*. Ischemic priapism is the more common form, and greater than 95% of men who present with priapism will have the ischemic type (4). It is typically a result of pharmacologic use/abuse, hematologic disorders, or neurogenic causes (Table 68.1) and results in a persistent, painful erection with no cavernosal blood flow. Cavernosal blood gas is acidotic, hypoxic, and hypercarbic, and the increased pressure within the closed corporal system gives rise to a compartment syndrome that compromises cavernosal tissue oxygenation. After 24 hours of ischemic priapism, there is evidence of irreversible smooth muscle cell necrosis, destruction of vascular endothelium, and exposure of the basement membrane with adherence of thrombocytes (5).

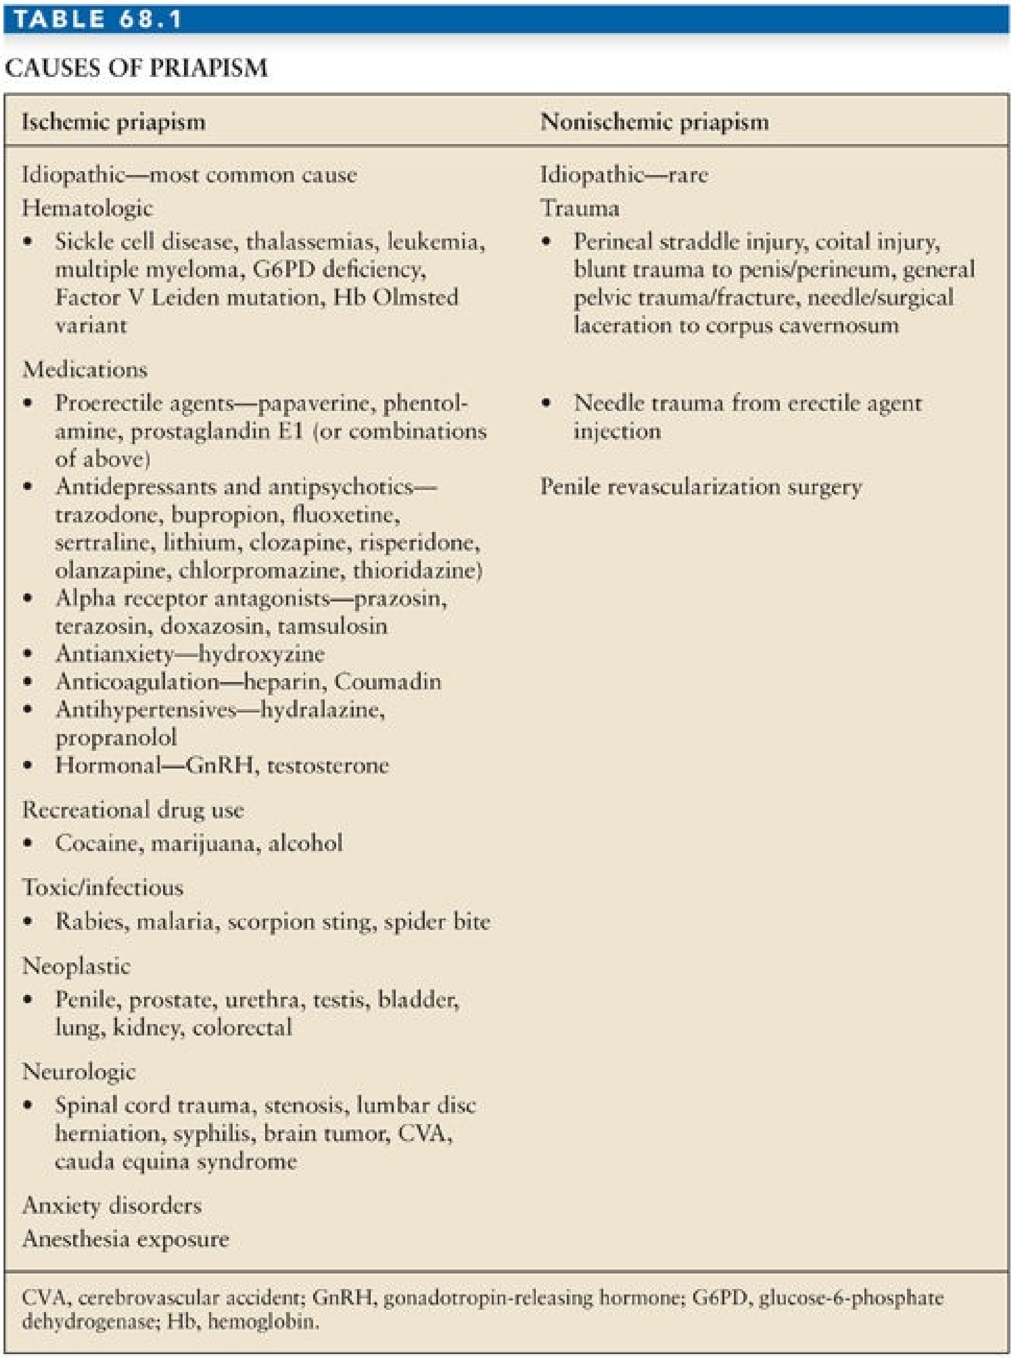

TABLE 68.1

CAUSES OF PRIAPISM

Ischemic priapism	Nonischemic priapism
Idiopathic—most common cause	Idiopathic—rare
Hematologic	Trauma
• Sickle cell disease, thalassemias, leukemia, multiple myeloma, G6PD deficiency, Factor V Leiden mutation, Hb Olmsted variant	• Perineal straddle injury, coital injury, blunt trauma to penis/perineum, general pelvic trauma/fracture, needle/surgical laceration to corpus cavernosum
Medications	
• Proerectile agents—papaverine, phentolamine, prostaglandin E1 (or combinations of above)	• Needle trauma from erectile agent injection
• Antidepressants and antipsychotics—trazodone, bupropion, fluoxetine, sertraline, lithium, clozapine, risperidone, olanzapine, chlorpromazine, thioridazine)	Penile revascularization surgery
• Alpha receptor antagonists—prazosin, terazosin, doxazosin, tamsulosin	
• Antianxiety—hydroxyzine	
• Anticoagulation—heparin, Coumadin	
• Antihypertensives—hydralazine, propranolol	
• Hormonal—GnRH, testosterone	
Recreational drug use	
• Cocaine, marijuana, alcohol	
Toxic/infectious	
• Rabies, malaria, scorpion sting, spider bite	
Neoplastic	
• Penile, prostate, urethra, testis, bladder, lung, kidney, colorectal	
Neurologic	
• Spinal cord trauma, stenosis, lumbar disc herniation, syphilis, brain tumor, CVA, cauda equina syndrome	
Anxiety disorders	
Anesthesia exposure	

CVA, cerebrovascular accident; GnRH, gonadotropin-releasing hormone; G6PD, glucose-6-phosphate dehydrogenase; Hb, hemoglobin.

Stuttering or recurrent priapism is a variant of ischemic priapism in which patients have recurrent, undesired erections characterized by prolongation and pain but a duration typically less than 3 hours (5). It is commonly encountered in sickle cell patients and episodes typically occur upon awakening from sleep and can be self-limited. These episodes are marked by intervals of detumescence and may become longer in both duration and severity until a full episode of ischemic priapism (>4 hours) results in as many as 28% of patients (6). Each episode confers a risk of fibrosis to the corpora cavernosa if not promptly recognized and treated to restore normal corporal blood flow and oxygenation.

Nonischemic priapism is a nonsexual, persistent erection that typically follows trauma to the perineum or genitalia resulting in unregulated cavernosal arterial inflow to the corporal bodies (1). The corpora are typically semirigid and nonpainful as oxygenated, arterial inflow is constant. Unlike ischemic priapism, corporal blood gas is neither hypoxic, hypercarbic, nor acidotic, and this type of priapism is not an emergency as the corporal tissue remains well oxygenated and painful symptoms are rare.

CLINICAL CHARACTERISTICS

Incidence/Prevalence

Epidemiologic data on the incidence of priapism are not abundant as such data depend on accurate recording of cases at clinics and hospitals throughout the world which does not regularly occur. Studies evaluating the incidence of priapism are typically performed in a homogenous population in which various risk factors may be present or absent, thus limiting the generalization of the results. Several such studies, however, do give some insight into the incidence of priapism in select populations. Kulmala and colleagues (7) using primary care databases determined the incidence of priapism in Finland from 1976 to 1990 to be 0.34 to 0.52 cases per 100,000 male patients per year. The incidence rates in the Netherlands and Australia were slightly higher at rates of 1.5 per 100,000 person-years and 0.84 per 100,000 person-years, respectively (2,8). New data taken from the National Emergency Department Sample database, which collects emergency department visit information from select states in the United States, has allowed a better understanding of the contemporary incidence of priapism episodes in the United States which was estimated to be 0.73 per 100,000 men per year from 2006 to 2009 (9). The incidence of hospitalization for priapism was 0.01 per 100,000 men per year, and although hospitalization for priapism is relatively rare, such an event is economically significant with an average cost of $41,909 to the health care system. In contrast, an emergency room visit for priapism has an average cost of $1,778 (9,10).

In certain select populations, however, the occurrence of priapism is known to be significantly higher. In Jamaica, where 1 in 300 children are born with sickle cell disease, the prevalence of men who have had an episode of priapism in the population is 42% and the risk of men with sickle cell disease developing an episode of priapism by the age of 20 is 89% (11). It is known that men with sickle cell disease have a lifetime risk of developing an episode of ischemic priapism of 29% to 42%, and with 20 to 25 million men worldwide who are homozygous for sickle cell disease, this represents a significant population at risk for priapism episodes (3).

Risk Factors

Priapism is associated with diverse disease states. Etiologic categories for ischemic priapism include idiopathic, which is the most common cause, neurologic conditions (multiple sclerosis, spinal cord tumor, acute spinal cord injury), hematologic dyscrasias (sickle cell disease, thalassemias, leukemia, multiple myeloma), malignancies (metastatic or local), vasoactive erectile medication therapy (prostaglandin E_1, papaverine), prescribed and recreational drug exposure (testosterone replacement, psychotropic and antidepressant medications, alcohol and illicit drugs), toxin-induced (scorpion sting or Phoneutria nigriventer spider bite) and rarely anxiety disorders, metabolic disease, or exposure to anesthesia (12,13).

Nonischemic priapism typically results from trauma to the perineum or genitalia such as a straddle injury, coital trauma, or blunt trauma such as a kick or strike. However, arteriocavernous fistulas can also result from needle lacerations occurring during penile injection therapy, direct injury during surgical procedures in the penis or perineum, or penile revascularization procedures.

PATHOPHYSIOLOGY

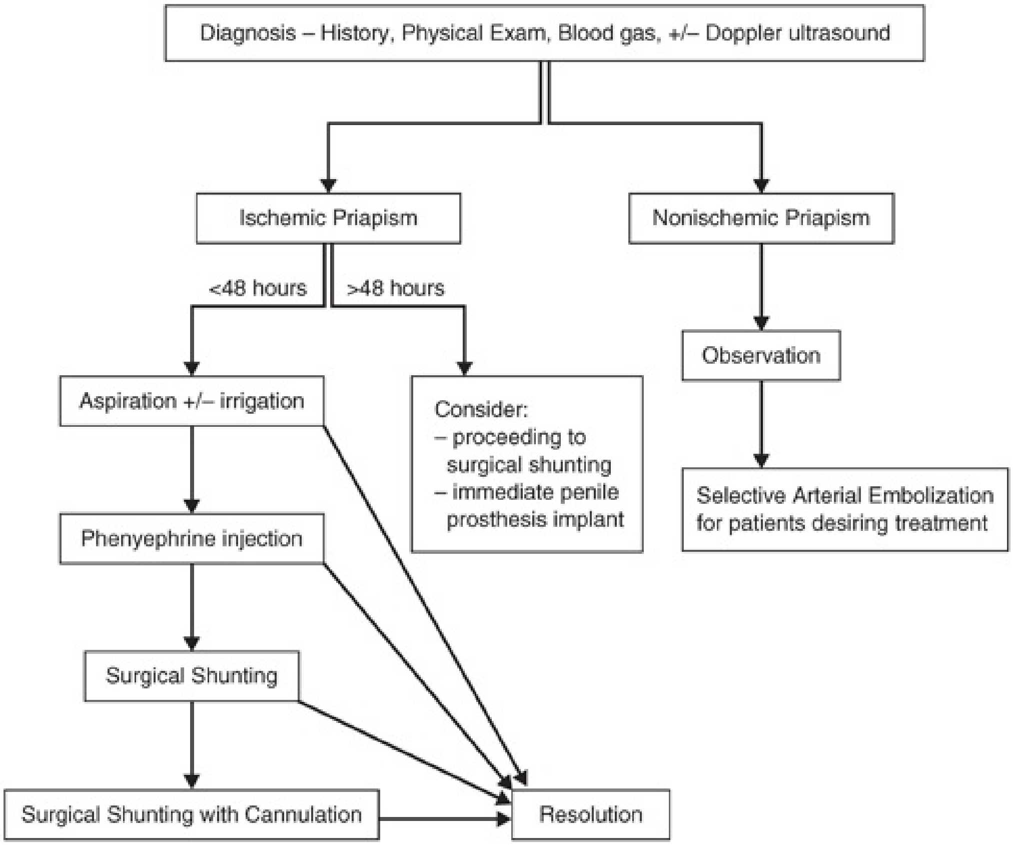
Ischemic priapism consists of an imbalance of vasoconstrictive and vasorelaxatory mechanisms that predispose the penis to prolonged tumescence and the development of hypoxia and acidosis. A new understanding of the molecular mechanisms leading to priapism has recently been advanced through the use of both transgenic and sickle cell disease rodent models that demonstrate multiple perturbations in these pathways contributing to the development of priapism. In endothelial nitric oxide synthase knockout and transgenic sickle cell mice, exaggerated erectile responses to cavernous nerve stimulation are observed consistent with priapism (14). The mechanism of priapism in these animals is believed to be due to chronically impaired basal endothelial nitric oxide bioavailability due to a defect in the nitric oxide signaling pathway. This results in downregulation of nitric oxide synthase activity and ultimately decreased cyclic guanosine monophosphate (cGMP) production with compensatory downregulation of phosphodiesterase type 5 (PDE5) expression in the basal state. When an erectogenic stimulus is experienced, cGMP accumulates in corporal smooth muscle causing uncontrolled dilation. With little PDE5 present to degrade the cGMP, complete, prolonged corporal body dilation ensues and priapism results (15). Adenosine overproduction has also been implicated in the development of priapism (16). Adenosine acts through the stimulation of adenylyl cyclase and synthesis of cyclic adenosine monophosphate, which activates protein kinase A and enhances smooth muscle relaxation. Increased adenosine production was present in the penis of sickle cell mice and mice that lacked adenosine deaminase, the enzyme responsible for degrading adenosine to inosine. The addition of adenosine deaminase to degrade adenosine resulted in smooth muscle contraction and resolution of priapism episodes in these animals (16).

Perturbations in the vasoconstrictive pathways that maintain penile flaccidity have also been demonstrated in sickle cell mouse penis (17). Sickle cell mouse penis demonstrates decreased Rho A activity leading to decreased ROCK2 expression and decreased total ROCK activity, all contributing to decreased basal vasoconstriction in the penis. The limited contractile ability of the corporal tissue leads to susceptibility of the tissue to excessive relaxation leading to priapism. Thus, priapism results from alterations in the vasoconstrictive and vasorelaxatory pathways of the penis that drives the organ into a state of smooth muscle hyperrelaxation and erection with little contractile reserve to counteract the process and return the penis to a flaccid state.

Ischemic priapism can also result from malignant infiltration of the penis by local or metastatic cancer, and priapism may be the presenting feature of metastatic disease to the penis in 27% of cases (18). The pathophysiology of malignant priapism can be secondary to either direct tumor infiltration of the corpora cavernosa or invasion of penile venous structures that inhibits drainage, promotes venous stasis, and leads to thrombosis within the penis (18).

DIAGNOSIS

Diagnosis and classification of priapism are based on clinical evaluation, including laboratory tests and corporal blood gas measurement via aspirated blood directly from the corpora cavernosa (12). A diagnostic and therapeutic algorithm is provided in Figure 68.1. Initial evaluation should focus on differentiation between ischemic and nonischemic priapism because this will guide both the type and urgency of further management. Patients should have a detailed history and physical examination with an emphasis on possible causative factors (see Table 68.1). Important historical factors are duration of current event, history of priapism, and baseline erectile function. A detailed medical and social history to evaluate for hematologic or neurologic conditions and review of both prescription and illicit drug use must be performed. Prolonged duration with progressively worsening penile pain favors ischemic priapism, whereas nonpainful, partial erection with preceding trauma, instrumentation, or surgery favors nonischemic priapism. Physical examination should be directed to the penis and perineum to evaluate degree of pain and rigidity while inspecting for any neurologic defect, pelvic or penile masses, or evidence of trauma. Laboratory evaluation includes a complete blood count and reticulocyte count to evaluate for anemia, infection, or other hematologic abnormalities. A sickle cell anemia screen can be used when appropriate. A urinalysis and urine toxicology screen for recent illicit, narcotic, or psychoactive drug use should be ordered.



Diagnosis – History, Physical Exam, Blood gas, +/– Doppler ultrasound
Ischemic Priapism
Nonischemic Priapism
<48 hours
>48 hours
Observation
Aspiration +/– irrigation
Consider:
– proceeding to surgical shunting
– immediate penile prosthesis implant
Selective Arterial Embolization for patients desiring treatment
Phenyephrine injection
Surgical Shunting
Surgical Shunting with Cannulation
Resolution

FIGURE 68.1 Algorithm for management of priapism.

Corporal blood gas analysis will aid in determining the type of priapism. Visual inspection of the initial aspirate can be useful with deoxygenated blood of ischemic priapism having a dark, thick, “crankcase oil” appearance versus the bright red appearance of oxygenated blood in nonischemic priapism. Acidotic (pH <7.25, pO_2 <30 mm Hg, pCO_2 >60 mm Hg) penile blood gas indicates ischemic priapism, whereas a blood gas consistent with arterial blood is suggestive of nonischemic priapism. When the diagnosis is in question, color duplex Doppler ultrasound can be performed to evaluate cavernosal arterial inflow with a lack of arterial inflow being pathognomonic for ischemic priapism (12). Doppler ultrasound is also useful following interventions for priapism as it can delineate between persistent ischemia, resolved ischemia with penile edema or conversion of ischemic priapism to high-flow priapism (1).

MEDICAL THERAPY

Initial medical therapy aims to relieve penile pain and decompress the corporal bodies, thus restoring blood flow and oxygenation with the goal of minimizing tissue necrosis or injury. Ischemic priapism of >4 hours *requires* decompression of the corpora cavernosa, although one may proceed earlier in the case of severe pain. Treatment delay increases the risk of tissue injury and the risk for development of ED. There is no role for oral therapy in management of acute priapism, and initial therapy can be performed in the office setting or emergency department. A dorsal nerve block or local penile shaft block with lidocaine is typically applied. Then, a large-bore needle or 16- to 18-gauge angiocatheter is inserted directly into the penile shaft laterally until the tip has entered the corpus cavernosum. This allows for both therapeutic aspiration of old blood and injection of alpha-adrenergic agonists (5,19). Aspiration is performed with simultaneous compression of the penis below the needle insertion site until soft. Subsequent release of the compression allows the penis to fill with blood. Aspiration alone may result in detumescence in 36% of cases but has the additional benefits of relieving pressure and pain and allowing return of oxygenated blood to the corpora cavernosa even if it fails to achieve detumescence. Aspiration is followed by intracavernous injection with sympathomimetic drugs according to the American Urological Association Guidelines Panel (5). Due to potential side effects of hypertension, reflex bradycardia, or cardiac arrhythmia that may result from systemic absorption of agents, hemodynamic monitoring is recommended and alpha-adrenergic agonist therapy is contraindicated in patients with malignant or poorly controlled hypertension or patients with active monoamine oxidase inhibitor use (1). Phenylephrine, a selective alpha-1 agonist, diluted to a concentration of 100 βg per mL is preferred as it minimizes the risk of cardiovascular side effects (1). One milliliter or 100 βg is injected into the corpora cavernosa and the penis observed for 5 minutes (1).

If the penis remains rigid, then repeat aspiration and injection can be performed approximately every 5 minutes until detumescence results. This method may resolve ischemic priapism in as many as 80% of cases (12). If the penis remains erect after a reasonable duration and dose escalation of phenylephrine (1 mg total phenylephrine or >1 hour), then it is reasonable to perform another Doppler ultrasound to evaluate arterial flow in the penis or proceed to surgical shunting. Reevaluation with ultrasound may be helpful in this setting because it may differentiate between penile edema with restored corporal arterial flow versus persistent ischemic priapism. Ischemic priapism of extended duration, that is, >48 hours is unlikely to resolve with aspiration and injection and surgical shunting should be performed in a timely manner.

SURGICAL THERAPY

Surgical shunting of ischemic priapism is indicated following failure of resolution with repeated aspiration and injections or in patients who cannot tolerate injections due to conditions described in the previous section or who develop significant cardiovascular side effects from injection therapy. Surgical management of ischemic priapism involves the creation of a fistula that allows blood to drain from the corpora cavernosa to the glans penis, corpus spongiosum, or graft vein until the penile compartment syndrome has subsided. The fistula will then spontaneously close once the priapic event has resolved. Success of shunting is determined first by detumescence and then the appearance of red, oxygenated blood from the corpora cavernosa. Subsequent corporal blood gas measurements or penile duplex ultrasound can then confirm success. Surgical shunting is generally undertaken in a stepwise fashion with the least invasive procedure performed first and more invasive shunts undertaken only when preceding procedures have failed. Surgical shunt procedures are subdivided by their location on the penis and degree of invasiveness. Percutaneous distal shunt procedures (Winter, Ebbehoj, T-shunt) are typically first-line procedures that are easy to perform and have lower complication rates (1,20,21). Open distal shunts (Al-Ghorab, Burnett Corporal “snake”) typically follow percutaneous shunts and if these are unsuccessful, open proximal (corporospongiosal/Quackles) shunts may be used. If necessary, saphenous or deep/superficial dorsal vein shunting may be required, but this is rarely performed in the contemporary era.

Surgical Technique

Corporoglanular (Winter) Shunt

The Winter shunt can be performed under general or local anesthesia. If a local block is used, it should be a penile glans block to ensure adequate anesthesia to the surgical site. The tips of the rigid corpora cavernosa are palpated and then a large biopsy needle is inserted through the glans and advanced into the corpus cavernosum several times (1,20). The result is multiple core biopsy windows or fistulas between the glans and the distal end of each corporal body. Multiple fistulas are necessary to create sufficient communicating channels for blood egress and subsequent detumescence. The puncture site of the glans is closed with a figure-of-eight 3-0 chromic suture. The patient should be instructed to gently squeeze the penis every few minutes for the next 12 hours to minimize blood pooling in the penis. If a partial (>50%) or complete erection persists, the procedure may be repeated or an alternative shunt can be used. An adequate result is indicated by swelling of the glans and detumescence of the penis.

Corporoglanular (Ebbehoj and T-) Shunt

The Ebbehoj shunt procedure involves the use of a no. 11 scalpel blade passed percutaneously through the glans and into the corpus cavernosum (1,20). This results in a larger fistula between the glans and each tip of the corpus cavernosum than a Winter shunt (Fig. 68.2). The scalpel is inserted into the corpora away from the urethral meatus with care to avoid urethral injury and is then withdrawn to create an opening in the tunica albuginea between the glans and corporal bodies. A modification of the Ebbehoj shunt is the T procedure or T-shunt (1,20). A no. 10 scalpel blade is placed first vertically through the glans into the corpus cavernosum. The scalpel is then turned 90 degrees away from the urethra and withdrawn. The maneuver creates a T-shaped opening in the tunica albuginea. Both the Ebbehoj and T-shunt can be performed unilaterally or bilaterally when necessary. The T-shunt should provide a larger fistula between the corpora cavernosa and spongiosal tissue of the glans for subsequent blood egress and detumescence. The glans defect is closed with 3-0 chromic sutures.

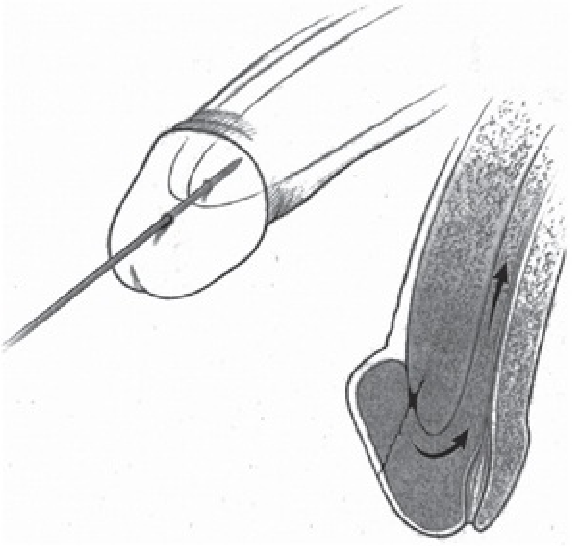


FIGURE 68.2 Corporoglanular (Winter) shunt. A needle is placed through the glans penis into the corpora cavernosa in order to make multiple core biopsy windows or fistulas between the glans and each corporal body. *Arrows* indicated return of blood flow via corpus spongiosum. (Adapted with permission from Broderick GA. Priapism. In: Wein AJ, Kavoussi LR, Novick AC, et al, eds. *Campbell-Walsh Urology*, 10th ed. Philadelphia: Saunders Elsevier, 2012:749–769. Copyright © 2012 Elsevier Inc. All rights reserved.)

Corporoglanular (Al-Ghorab) Shunt

If the previously described distal shunts are unsuccessful, then an Al-Ghorab shunt is performed (1) (Fig. 68.3). Failure of previous distal shunts is typically due to the window between the corpora cavernosa and corpus spongiosum being too small to allow blood egress from the cavernosa. An Al-Ghorab shunt is typically performed under general anesthesia and a penile glans block is additionally applied. A tourniquet is placed around the base of the penis and then a 2-cm transverse incision is made on the dorsum of the glans 1 cm distal to the coronal sulcus. A transverse incision performed in the distal penile shaft proximal to the corona is not recommended because this may severe sensory nerves to the dorsal aspect of the glans and potentially lead to distal atrophy. The tips of the corpora cavernosa are then separated from the glans and transfixed with 2-0 sutures of Vicryl and grasped with a Kocher clamp to allow traction and prevent withdrawal during detumescence. A conical segment of tunica albuginea approximately 5 mm in diameter should be sharply excised from the distal end of each corporal body. Dark blood will drain from the corporal bodies, and once detumescence occurs, reapproximation of the skin with 3-0 chromic sutures is performed. Care should be taken not to obliterate the spongy vascular space of the glans penis.

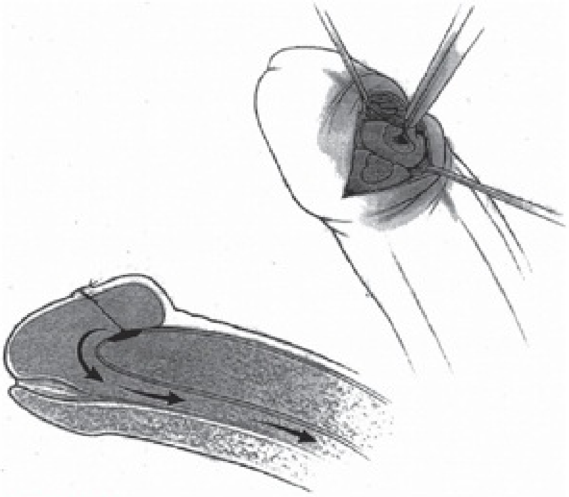

FIGURE 68.3 Corporoglanular (Al-Ghorab) shunt. An incision is made dorsally into the glans penis, and portions of the distal corpus cavernosum are excised as a vent for blood drainage. *Arrows* indicated return of blood flow via corpus spongiosum. (Adapted with permission from Broderick GA. Priapism. In: Wein AJ, Kavoussi LR, Novick AC, et al, eds. *Campbell-Walsh Urology*, 10th ed. Philadelphia: Saunders Elsevier, 2012:749–769. Corporal Cannulation Techniques

Corporal cannulation has been shown to be efficacious for priapism episodes of extended durations (>36 hours). These techniques involve the addition of corporal instrumentation with sounds or dilators to the previously described distal shunt techniques to facilitate evacuation of congested, clotted blood. Brant and colleagues (22) described the use of “tunneling” in a series of seven patients in which a bilateral T-shunt procedure was performed as previously described. A 20Fr straight sound was introduced through each of the glans incisions, into the corpora, and advanced to the level of the crura. This technique creates an intracavernous “tunnel” from proximal to distal, aids in the evacuation of blood and reestablishment of cavernous blood flow.

Burnett and Pierorazio (23) described a modification of the Al-Ghorab shunt involving transglanular insertion of a size 7/8 Hegar dilator into the corporal bodies. An Al-Ghorab shunt is first performed bilaterally under general anesthesia with a penile block. Once the surgical windows into the distal corporal ends have been created a 7/8 Hegar dilator is inserted in a retrograde fashion through the tunical window and advanced proximally while applying a gentle boring motion to release congested blood (23). Following removal of the dilator, manual evacuation of blood through the channel with proximal to distal compression is performed. The glans incision is then closed with a 4-0 chromic suture. This technique corrected priapism in 8 of 10 men who had a mean priapism duration of 75 hours (24). The developers of these cannulation techniques suggest the advantages of a more complete evacuation of congested blood from the cavernosal bodies leading to increased shunt patency rates, exploitation of the favorable venous drainage of the glans and corpus spongiosum, a lower complication rate, and potential for recovery of erectile function even with priapism episodes of extremely extended durations (22–24).

Proximal Shunts

Corporospongiosal Shunts

A proximal corporospongiosal shunt is performed in rare circumstances (1,20). When distal shunts are unsuccessful or technically unachievable, then a proximal shunt may be required to reestablish blood drainage and allow for detumescence. The disadvantages of corporospongiosal shunts are low shunt patency rates, high rates of ED, and number of potential complications. To perform a Quackle (unilateral) or Sacher (bilateral) shunt, the patient is placed in lithotomy position and a perineal incision is performed. The bulbocavernous muscle is then dissected off the corpus spongiosum. A longitudinal incision or excisions of a 1 cm long ellipse of tissue is made in the spongiosal and corporal bodies in a parallel fashion so that the defects may then be sutured together. Care must be taken to avoid incising the urethra which would result in a fistula. The walls of the two incisions are then sewn together in a running fashion using a 5-0 polydioxanone suture. If detumescence is not achieved with unilateral shunt creation, then a bilateral shunt may be required and the right and left side must be separated by at least 1 cm to decreased risk of urethral stricture at the point of spongiosal to corporal communication (1).

Corporo-Saphenous Vein Shunt

The Grayhack shunt is a rarely performed procedure due to technical difficulties of the surgical approach, lack of efficacy, and complication rate (1,20). First, an incision is made at the base of the penis and the tunica albuginea of the corpus cavernosum is exposed. The femoral artery is then palpated and an incision is made at the saphenofemoral junction located approximately 3 to 4 cm below the inguinal ligament. After identifying the saphenous vein, it is mobilized for a distance of 10 cm distal to the fossa ovalis. It is then ligated distally and the index finger is used to tunnel beneath the skin to join the two incisions. The vein is passed through the tunnel without tension or torsion. An ellipse of tunica albuginea approximately 1.5 by 0.5 cm is excised and the vein is then spatulated an anastomosed to the tunica albuginea using a continuous 5-0 polydioxanone suture. A dry dressing is applied and intermittent squeezing of the penis is recommended to facilitate blood egress.

Corporo-Deep Dorsal Vein Shunt

The Barry shunt is a last resort for patients with severe priapism refractory to distal shunt maneuvers (1,20). For this shunt, a 4-cm skin incision is made at the base of the penis. The superficial or deep dorsal vein is identified with care taken to avoid injury to the dorsal artery or sensory nerves. After ligation and division, the proximal limb is spatulated ventrally and anastomosed to the corpora cavernosa in an end-to-side fashion in a tension-free manner. The penile skin is closed over the surgical site.

PENILE PROSTHESIS INSERTION

Penile prosthesis implantation plays a role in the management of acute priapism episodes when it is anticipated than penile shunting procedures will likely result in failure. The International Society for Sexual Medicine Standards Committee has established priapism episodes of greater than 72 hours duration as cases where substantial cavernous thrombosis is likely to have occurred rendering blood aspiration from the corporal bodies unfeasible (25). The touted advantages of immediate penile prosthesis implantation are a technically easier surgery and obviation of penile length loss associated with penile fibrosis which inevitably follows priapism events. Several series of "early" penile prosthesis insertion have been described, the largest of which was presented by Ralph and colleagues in 2009 (26). The study involved 50 men with prolonged priapism who failed initial therapy with aspiration, irrigation, and shunting. All men underwent successful implantation of either a malleable prosthesis (43 men) or three-piece inflatable prosthesis (7 men).

MANAGEMENT OF NONISCHEMIC PRIAPISM

Initial management of nonischemic priapism is observation due to its lack of ischemic damage and long-term consequences as well as a spontaneous resolution rate of nearly 50% to 63% (4,5). Patients seeking therapy beyond observation must be counseled on the spontaneous resolution rate that can occur even after months of observation and the potential complications of invasive treatments. Penile arteriography with selective arterial embolization is typically performed as first-line therapy with resolution rates of 75% to 100% (5,27). The use of nonpermanent materials such as autologous clot and absorbable gels is preferred over permanent materials because they have been associated with lower rates of postoperative ED (5% nonpermanent versus 39% permanent) (27). However, recent reviews have found the rates of ED following permanent embolic material use to be much lower (11.5% permanent versus 3% nonpermanent) but still not as low as nonpermanent materials (27). Second-line surgical management is arterial ligation with the use of intraoperative penile ultrasound to localize the fistula. Complications of invasive management of nonischemic priapism include ED, penile gangrene, gluteal ischemia, perineal abscess formation, and purulent cavernositis (12).

PERSPECTIVES

The most common complications of priapism and its subsequent treatment are ED, penile deformity, and possibly even genital tissue loss. The most critical factor in maintaining potency in men presenting with ischemic priapism is immediate treatment; however, it is important to recognize that these sequelae may occur despite early successful management of a priapism episode. Patients treated within 12 to 24 hours will have an increased likelihood of maintaining erectile function than those with delayed treatment. Prolonged episodes of priapism (>36 hours) and recurrent priapism are more likely to result in ED due to impaired smooth muscle function and fibrosis, and these patients will likely require penile prosthesis implantation as pharmacologic erectogenic therapy will inevitably fail. Erectile function is best preserved in the setting of nonischemic priapism. Nonischemic priapism is not a surgical emergency and is managed by observation initially with high spontaneous resolution rates. Arterial embolization may be used as treatment but carries associated risks including development of erectile dysfunction.

Proximal shunting procedures are primarily historical and rarely used in contemporary practice. Distal corporoglanular and corporospongiosal shunt procedures are the preferred surgical management techniques for ischemic priapism, and the addition of cannulation techniques have improved the efficacy of these procedures even for prolonged ischemic events. Immediate penile prosthesis insertion is a reasonable option for the treatment of prolonged or refractory ischemic priapism. Advantages of this approach include preservation of sexual function, maintenance of penile length, and the relative ease of performing the procedure before penile fibrosis ensues.

COMPLICATIONS

Complications arising due to shunt procedures are urethral damage and fistula formation, bleeding, purulent cavernositis, skin necrosis, abscess formation, and pulmonary embolism, which can occur after the Grayhack procedure. The majority of surgical shunts will close with time and it is generally thought that shunting does not in itself cause permanent ED. Failure of venous shunts to close spontaneously can result in venogenic ED due to venous leak. However, penile vascular dysfunction following shunt procedures may be a direct result of the priapism episode itself, with ischemia leading to fibrosis of the erectile tissue.

CHAPTER 69 PENILE PROSTHESIS IMPLANTATION

ROBERT M. COWARD AND CULLEY C. CARSON

Although erectile dysfunction has been described since ancient times, adequate treatment has only been available for the last four decades. The era of implantable devices began with the development of silicone-based prosthetic materials in the late 1960s, as a result of the United States space program (1). Modern penile prosthetic devices were first developed in the early 1970s, when Small et al. (2), along with Scott et al. (3), reported the implantation of penile prosthetic devices into the corpora cavernosa to fill the cavernous space and provide a physiologically functional erection with good cosmetic results. These devices have undergone multiple redesigns and improvements between the early prosthetic devices and the currently available inflatable penile prostheses. Mechanical malfunction rates in these early devices were reported in excess of 60% of cases. Current inflatable prosthetic devices have a far improved mechanical reliability, with 81% to 94%, 68% to 89%, and 57% to 76% at 5, 10, and 15 years, respectively (4). Design changes over the past several decades have included replacement of stainless steel connectors with plastic connectors, addition of nonkinked tubing, single-design construction, Teflon cylinder input sleeves, multiple-layer cylinders, and most recently, the technologic advances in infection prevention in implant design.

The currently available devices can be divided into semirigid, mechanical, and multiple-component inflatable penile prostheses, of which there are two- and three-piece models available (Table 69.1). The semirigid rod and mechanical prostheses available today are the successors of the earliest devices designed in the 1970s. These devices, although easier to implant, have few advantages over the newer inflatable devices, as infection and mechanical malfunction rates are similar. The Genesis (Coloplast Inc, Minneapolis, Minnesota) is the currently available semirigid rod device that consists of a central metal core and a silicone elastomer rod (Fig. 69.1). The mechanical Spectra (American Medical Systems, Minnetonka, Minnesota) implant employs a spring and cable design with alternating titanium and polyethylene segments (Fig. 69.2). The Genesis is the only available malleable device with a hydrophilic coating that allows for the impregnation of antibiotics.

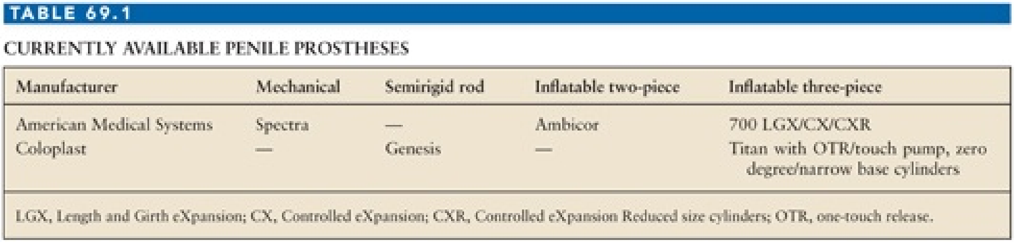

TABLE 69.1

CURRENTLY AVAILABLE PENILE PROSTHESES

Manufacturer	Mechanical	Semirigid rod	Inflatable two-piece	Inflatable three-piece
American Medical Systems	Spectra	—	Ambicor	700 LGX/CX/CXR
Coloplast	—	Genesis	—	Titan with OTR/touch pump, zero degree/narrow base cylinders

LGX, Length and Girth eXpansion; CX, Controlled eXpansion; CXR, Controlled eXpansion Reduced size cylinders; OTR, one-touch release.

The three-piece inflatable penile prostheses continue to be the most satisfactory prostheses once they are implanted, provided they remain functional. These prosthetic devices produce the most natural-appearing rigidity in girth and length and excellent flaccidity for optimal concealment. The three-piece inflatable penile prostheses vary in construction from three-layer silicon/Dacron/Lycra/silicone in the AMS 700 Series (American Medical Systems, Minnetonka, Minnesota) (Fig. 69.3) to a single layer of Bioflex, a polyurethane material, in the Coloplast Titan series (Coloplast Inc, Minneapolis, Minnesota) (Fig. 69.4). The Titan model is coated with polyvinylpyrrolidone, a hydrophilic material that allows absorption of an antibiotic solution of the surgeon’s choice. The preimplantation antibiotic “dip” provides a hydrophilic layer to resist bacterial adherence. The AMS 700 implants are impregnated with InhibiZone, a proprietary combination of rifampin and minocycline that is U.S. Food and Drug Administration (FDA) approved to reduce infections. Options with both available inflatable devices include standard or narrow cylinders and girth expansion and/or length elongation. Numerous trials have shown comparable efficacy, satisfaction rates, mechanical reliability, and infection rates between the two currently available inflatable devices.

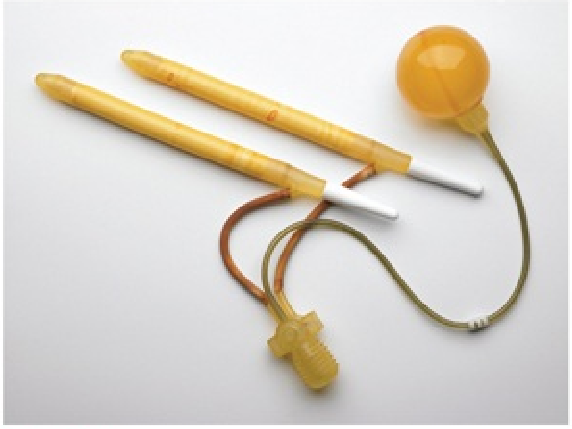

FIGURE 69.3 American Medical Systems 700 LGX three-piece inflatable penile prosthesis. (Courtesy of American Medical Systems, Inc.)

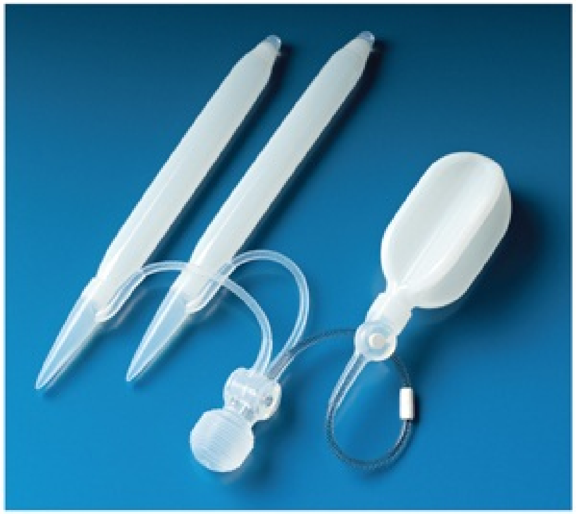

FIGURE 69.4 Coloplast Titan touch zero-degree three-piece inflatable penile prosthesis. (Courtesy of Coloplast.)

To improve ease of surgical implantation and avoid the portion of the prosthesis placed within the abdominal region, two-piece devices were designed. Because these two-piece inflatable prostheses remove the separate reservoir, additional fluid is available either by a larger scrotal pump or a combination of proximal cylinder and pump reservoir. Although these devices provide adequate penile stiffness in many patients, the limited reservoir capacity decreases the flaccidity and, in some patients, may diminish rigidity. These prostheses are especially difficult to deflate in patients with small penises and may provide inadequate rigidity in patients with longer penises. Although less optimal than three-piece devices, these two-piece implants are ideal for patients in whom reservoir placement is absolutely contraindicated. However, ectopic reservoir placement is an option for those that a three-piece device is desired, and previous surgical history precludes the ability to safely place the reservoir in the standard location. The only currently available two-piece inflatable penile prosthesis is the AMS Ambicor (American Medical Systems, Minnetonka, Minnesota) (Fig. 69.5).

DIAGNOSIS

The diagnosis of erectile dysfunction can be obtained by history. The clinician should determine whether the erectile dysfunction is situational or constant, whether the degree of dysfunction is partial or total, and also include the details of the relationship with the partner. Any coexisting conditions such as diabetes, vascular disease, smoking, medications (especially steroids, hormones, antihypertensives, or antidepressants), and use of alcohol or drugs should be identified. Physical examination should include the body habitus, hair distribution, external genitalia, and lower extremity pulses. Special attention will be directed to the testicles and penis to rule out hypogonadism and penile deformity such as Peyronie’s disease. Evaluation of the penile vasculature with penile Doppler ultrasound is useful in some patients in securing the diagnosis.

INDICATIONS FOR SURGERY

Although there are a variety of penile prosthesis designs currently available for implantation, not all patients with erectile dysfunction are candidates for penile prosthesis implantation. Penile prostheses are generally the procedure of last resort for those men failing more conservative measures such as oral phosphodiesterase type 5 (PDE5) inhibitors, vacuum erection device, urethral alprostadil, and intracavernosal injection therapy. For those men in whom penile prostheses are suggested, careful counseling before penile implant procedures will limit many of the problems with postoperative dissatisfaction. Once the discussion and demonstration of penile implant varieties has been carried out, patients can be counseled about the most appropriate penile prosthesis for their individual use. Patients may choose a specific prosthetic type based on their needs and preferences (1). Younger patients with normal manual dexterity and patients who wear form-fitting clothing, or who shower in public at athletic facilities, often choose a three-piece inflatable penile prosthesis, as the penile appearance in the flaccid position is better than other designs. For these patients, implantation of a semirigid rod penile prosthesis requires a significant lifestyle change; hence, they are better served with an inflatable device. Similarly, patients with Peyronie’s disease, secondary implantation, or significant peripheral neuropathy, such as that occurring in severe diabetes, are best served with an inflatable penile prosthesis, as intracavernosal pressures are decreased between uses, and the possibility of extrusion is diminished.

For patients in whom the convenience of inflation and deflation are not important, the risks and mechanical malfunctions may outweigh the disadvantages of a malleable penile prosthesis. Such patients as paraplegics who require external urinary collection device, those with inadequate manual dexterity, or those with significant obesity may be better served with a malleable penile prosthesis.

ALTERNATIVE THERAPY

Alternative therapy includes sexual counseling, oral pharmacotherapy with PDE5 inhibitors, vacuum erection devices, intracavernosal injection therapy, and intraurethral suppositories. Less commonly used therapies such as penile vascular (arterial or venous) surgery is discussed in Chapter 72.

SURGICAL TECHNIQUE

Surgical implantation of penile prostheses can be carried out using several surgical approaches and incisions. Semirigid and mechanical malleable prostheses can be implanted through a distal penile approach. Multiple-piece prostheses can be implanted by either the infrapubic or penoscrotal approach. Although individual surgeons have a variety of rationales for each of these approaches, there does not appear to be any clear advantage in patient satisfaction or outcome of the two approaches. Patient anatomy may dictate appropriate choice. Patients with previous abdominal surgical procedures where reservoir placement is difficult may be better served with an infrapubic approach, whereas patients with morbid obesity may be better approached through a penoscrotal incision. Two-piece devices, because there is no separate reservoir, are best implanted through a penoscrotal incision.

Infection prevention is of utmost importance during placement of a penile implant. Perioperative antibiotic treatment is critical in diminishing incidence of infection and prosthetic removal. Importantly, the recently introduced InhibiZone impregnated coating on the AMS 700 series implants and the lubricious hydrophilic coating of the Coloplast Titan series implants have reduced infection risk by threefold. Contemporary series report an infection rate of approximately 1% to 3% (5). Eid et al. (6) have described a “no-touch” technique, which takes meticulous care in preventing the device from touching the skin during implantation and has decreased the overall infection rate of virgin and revision cases to 0.46%. Other studies have shown the risk for infection in revision penile prosthesis cases to vary from 6.7% to 18.8% (5). A perioperative dosage of an intravenous antibiotic agent is recommended by the American Urological Association and should be administered within 1 to 2 hours of the incision and continued for 24 hours postoperatively. Recommended agents include an aminoglycoside plus a first-generation cephalosporin, second-generation cephalosporin, or vancomycin for prophylaxis of the most common pathogenic skin flora (5). Patients may be discharged with a continued course of oral antibiotic therapy at the surgeon’s discretion. The use of antibiotic-coated penile implants, while reducing the incidence of postoperative infection, does not preclude the need for systemic, perioperative antibiotics.

Penoscrotal Approach

Three-piece inflatable penile prostheses, as well as semirigid and two-piece prostheses, can be implanted by a transverse or vertical penoscrotal incision. This approach has distinct advantages in obese patients and is the most common approach for routine penile prosthesis implantation. The scrotum is carefully clipped, and the lower abdomen, genitals, and upper thighs are prepped. Various methods of skin prepping have been described including prolonged preoperative scrubs and most recently alcohol-based solution; however, these are surgeon-dependent. Because the penoscrotal approach requires differentiation of corpora cavernosa from the corpus spongiosum during dissection, initial placement of a Foley catheter may facilitate exposure. Prior to making the incision, a local anesthetic dorsal penile block with plain bupivacaine to decrease postoperative pain may be used (7). A penile ventral ring block is not performed, as it may distort the tissue planes of the initial dissection. The incision is placed in the upper portion of the scrotum and is usually transverse horizontal, one fingerbreadth below the penoscrotal junction. The Scott/Lone Star retractor (Lone Star Medical Products; Stafford, Texas) facilitates exposure with this incision (Fig. 69.6). Once the skin incision has been carried out, a blunt Henry sweep maneuver with an opposite spreading motion of two hooked index fingers aids the dissection, as it is carried down to the corpora cavernosa bilaterally (8). Buck's fascia is opened at the penoscrotal junction over each corpus. The corpus spongiosum is exposed. The midline spongiosal attachments of the scrotal septum may be taken down sharply for better proximal corporal exposure, and rake hooks are gently used with the Lone Star retractor to secure the bilateral testicles inferiorly, and six blunt hooks are useful to retract the lateral and superior aspects of the skin incision (Fig. 69.7).

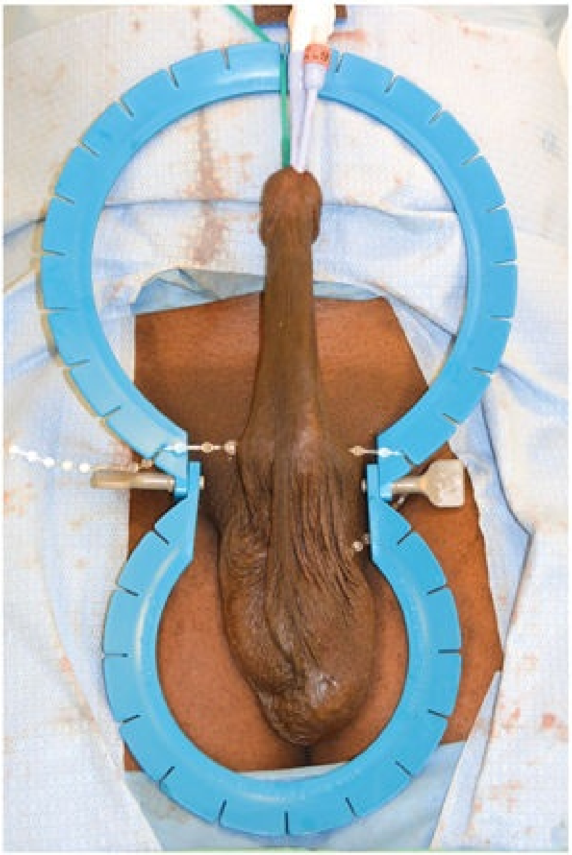

FIGURE 69.6 Initial setup for penoscrotal approach.

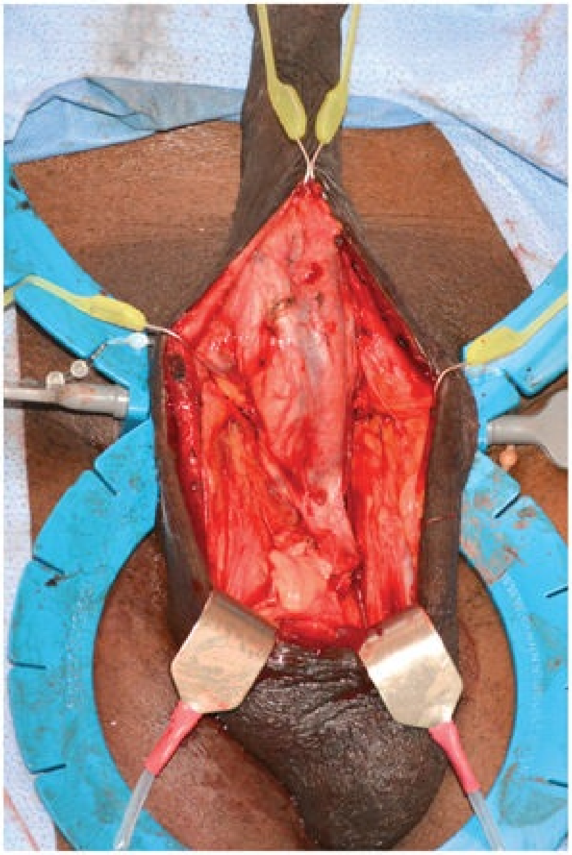

FIGURE 69.7 Corporal exposure using the Scott Lone Star Retractor.

With the shiny white tunica albuginea of the corpora cavernosa exposed, 2-0 absorbable synthetic stay sutures are placed on either side of the chosen location for each corporotomy. Care is taken that the corporotomies are symmetric in order to make the later corporal sizing measurements more straightforward. The corporal incision should be placed proximal enough so the input tubing is not palpable, avoiding the so-called “tailpipe penis” but must still allow easy exit of the input tubing and minimize cylinder to input tubing contact. The corporotomy incisions of approximately 1.5 cm are then carried out with scalpel or electrocautery between the stay sutures and the corpora cavernosa entered. Metzenbaum scissors may then be used to carefully initiate the tunneling of the corpora cavernosa, gently spreading the cavernosal tissue. Hegar, Brooks, Pratt, or Dilamezinsert dilators from size 9 to 12 may be used if necessary. In the absence of corporal fibrosis, the authors prefer a single pass with the Furlow introducer, which saves time with dilation and measurement with a single step and results in less postoperative pain (9) (Fig. 69.8). The corpora are dilated both proximally until the ischial tuberosities are encountered and distally palpating the glans penis to identify the distal most aspect of the corpora. To avoid urethral injury or corporal crossover, care is taken to maintain the urethra in a fixed position during distal dilation by bluntly grasping the glans and fossa navicularis between the thumb and index finger of the nondominant hand. The key to safe distal dilation is to direct the dilator laterally toward the ipsilateral shoulder, as it is advanced toward the glans. If concern arises for urethral injury, the corporotomy may be irrigated using a bulb syringe as a distal fluid challenge test to check for irrigant egression from the urethra. If corporal fibrosis is encountered, Rosello cavernatomes (Coloplast Inc, Minneapolis, Minnesota) may be used to dilate to size 12. In severe cases of fibrosis, the initial plane may be obtained with the careful passage of an Otis urethrotome. The advanced technique of corporal excavation (10), not further described herein, is recommended if a safe plane of dilation is unable to be achieved blindly. Once dilation has been adequately carried out bilaterally, the Furlow introducer or Dilamezinsert is used to measure the corporal length using the stay suture as a central point of reference. The proximal and distal measurements are added to identify total corporal length and obtain appropriately sized inflatable cylinders with added rear tip extenders. The measured length should be symmetric between the bilateral corpora but occasionally may differ by up to 1 cm and can be corrected with rear tip extenders. If significantly asymmetric corporal lengths are determined, the surgeon should be concerned about proximal perforation or distal crossover. To check for proximal perforation, a Brooks dilator can be placed in each proximal corpus as a “field goal test.” The dilators should symmetrically resemble a field goal without clinking together at the tips. Once the measurement has been obtained, additional interrupted sutures may be placed for later corporotomy closure if necessary prior to implantation of the cylinders. The advantage to this technique is the elimination of suture needles close to the area of the inflatable cylinder, diminishing the possibility of cylinder damage during corporotomy closure.

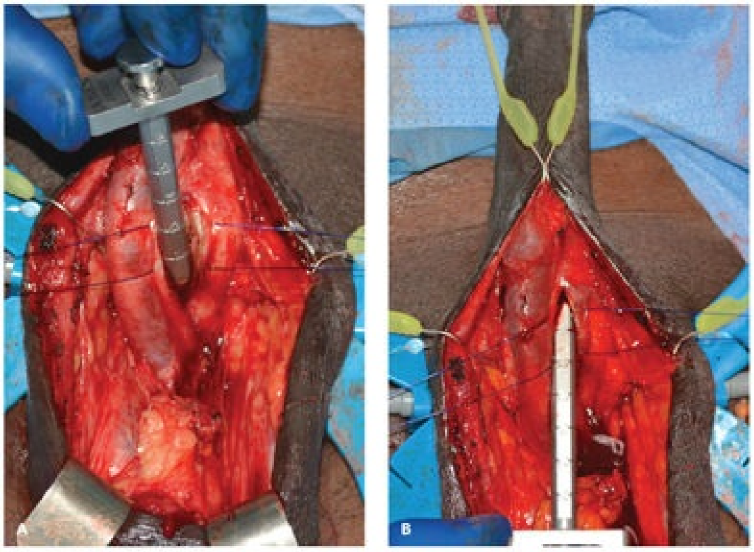

FIGURE 69.8 A single pass with the Furlow introducer for corporal dilation, proximally (A) and distally (B).

Dissection for reservoir placement is then carried out, either with a second separate infrapubic incision or more commonly is performed through the same penoscrotal incision (Fig. 69.9). The scrotal skin incision is retracted to the area of the external inguinal ring and dissection is carried out medial to the spermatic cord, superolateral to the corporotomy, and just up and over the pubis. Traditionally, the reservoir is placed on the right side but may be placed on either side at the surgeon's discretion. The bladder is completely drained before proceeding. The transversalis fascia is identified and incised sharply using Metzenbaum scissors placed firmly against the pubic tubercle. Dissection is carried out using a combination of sharp and blunt dissection. Dilation of the space is performed with blunt dissection with the index finger after incision of the transversalis fascia or with gentle spreading of a large Kelly clamp or long nasal speculum. The reservoir balloon is then positioned over the index finger and placed into the perivesical space of Retzius. Inflation of the reservoir with injectable saline is carried out with care that no backpressure is observed. If refilling of the syringe occurs, the reservoir is removed and repositioned or the reservoir pocket must be enlarged. As the reservoir is filled, the tubing should be seen slightly retracting into the space. If the tubing is increasingly moving out of the space while filling, the reservoir is likely malpositioned. After filling the reservoir, the tubing is gently pulled so the reservoir is positioned with the hub right at the fascial opening to aid explantation, if necessary in the future. The urine in the catheter tubing may be checked for hematuria to quickly confirm no injury to the bladder has occurred.

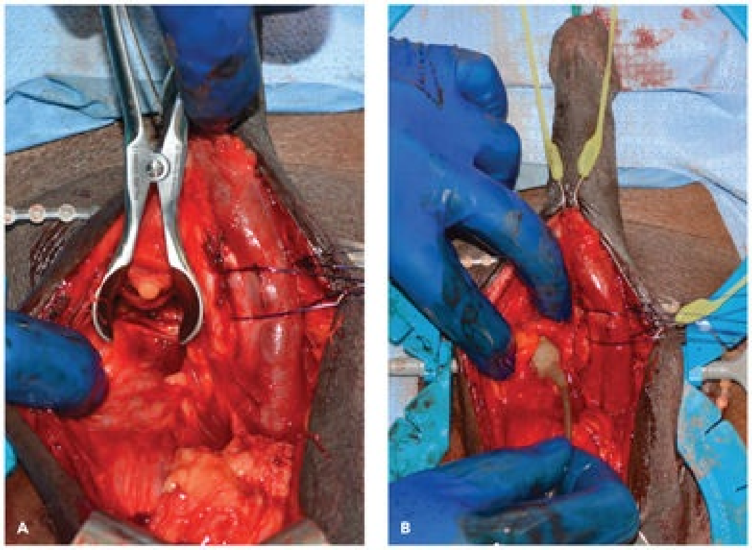

FIGURE 69.9 The reservoir space is developed with a nasal speculum (A) and the reservoir is placed through the incision in transversalis fascia medial to the spermatic cord and into the space of Retzius (B).

A recently described advancement in the surgical technique of penile implant surgery is that of ectopic reservoir placement. In ectopic reservoir placement, instead of being placed posterior to transversalis fascia in the perivesical space of Retzius, the reservoir is placed posterior to the rectus abdominis but anterior to transversalis fascia. The advantage to this technique is that it avoids the morbidity of complications resulting from traditional reservoir placement in patients who have previously had the space obliterated. Complications avoided include bowel, vascular, and bladder injuries that can occur with traditional reservoir placement after robotic-assisted laparoscopic prostatectomy, laparoscopic herniorrhaphy, or renal transplant. In addition to a separate incision, the space can be created from the penoscrotal approach by passing a long clamp such as a lung grasping forceps, ring forceps, or long nasal speculum into the medial leaflet of the external inguinal ring in a cephalad direction with gentle spreading of the clamp, developing the submuscular space posterior to the rectus (11). Early results of this technique support its safety and efficacy, with a complication rate attributable to the ectopic reservoir placement to a total less than 3%, including herniation, palpability requiring revision, and autoinflation (12).

Once the reservoir is placed, the implant is prepared on the back table by removing all air bubbles and then brought into the field. At this time, surgical gloves may be changed and an additional drape may be placed just beneath the incision and over the patient’s lap to minimize contact of the device with the working field. Rear tip extenders of various sizes are available to be placed on the proximal cylinder end to adjust length. The cylinders are positioned within the dilated corpora cavernosa using the Furlow introducer and Keith needle; the cylinders are pulled into position by the suture attached to the tip of each cylinder (Fig. 69.10). Once positioned, it is essential to visualize the cylinder in the corpus cavernosum to ensure that it is flat, there is no kinking, and complete proximal and distal seating has taken place. Closure of the corpora cavernosa is carried out using the preplaced sutures while maintaining distal traction on the cylinder suture to ensure adequate seating. Following placement of the cylinders and closure of the corporotomy incisions, cylinder inflation can be tested, if necessary, to identify any abnormalities in position, curvature, or other problems with the cylinders. By connecting a syringe of sterile injectable saline to the open end of the pump’s input tubing, manual inflation of the device is performed to check the proper position of the cylinders.

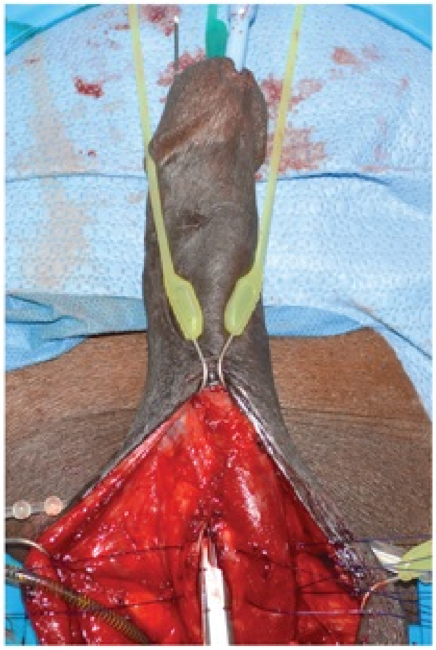

FIGURE 69.10 The Furlow introducer is used to deploy the Keith needle through the glans in order to pull the cylinder into place distally by its attached suture.

The pump is positioned in the most dependent portion of the scrotum. The pump may be placed inferiorly between the testicles or more commonly is placed within a subdartos pouch. For creation of a subdartos pouch, a small incision is made in the inferior scrotal midline dartos fascia between two Allis clamps, and the pouch is created using gentle spreading of a long nasal speculum or ring forceps. Alternatively, the most dependent part of the scrotum may be everted up through the penoscrotal incision with the index and middle fingers, and the dartos may be gently spread off of the underlying skin with a sponge (Fig. 69.11). The pump is then positioned into the pouch and may be secured using a Babcock clamp, whereas an interrupted or purse-string 3-0 absorbable suture is used to secure the pump and tubing down into its pouch.

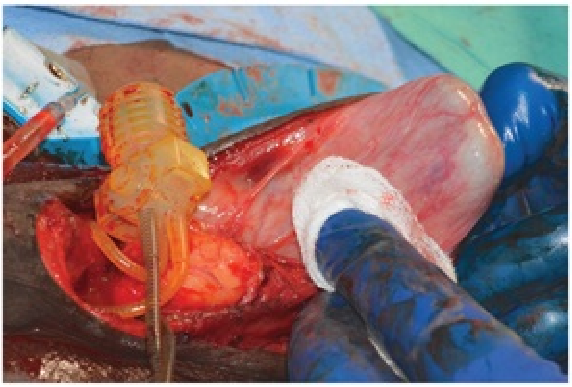

FIGURE 69.11 The most dependent part of the scrotum is everted up through the incision and the dartos is gently spread off of the underlying skin with a sponge to create a subdartos pouch for the pump.

After pump placement, the tubing between the reservoir and pump is then connected. The tubing is tailored to eliminate excessive length but to allow for adequate pump positioning prior to making the connection. Shodded clamps are used to compress the tubing, and the ends of the tubing, once tailored, are flushed with saline to eliminate bubbles, small particles, and blood clots. Tubing connection is then carried out using quick connectors, snap-on connectors, or suture tie plastic connectors. In revision prosthesis cases, in which a residual tubing segment is connected to a new device piece, suture tie plastic connectors must be used. After the tubing is connected, the adequacy of the connection is tested by gently pulling on the connectors. All shodded clamps are removed and the device is cycled multiple times to ensure adequate location, placement, and penile rigidity (Fig. 69.12).

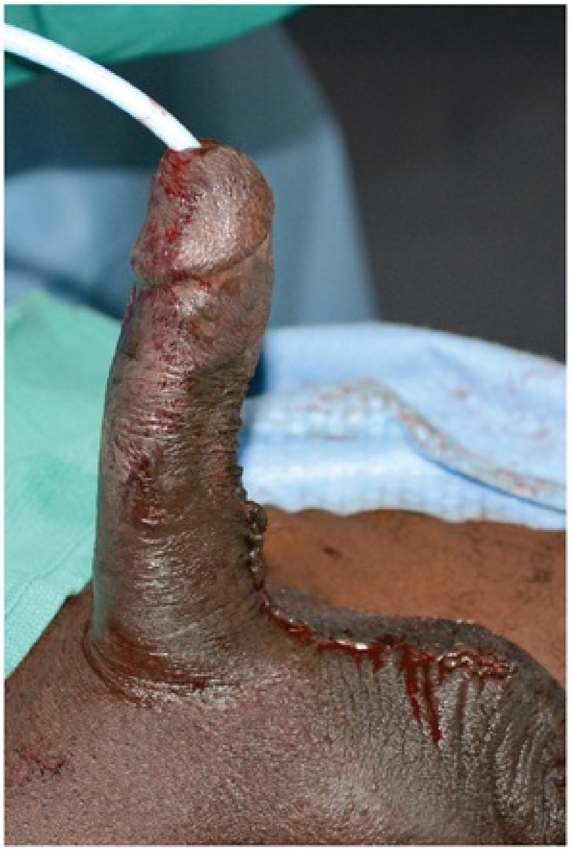

FIGURE 69.12 The implanted device is tested.

In patients with Peyronie’s disease, mild curvature is commonly overcome with the inflatable penile prosthesis. If the device is test inflated after implantation and significant residual curvature is encountered, however, several options are available. The most commonly used and effective technique is penile modeling (13). During modeling, the cylinders are fully inflated and the cylinder exit tubing is clamped with shodded clamps to prevent excessive backpressure to the pump. Two fingers are firmly pressed on the corporotomy sites by the assistant to prevent blow-out of the cylinder through the corporotomies during modeling. The shaft is then forcibly bent in the direction opposite the curvature for approximately 90 seconds to rupture the plaque, and this maneuver may be repeated several times until desired results are achieved. In difficult cases of severe residual curvature, other options for straightening at this juncture include concomitant tunical plication, relaxing tunical incisions, or plaque incision and grafting (13). If anticipated preoperatively, the case may begin with an artificial erection of injectable saline for characterization of the curvature, and a vertical incision should be used, which can be extended ventrally onto the shaft for placement of the plication sutures prior to implantation of the device (14).

For closure, a deep dartos layer with 3-0 absorbable sutures called a Lentz stitch is helpful to keep the tubing maintained in a posterior location in the scrotum so it is not palpable beneath the incision. Suction drains may be used at the surgeon’s discretion. A formal dartos layer is then reapproximated with 3-0 absorbable suture, and finally, skin closure is carried out with a running horizontal mattress suture in the standard fashion. In men with a penoscrotal skin web, the horizontal skin incision can be closed in a vertical midline Heineke-Mikulicz fashion to enhance functional penile length. Alternatively, in the case of a scrotal web, a ventral phalloplasty may be performed as part of the initial incision. As described by Miranda-Sousa et al. (15), a checkmark-shaped incision in an asymmetric V shape, longer in the inferior segment, may be made on each side of the web to excise a diamond-shaped piece of skin at the start of the case, with a vertical midline closure. After closure, a dressing of a topical skin adhesive or antibiotic ointment is applied. A “mummy wrap” may be applied with 4-inch Kerlix gauze in a figure of eight fashion, whereas the pump is maintained in its dependent position during the wrap (8).

The penile prosthesis remains deflated for 4 weeks while healing occurs. Prior to activation, the patient is advised to retract the pump into his scrotum on a daily basis and tight underwear and athletic supports are avoided to maintain pump position. A return office visit for activation of the device is carried out once discomfort has resolved. Patients are advised to inflate and deflate the device on a daily basis for 4 weeks to allow tissue expansion around the prosthesis. Most patients can then begin use of their device 4 to 6 weeks after implantation.

Infrapubic Approach

The infrapubic approach allows better visualization of the reservoir placement than the penoscrotal approach. However, because of the proximity of the dorsal neurovascular bundle in the infrapubic approach, injury is possible, resulting in decreased distal penile sensation in some patients. The infrapubic approach is usually carried out with a horizontal incision approximately one fingerbreadth below the pubic symphysis, allowing implantation with an easily concealed incision once the pubic hair regrows. In patients with significant obesity or a previous midline incision, however, a midline incision carried out just to the base of the penis facilitates exposure of the corpora cavernosa and improves the ability for corporal dilation. After division of Colles and Scarpa fascia, the dissection is continued to the rectus fascia. The rectus fascia is incised horizontally and dissected cephalad for approximately 2 to 3 cm. A midline separation of the rectus muscles is carried out using sharp and blunt dissection. A pouch is created bluntly beneath the rectus muscles to comfortably insert the inflatable reservoir without compression. The previously described methods of reservoir placement in the section for the penoscrotal approach, including ectopic reservoir placement, may also be used during an infrapubic approach.

Dissection is then carried out over the corpora cavernosa. Sharp and blunt dissection is begun on either side of the fundiform ligament identifying the dorsal neurovascular bundle. Note that the dorsal nerves of the penis lay approximately 2 to 3 mm lateral to the deep dorsal vein. A directly visualized dorsal nerve block with plain bupivacaine may be performed at this time if desired to decrease postoperative pain (7). Once Buck’s fascia has been dissected free from the tunica albuginea, the shiny white tunica albuginea is fixed with traction stay sutures of 2-0 absorbable, synthetic suture. Incision, dilation, and sizing of the corpora cavernosa are similar to that described previously for the penoscrotal approach. Cylinder placement follows next as previously described earlier in a similar manner as with the penoscrotal approach.

A finger is then placed in the most dependent portion of the scrotum lateral to the testicle on the right or left side. The finger is then pushed to the area of the external inguinal ring and any adipose tissue in this area is dissected free to expose the dartos fascia. Following development of the subdartos pouch for the pump, the pump is positioned in the most dependent portion of the scrotum and temporarily fixed into position using a Babcock clamp. The inflatable reservoir is then placed in the previously constructed position and filled with an appropriate volume of sterile injectable saline. Before connection, it is important to release pressure on the filling syringe and determine if any backfilling is seen. The tubing is tailored to the appropriate length and connected in a similar manner as previously described for the penoscrotal approach.

Suction drains may be used at the surgeon’s discretion. Following test inflation and deflation, thorough irrigation with antibiotic solution is carried out and the rectus fascia closed with interrupted absorbable synthetic sutures if this approach was used for reservoir placement. The wound is then closed in the standard fashion with two layers of subcutaneous tissue and a subcuticular skin suture. A dressing is applied as previously described, a Foley catheter placed if necessary, and a 10-pound sandbag is placed over the incision during the immediate recovery.

Postoperatively, patients are instructed to maintain their penis in a Sutherland position for 4 to 6 weeks. Tight underwear and athletic supporters are not used in an effort to maintain the pump in its most dependent position.

Distal Penile (Subcoronal) Approach

A distal penile (subcoronal) approach is usually the best approach for insertion of a semirigid or mechanical penile prosthesis. This incision heals well, allows complete corporal dilation, and facilitates rod placement. A local anesthetic dorsal penile and ring block with plain bupivacaine is performed to decrease postoperative pain (7). After placement of a Foley urethral catheter, a dorsal circumcoronal incision is carried out over 180 degrees of the subcoronal region of the penis along the previous circumcision scar. Dissection is carried down to the layer of Buck’s fascia, taking care to avoid the dorsal penile nerves, which course dorsally within Buck’s fascia just lateral to the visible dorsal vein. After Buck’s fascia is identified, stay sutures are applied to the two corpora through the tunica albuginea lateral to the penile nerves, and longitudinal incisions are made. These longitudinal incisions can be extended proximally as much as is necessary for dilation and cylinder insertion. The corporal dissection is begun with Metzenbaum scissors to establish a track in the corporal tissue. Dilation then follows with Hegar, Brooks, or Dilamezinsert dilators to 9 to 11 cm depending on required cylinder girth. A single pass with the Furlow provides adequate dilation in the absence of corporal fibrosis, saves time, and results in less postoperative pain (9). Once the corpora are sized using a Furlow introducer or other dilator, the cylinders can be placed. A small vein retractor can be used to facilitate placement of the distal end of the cylinder. The corporotomy is closed with 2-0 absorbable, synthetic sutures. A noncompression dressing is applied.

OUTCOMES

Complications

Despite careful counseling, many patients enter penile prosthesis procedures with expectations that cannot be met by penile prosthesis surgery. Complaints about decreased penile length compared with preimplant state, decreased penile sensation, “coolness” of the penis and glans penis, and chronic pain, as well as partner dissatisfaction, are among the complaints patients may voice despite adequate surgical implantation and satisfactory mechanical functioning. Fortunately, these complaints are unusual and more than 90% of patients report satisfaction with their prostheses (4). Many patients who are dissatisfied with their penile prostheses will benefit from sexual counseling or continued counseling assistance from the implanting surgeon to be sure that they are able to operate the device satisfactorily and understand its use.

Most patients’ dissatisfaction results from difficulty with operation of the device and unrealistic expectations. Preoperative discussions with patients should include the concept that penile prostheses do not create normal erections but only support the penis for sexual activity. Penile prosthesis surgery brings about the ability to resume sexual functioning and vaginal penetration, but decreased penile sensation, length, and engorgement may result. Patients should also be advised that a penile prosthesis will not improve libido or ejaculation. Patients frequently report delayed or difficult ejaculation initially following penile prosthesis surgery. This delay is primarily a result of inadequate preparation, stimulation, and psychological adjustment to the prosthesis. Most patients require 3 to 6 months of prosthesis use with careful attention to presexual stimulation before ejaculation routinely returns to preoperative levels. Because the prosthesis neither improves nor detracts from preoperative ejaculatory ability, patients must be counseled regarding their preoperative ejaculatory ability before prosthesis placement.

The most worrisome postoperative complication is infection, which occurs in fewer than 10% of all patients (5). Perioperative prosthetic infections can, however, occur at any time in the postoperative period in patients with penile or other prosthetic devices. Patients continue to be at risk for hematogenous seeded infections from gastrointestinal, dental, or urologic manipulations as well as remote infections. Patients must be counseled to request antibiotic coverage if remote infections occur. Gram-positive organisms such as *Staphylococcus epidermidis* cause most periprosthetic infections, but gram-negative organisms such as *Escherichia coli* and *Pseudomonas* are also common culprits. Severe gangrenous infections with a combination of gram-negative and anaerobic organisms have also been identified and frequently result in significant disability and tissue loss. Patients at increased risk for perioperative infections include diabetics, patients undergoing penile straightening procedures or circumcision with prosthetic implantation, patients with urinary tract bacterial colonization, and immunocompromised patients, such as posttransplant patients. Spinal cord injury patients have also been reported to have a specially increased risk of infections, with rates reported as high as 15%.

Appropriate treatment of prosthetic infections requires early and immediate identification with institution of parenteral antibiotic therapy and early prosthesis removal (16). Conservative treatment would dictate a healing period of 3 to 6 months followed by repeat prosthesis implantation. Better long-term results with no additional morbidity can be achieved with the prosthesis immediate salvage technique reported by Mulcahy (17). This technique—which requires removal of the infected implant and two rounds of vigorous irrigation using solutions of antibiotics, povidone iodine, and hydrogen peroxide prior to immediate replacement with a new device—is successful in more than 75% of infected prostheses (16).

The most common complication of penile prosthesis function is mechanical malfunction. After a decline from early rates as high as 61%, the current inflatable prosthetic devices have mechanical reliability rates of 81% to 94%, 68% to 89%, and 57% to 76% at 5, 10, and 15 years, respectively (4). Aneurismal dilation of inflatable cylinders, reservoir leakage, and pump malfunction have been limited by device modifications. Fluid leak, however, continues to be a problem for many inflatable penile prostheses. These mechanical malfunctions require replacement of the leaking portion of the inflatable portion of the prosthesis. If nonfunctioning prosthesis has been in place more than 2 years, however, it is usual practice to replace the entire device to reduce further mechanical malfunction.

Semirigid rod penile prostheses are associated with fewer mechanical problems; the most common complication associated with these prostheses is cylinder erosion through skin or urethra. Prosthesis fracture or breakage has been reported, and patients may return 6 to 8 years post-implantation with complaints of decreased rigidity of their semirigid rod, indicating fracture of central prosthetic cylinder wires. These wire fractures cannot usually be appreciated radiographically unless the prosthesis is put on stretch once it has been explanted. Replacement of these devices is indicated when patients note decreased rigidity. Prosthesis extrusion or erosion is most common in diabetics and spinal cord injury patients, especially those requiring urinary management with catheter placement or of condom catheter collection devices.

Extrusion can also occur beneath the penile skin distally from vigorous dilation or remotely from trauma or repeated use. These extrusions are characterized by distal penile pain with use.

Correction can be carried out with the use of a patch graft, but a better approach is rerouting with no grafting material. Rerouting is associated with less infection and pain and a reduced recurrence rate.

Results

Long-term function and use have been confirmed in studies of patients with implants as long as 10 years (18). Overall satisfaction rates from long-term series of three-piece inflatable penile prostheses range from 92% to 100% among patients and 91% to 95% among partners. In addition, 86% to 88% of patients would recommend the prosthesis to a friend (4). Studies have confirmed that patient satisfaction among men with penile implants is greater than any other erectile dysfunction (ED) treatment modality (1).

CHAPTER 70 PENILE VASCULAR SURGERY

JACK M. ZUCKERMAN AND KURT MCCAMMON

Erectile dysfunction (ED) negatively impacts quality of life for a diverse spectrum of the worldwide population. In the United States, its prevalence in men 40 to 70 years of age has been estimated around 50% (1), and the incidence of ED increases with each decade of life (2). Many patients with ED have a variety of risk factors, including atherosclerotic arterial disease, diabetes mellitus, hypertension, and tobacco abuse leading to arteriogenic or neurogenic ED. Not surprisingly, coronary artery disease (CAD) has been shown to have a direct correlation with pudendal artery stenosis leading to arterial insufficiency and ED (3).

In the aging male, ED most commonly is a manifestation of the patients overall health, specifically vascular health. Sustaining a rigid erection requires adequate perfusion of the corpora cavernosa through a robust arterial inflow as well as increased resistance to venous outflow. Systemic risk factors affecting either arterial inflow or venous outflow, therefore, can be expected to negatively impact erectile function. Endothelial dysfunction commonly affects both pudendal and coronary arteries (4). For patients without known vascular disease, a new ED diagnosis may represent a harbinger of future adverse events, such as myocardial infarction or cerebrovascular insult. Montorsi and colleagues identified a significant lag of 39 months between presentation of ED and CAD, suggesting that the smaller penile vessels are affected by arterial disease prior to the larger caliber coronary arteries (5).

Although common in the elderly population, young and middle-aged men (age teens to 40 or 50 years) present less often for evaluation of ED. Although practitioners now commonly consider vascular disease in the older patient with ED, younger men are more likely to be diagnosed with a psychogenic etiology for their impotence. Ironically, as these young men are often otherwise healthy, it is this very population who may be found to have isolated vascular lesions amenable to curative surgical intervention.

Traumatic injuries are a less frequent etiology of ED. Pelvic fractures, which are the primary traumatic injury associated with ED, are relatively rare and occur in less than 10% of blunt trauma (6,7). Pelvic fractures most often result from a high-energy impact, which has implications for nearby genitourinary organs, primarily bladder and urethra. Pelvic fracture urethral injuries (PFUIs) with disruption of the membranous urethra have been reported in up to 10%, and bladder injuries occur slightly more frequently (6–9). Despite the polytrauma setting in which most pelvic fractures occur, improvements in trauma resuscitation have resulted in dramatically reduced mortality for these patients. Demetriades and colleagues described a large series of traumatic pelvic fractures and found an overall mortality rate of only 13.6%, of which less than 1% died as a direct result of the pelvic fracture (6). These improvements in survivability subsequently result in a larger portion of these patients suffering from chronic problems related to their injuries, including sexual dysfunction. This is particularly problematic for the young adult patient at the beginning of his sexual life.

The distal internal pudendal, common penile, and cavernosal arteries are also susceptible to blunt trauma less obvious than an injury that causes a pelvic fracture. Given their location within Alcock canal and proximity to the ischiopubic rami, these arteries can be injured simply bicycle riding or by a straddle injury, such as perineal trauma attempting advanced “rail tricks” on a skateboard or snowboard (10).

Similar to focal arterial insufficiency, ED secondary to veno-occlusive disease (venogenic ED [VED]) is an etiology found in a portion of younger patients and may be amenable to surgical intervention. Failure of full expansion of the sinus spaces secondary to diffuse smooth muscle dysfunction or replacement with fibrous tissue accounts for much of the identified veno-occlusive dysfunction. Additionally, alterations within the tunica albuginea, specifically atrophy of the collagen composition leading to tissue laxity, have been suggested to account for a portion of patients with diffuse veno-occlusive dysfunction (11). These etiologies are thought to occur primarily in older men, especially those with other associated conditions, such as having undergone radical prostatectomy or pelvic radiation (12,13). However, in younger patients, focal defects in the integrity of the tunica albuginea or congenital abnormal venous channels may also result in VED. These patients often present with primary ED, present since initial sexual encounters. Penile trauma, surgery for priapism or Peyronie disease, and previous endoscopic incisions of urethral strictures can all lead to defects in the corporal veno-occlusive mechanism (14).

In this chapter, we will discuss the vascular surgical management for ED in patients with focal anatomic defects in either arterial inflow or venous outflow. We review the diagnosis, patient selection, evaluation and treatment outcomes, and complications.

PHYSIOLOGY OF ERECTILE FUNCTION

Penile erection begins with autonomic cavernosal nerve stimulation (15). Nitric oxide (NO) synthase, an enzyme in lacunar space vascular endothelial cells and autonomic cavernosal nerve endings, facilitates the synthesis of NO from molecular oxygen and L-arginine. During sexual stimulation, NO activates guanylyl cyclase, an enzyme that facilitates the synthesis of the second messenger, cyclic guanosine monophosphate (cGMP) from guanosine triphosphate. The elevated concentrations of cGMP result in lowered intracellular calcium, thus promoting penile smooth muscle relaxation. Biologic consequences of NO-cGMP relaxation include increased arterial blood inflow, engorgement of the lacunar spaces, lengthening and enlargement of the corporal erectile tissue within the constrained tunica albuginea, and eventual subtunical venule occlusion with increased penile venous outflow resistance and corporal veno-occlusive function (16).

DIAGNOSIS

Younger men with ED and the absence of other vascular risk factors represent the ideal patient population to evaluate for vasculogenic and/or VED. Evaluation should begin with a comprehensive history and physical examination, specifically a detailed past urologic history. Common risk factors for ED should be ruled out, such as medication side effects, cardiovascular disease, diabetes, tobacco use, and psychological disorders. History may reveal a history of pelvic fracture or penile/perineal trauma. Distance bicycle riding is a known risk factor for pudendal arterial injury, which may lead to arteriogenic ED and should be assessed (17). Patients with congenital veno-occlusive dysfunction may complain of complete lifelong ED or rapid loss of erection. Any past genitourinary procedures, especially penile surgeries must be documented. A limited endocrine evaluation should be obtained, including a morning testosterone.

Patients suspected of either arteriogenic or VED should be offered a progressive diagnostic evaluation (Fig. 70.1). Penile color duplex Doppler ultrasonography is the best initial study. This test allows a rapid assessment of both penile arterial inflow and veno-occlusion. Additionally, it allows direct observation of the erectile response to intracavernosal injection of a vasodilating agent. Patients are administered 20 μg of prostaglandin E_1, and the duplex is performed 10 minutes following administration. We determine patients to have arterial insufficiency if their peak systolic velocities for the dorsal or cavernosal arteries are less than 30 cm per second (18,19). Prolonged systolic rise time, especially greater than 100 milliseconds, is also associated with atherosclerotic ED.

Revascularization

FIGURE 70.1 Diagnostic algorithm for arterial or venogenic erectile dysfunction (*VED*). *DICC*, direct infusion cavernosometry and cavernosography; *EDV*, end diastolic velocity; *ICI*, intra-cavernosal injection; *RI*, resistive index; *PDE5*, phosphodiesterase type 5.

In patients with normal arterial inflow, venous leak is ruled out if the resistive index is >0.9 and/or the end-diastolic velocity approaches zero (less than 5 cm per second). Venous leak is suggested when the resistive index is <0.75 and the dorsal vein velocity is >10 cm per second (18). Finally, during the penile duplex ultrasound, the deep inferior epigastric arteries (DIEA) are also evaluated, giving us important information about vessel size, blood flow within the vessel, and where the vessel begins its intramuscular course in the event these vessels are used for arterial bypass surgery. During the entire procedure, it is crucial to provide a private, quiet, and comfortable environment for testing because patient anxiety will effectively counteract the dilatory effect of the injected agent and reduce the reliability of the results. Those patients not achieving a sufficient erection following injection of the vasodilating agent, whether secondary to anxiety and sympathetic discharge or concomitant arterial pathology, cannot be adequately evaluated for veno-occlusive dysfunction. Penile duplex interpreted in that scenario have been shown more commonly to falsely diagnose venous leak (20). Conversely, patients achieving a normal rigid erection following administration of a vasoactive intracavernosal agent lessen the likelihood of significant arterial or venous pathology.

If arterial insufficiency is suggested, patients being considered for surgical intervention should undergo a selective internal pudendal angiogram to evaluate for pudendal or common penile artery occlusion. We also evaluate the inferior epigastric arteries during this angiogram because these will serve as the donor vessels during any future revascularization. More recently, we have obtained computerized tomography (CT) angiography to help clarify the course of the deep inferior epigastric artery (DIEA). We have found this especially helpful in those patients who show an early entry of the DIEA into the rectus muscle. Patients in whom venogenic impotence is suggested on penile duplex do not require a pudendal angiogram.

Direct infusion cavernosometry and cavernosography (DICC) are the definitive tests for diagnosing VED and identifying sites of leakage. We perform this study in all patients being considered for venous surgery. Small gauge needles are placed into each of the corpora cavernosa. One is connected to a pressure transducer, and the other is connected to an infusion pump with metered delivery rates of heparinized saline. After injection of a vasodilating agent, the need for a flow rate of >20 mL per minute of saline to maintain a rigid erection at an intracorporeal pressure of at least 90 mm Hg is indicative of corporal veno-occlusive dysfunction. A maintenance flow rate between 10 and 20 mL per minute is considered borderline for venous leakage. Excessively high maintenance flows (>50 mL per minute) usually indicate massive venous runoff, and these patients do not do well with veno-occlusive surgery (21). Pressure decay of more than 30 mm Hg within 30 seconds is also suggestive of venous leak. Isosmotic contrast material is then infused into the corpora at the previously defined maintenance flow rate from cavernosometry and then anteroposterior and oblique radiographs of the penis are taken. The most common sites of venous leakage seen in patients with veno-occlusive dysfunction are the deep dorsal vein, the cavernosal veins, and the circumflex veins at the base of the penis. A large amount of drainage into all of these systems is also a contraindication to surgery.

More recently, CT imaging has been suggested in lieu of DICC to evaluate the penile venous drainage. After injection of a vasodilating agent, Virag and Paul reported on 38 patients who had dilute contrast injected into the corporal bodies and three-dimensional CT reconstructions obtained to evaluate prominent venous drainage (22). They suggest that this may be an option in the future that is less invasive and easier to perform. At this time, however, protocols for its use in the diagnosis of venous leak are not well defined, and we continue to perform DICC prior to any venous procedure for VED.

ALTERNATIVE TREATMENT OPTIONS

All men thought to have either focal arteriogenic or VED should undergo a trial of medical management. Many patients, regardless of the etiology of their ED, will respond to medical management with oral phosphodiesterase type 5 (PDE5) inhibitors. It has been suggested that a PDE5 trial may be performed in most men even prior to an extensive workup because their efficacy lessens the likelihood of surgically significant arterial or venous pathology (23). Other conservative options include a vacuum erection device with or without a penile band. The band is an especially useful conservative option in patients with VED because it acts to counteract the leak. Patients not responding to these agents should be offered a trial of intracavernosal injections with either prostaglandin E_1, papaverine, and/or phentolamine. Intraurethral prostaglandin (MUSE) is also an option for patients not willing to attempt penile injections. Patients not responsive to more conservative measures should be counseled on available surgical options, including arterial or venous surgery (when indicated) or penile prosthesis placement.

ARTERIOGENIC ERECTILE DYSFUNCTION

Patient Selection

Patient selection is paramount when considering penile arterial bypass for the treatment of ED. All patients should have a normal neurologic and endocrine evaluation. Younger patients without associated vascular comorbidities will achieve the most optimal outcome, although limited comorbid conditions are not an absolute contraindication. Current and past tobacco use will lead to worse outcomes, and patients should be counseled accordingly (24). All patients should have the diagnosis confirmed with penile duplex ultrasound without suggestion of veno-occlusive dysfunction. Focal lesions should be confirmed with selective pudendal angiography and appropriate recipient and donor vessels should be identified. At our institution, we primarily offer revascularization to patients with bilateral complete occlusion of the internal pudendal or common penile arteries without reconstitution through collaterals; however, arterial bypass has been performed in patients with unilateral lesions only.

Surgical Technique

All our penile revascularization surgeries are performed in a similar fashion, by anastomosing the deep inferior epigastric artery (IEA) to the dorsal penile artery in an end-to-side fashion (Fig. 70.2). The side chosen for anastomosis is based on the vessel with the largest diameter both on angiogram and intraoperative findings. Occasionally, we do anastomose the right IEA to the left dorsal penile artery, or vice versa, but this is rare. Each surgery is performed using a two-team approach with urology and plastic and reconstructive surgery working simultaneously. All anastomoses are performed using standard microvascular technique.

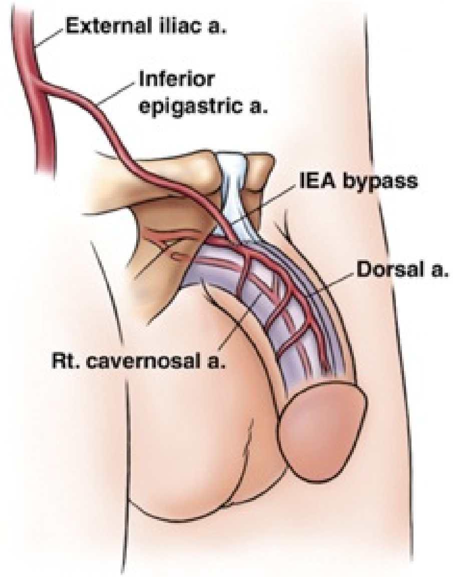

FIGURE 70.2 Arterial anatomy for penile revascularization. *IEA*, inferior epigastric artery.

Patients are admitted to the hospital the day of surgery. They are taken to the operating room and placed on general endotracheal anesthesia. All are given preoperative prophylactic antibiotics usually with a second-generation cephalosporin within 60 minutes of the skin incision. Patients are positioned supine with a slight frog leg then prepped with Betadine and draped using sterile technique from the xiphoid down to the knees. The procedure begins with isolation of the dorsal arteries bilaterally. A small infrapubic incision is made just above the penis. Dissection is carried down until the superficial dorsal vein is identified and either mobilized or ligated. Buck fascia is opened in the midline on top of the deep dorsal vein and mobilized laterally. The dorsal arteries are identified bilaterally and secured with a vessel loop.

After controlling the dorsal arteries, confirming the feasibility of the vascular anastomosis and selecting the best recipient vessel, we begin dissection of the deep IEA. A paramedian incision is extended from the pubic symphysis past the umbilicus for several centimeters on the selected side. The lateral aspect of the anterior rectus sheath is identified and incised through its entire length. The lateral border of the rectus abdominis is elevated and retracted medially, revealing the deep IEA beneath it. The artery is dissected free superiorly as far as necessary to provide adequate pedicle length for the anastomosis, usually to the level of the umbilicus (Fig. 70.3). If the artery enters the rectus muscle early in its course, it is carefully freed from the muscular attachments with bipolar forceps. We always harvest the artery with its attached vena comitantes.

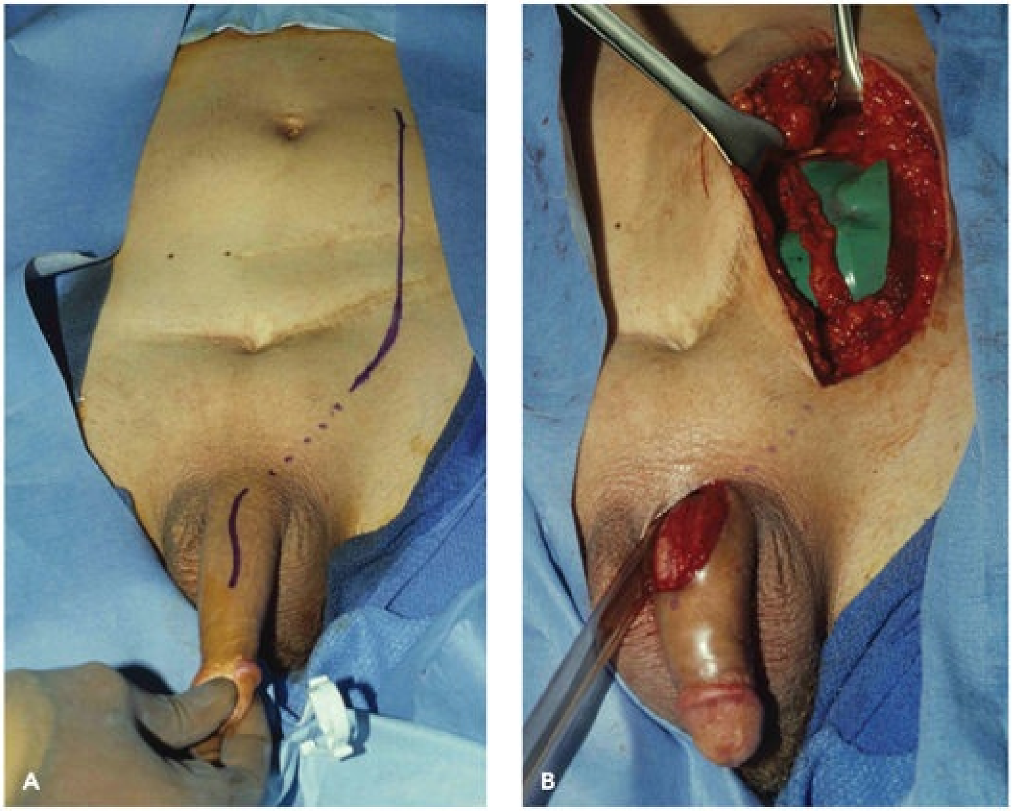

FIGURE 70.3 **A and B:** Dissection of the IEA and dorsal penile artery.

We then divide the deep inferior epigastric vascular pedicle at the distal extent of our dissection and pass it, with the help of a 36Fr chest tube, in a subfascial manner to the dorsum of the penis. Small hemoclips secure the vessel during passage. Gentle suction on the tube can aid in the transposition of the vessel. An operating microscope is then brought into the field. Vessel clamps are placed on the selected dorsal artery and an arteriotomy is made. The arteriotomy must be made with care. In most cases, the internal diameter of the dorsal penile artery is quite small with the majority of the vessel diameter related to the thickness of the media of the vessel wall. Rather than excision of vessel wall for arteriotomy, one should perform a careful incision of the vessel wall (Fig. 70.4). The donor IEA is anastomosed to the dorsal artery in an end-to-side fashion using interrupted 10-0 Prolene suture on a 75-micron needle (Fig. 70.5). The patency of the anastomosis is confirmed with Doppler ultrasound intraoperatively, and revisions are made if necessary. A closed suction drain is placed beneath the rectus muscle and the incisions are closed in layers with a subcuticular closure of the skin.

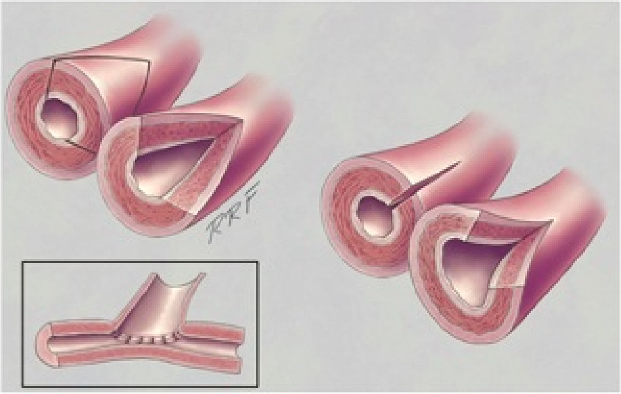

FIGURE 70.4 End-to-side microvascular arterial anastomosis. Inset: sagital view after completion of the microvascular anastomosis.

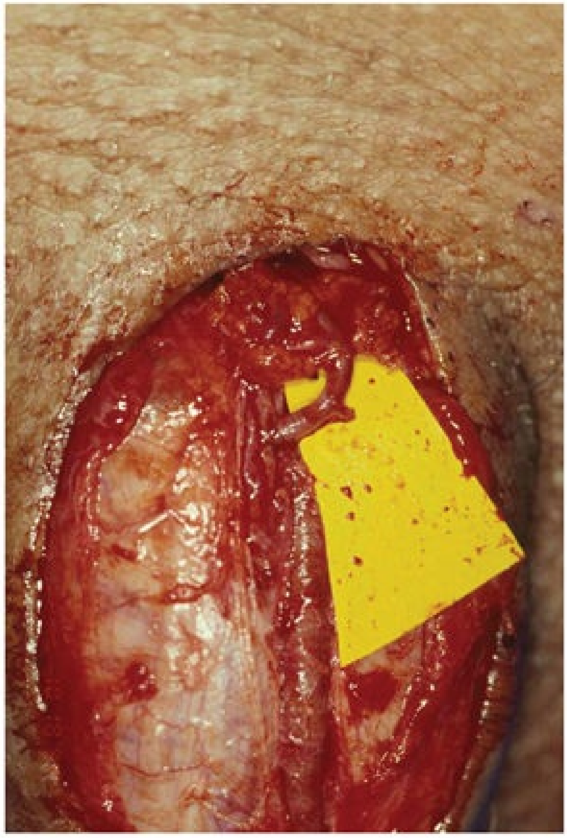

FIGURE 70.5 Completed arterial anastomosis.

Postoperatively, patients are maintained on bedrest for 2 to 3 days and most often discharged home on postoperative day 4 or 5. All patients receive subcutaneous heparin while inpatient for deep venous thrombosis prophylaxis, and 81 mg of aspirin is prescribed postoperatively in an effort to decrease the risk for graft thrombosis. Patients are seen back in the office weekly for a wound examination. A repeat penile duplex is obtained in all patients no sooner than 6 weeks postoperatively. Patients not achieving spontaneous erections at initial follow up are offered pharmacologic assistance with either oral PDE5 inhibitors or intracavernosal injections to augment their erections.

Outcomes and Complications

Surgeons have been performing penile revascularization for arteriogenic ED for nearly 40 years (25). Although initial results were poor, subsequent modifications to the original procedure have shown improved outcomes as demonstrated by more contemporary series (24,26–29). A variety of surgical techniques have been described in the literature with varying success. It is often difficult to objectively compare them because both the measures of success and included patient populations are often quite disparate.

The majority of case series following penile arterial bypass grafting include patients with a variety of ED etiologies who were subsequently found to have arterial insufficiency. Kayigil and colleagues reported on 110 patients undergoing penile revascularization (29). Procedures were performed using a Furlow-Fisher modification of the Virag procedure with an end-to-side anastomosis of the IEA to the deep dorsal vein. The vein was then ligated proximal to the arteriovenous anastomosis. They found an overall success rate based on International Index of Erectile Function (IIEF) questionnaires of 72.7%, although this decreased significantly over time in those with extended follow-up. Results were complicated by graft thrombosis in 11 patients (10%), penile edema in 9%, and glans hypervascularity in 6%, requiring subcoronal venous ligation. In this series, two patients had ED as a result of a pelvic fracture, but the results of these patients were not independently reported.

Vardi and associates presented their results performing penile revascularization in 52 patients with a variety of operative techniques, including IEA to either the dorsal artery, dorsal vein, or both the artery and the vein (24). All were performed in an end-to-side fashion. Of their patients, 10 developed arteriogenic ED following a pelvic fracture. They defined success as erections satisfactory for intercourse without use of pharmacologic assistance. Overall, their success at a mean follow-up of 70.8 months was 48% using this strict definition. Specifically, looking at patients with ED from a pelvic fracture, 50% had satisfactory erectile function with at least 2 years of follow-up. They found that younger patients (<28 years of age) had significantly improved outcomes compared with older patients. Nonsmokers also had improved outcomes compared with active tobacco users.

We recently reported our own experience performing an IEA to dorsal penile artery end-to-side anastomosis in 17 patients with arteriogenic ED following PFUIs (30). The average age was 32.7 years, and mean follow-up was 3.1 years (0.3 to 9.5 years). Success, defined as ability to obtain an erection sufficient for intercourse, was enjoyed by 14 of the 17 patients (82%). Of the patients not achieving a successful outcome, two were active smokers and one was simply lost to follow-up. Postoperative duplex parameters normalized and no patients experienced thrombosis of the anastomosis (Table 70.1). Four patients (24%) experienced early (<3 months) postop complications, including an abdominal wall hematoma requiring evacuation in one (Clavian grade IIIb), penile edema requiring an extended hospital stay in two (Clavian grade I), and a superficial surgical site infection requiring outpatient antibiotics in one (Clavian grade II) (31). There were no late (>3 months) complications. Only one patient underwent subsequent ED surgery with placement of inflatable penile prosthesis.

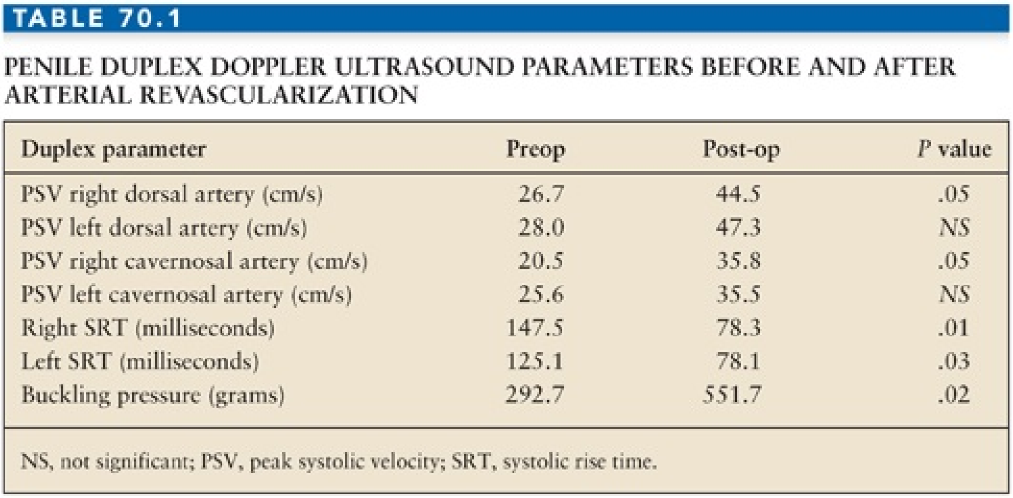

TABLE 70.1

PENILE DUPLEX DOPPLER ULTRASOUND PARAMETERS BEFORE AND AFTER ARTERIAL REVASCULARIZATION

Duplex parameter	Preop	Post-op	*P* value
PSV right dorsal artery (cm/s)	26.7	44.5	.05
PSV left dorsal artery (cm/s)	28.0	47.3	NS
PSV right cavernosal artery (cm/s)	20.5	35.8	.05
PSV left cavernosal artery (cm/s)	25.6	35.5	NS
Right SRT (milliseconds)	147.5	78.3	.01
Left SRT (milliseconds)	125.1	78.1	.03
Buckling pressure (grams)	292.7	551.7	.02

NS, not significant; PSV, peak systolic velocity; SRT, systolic rise time.

Early in our experience, we chose to perform an end-to-side anastomosis of the IEA to the dorsal penile artery and have continued this approach in all our patients. We initially chose this technique based on prior reports showing problems with glans hyperemia as well as graft thrombosis likely secondary to the venous valves inherent in any arteriovenous anastomosis (32–34). Our surgical approach has not changed significantly over time because we have found it efficacious in the majority of our patients. Although an end-to-end IEA to dorsal penile artery anastomosis has been described with acceptable outcomes (28), we feel that the end-to-side approach has a theoretical advantage of allowing a bidirectional flow of blood following microvascular anastomosis and the potential to allow more collateralization from the dorsal to the cavernosal artery (Figs. 70.6 and 70.7). However, given the lack of direct comparison between these two techniques and the relatively high success rate of each of them with this difficult patient population, it is likely more important that the surgeons use the approach they feel most comfortable performing.

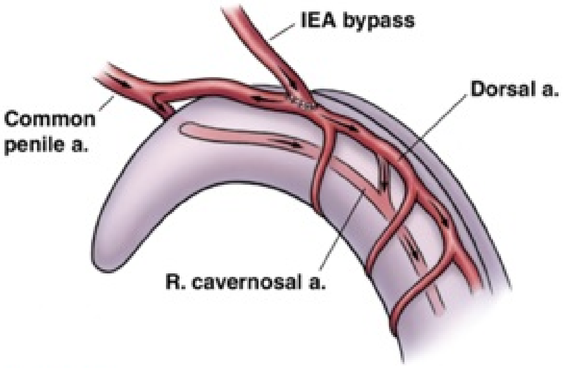

FIGURE 70.6 Blood flow following arterial revascularization. *IEA*, inferior epigastric artery.

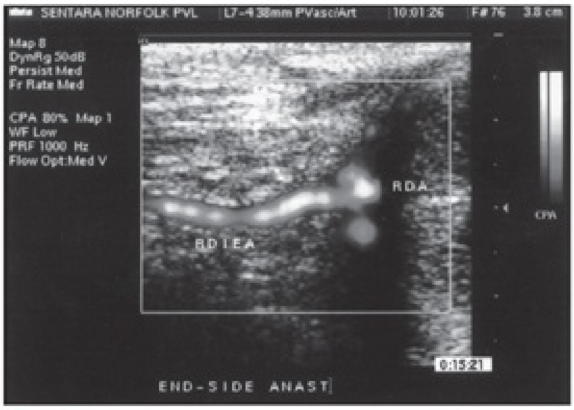

FIGURE 70.7 Duplex Doppler ultrasound demonstrating bidirectional blood flow following revascularization.

As we enter an era of more cost conscious health care, it is important to consider whether a treatment is cost-effective. The charges for the initial procedure and hospital stay in current dollars for one of our recent patients was $32,245. A portion of this cost is obviously related to the extended inpatient stay, which we have not found has significantly decreased over the course of our experience performing this procedure. Much of this hospital stay is related to the extended period bedrest (2 to 3 days) that we feel is essential for the success of these procedures. Placement of an inflatable penile prosthesis is a potential alternative procedure in some of these patients to treat their ED. Similar cost analysis for initial placement of the shows charges of $36,825, slightly higher than the cost of revascularization. The implant itself makes up a portion of the increased costs. In addition to increased costs of initial placement, given the traditionally younger cohort that comprises this population, patients can expect one or more device revisions over their lifetime, adding additional costs and morbidity.

Similar to other aspects of vascular surgery, endovascular treatment of internal pudendal stenosis in men with arteriogenic ED failing medical management has been reported (35). Rogers and associates reported on the use of a Zotarolimus-eluting stent in 30 patients for significant unilateral or bilateral internal pudendal artery stenosis. Preoperative workup was appropriate, including IIEF questionnaires, penile duplex ultrasounds, and pelvic angiograms. They did not note any adverse events secondary to stent placement. On follow-up duplex ultrasound at 6 months, the peak systolic velocity in the cavernosal arteries increased an average 22.5 cm per second. Intention to treat analysis demonstrated that 59.3% of patients experienced at least a 4-point increase in their IIEF score at 6 months following the procedure (mean 12.5 point increase overall). On follow-up angiogram at 6 months postprocedure, binary restenosis of the stent was noted in 34% of patients despite dual antiplatelet therapy with aspirin and clopidogrel through that time point. Currently, endovascular stenting remains investigational and long-term follow-up remains unknown. However, the minimally invasive nature and relatively less morbidity associated with the procedure may make this an attractive option for patients in the future.

CORPORAL VENO-OCCLUSIVE ERECTILE DYSFUNCTION

Patient Selection

As with patients being considered for arterial bypass procedures, patient selection for surgical intervention in the setting of VED is equally critical. Long-term outcomes following venous surgeries have been poor, and patients should be counseled accordingly. All patients being considered for venous surgery for VED must have venous leak suggested by history and diagnosed with penile duplex Doppler ultrasound. The location of the leak and confirmation of the diagnosis should be obtained with DICC prior to intervention. As mentioned previously, those patients with diffuse corporal dysfunction rather than an area of focal leak do not fare as well following venous surgery and should be encouraged to pursue alternative treatment options. Ideally, patients selected for surgery are younger (<50 to 60 years of age) with limited comorbidities, specifically limited or no concomitant vascular disease. It is imperative to document adequate arterial inflow on preoperative duplex ultrasound.

Patients should be offered a trial of more conservative treatment options prior to venous surgery. Those with mild venous leak may respond to oral PDE5 inhibitors. Intracavernosal injections can allow for a functional erection in men with a moderate leak, especially when combined with a penile band. Vacuum erection devices may be used as monotherapy or combined with either PDE5 inhibitors or injection therapy. Finally, patients should be counseled on penile prosthesis placement as an alternative surgical option.

Surgical Technique

The procedure is performed under general endotracheal, or less commonly spinal, anesthesia. A second-generation cephalosporin or fluoroquinolone antibiotic are administered within 60 minutes of skin incision. The patient is positioned on the table in the supine position with a slight abduction to the legs for access to the perineum and then prepped and draped in sterile fashion. Alternatively, dorsal lithotomy position can be used if further access to the perineum is required. A thorough understanding of penile venous anatomy is imperative for a successful procedure (Fig. 70.8).

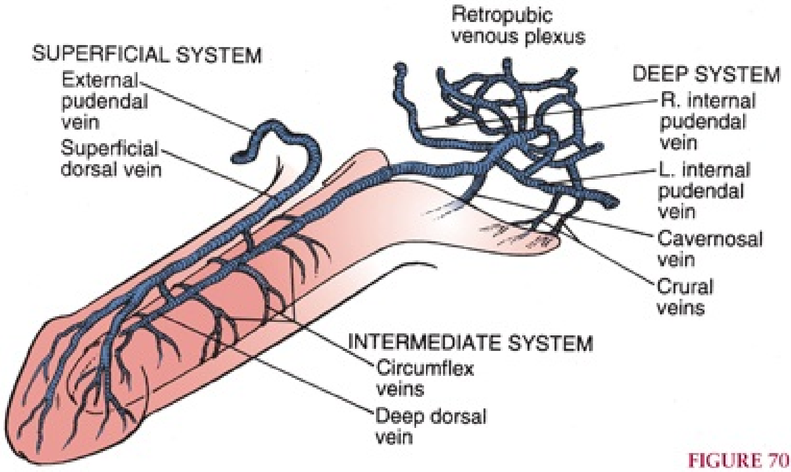

FIGURE 70.8 Penile venous anatomy.

A variety of incisions can be used for dorsal vein ligation, including dorsal penopubic, parapenile, or dorsal longitudinal penile (Fig. 70.9). A circumcising incision also provides reasonable exposure, although this can be associated with postoperative numbness. Whichever approach chosen, superficial tissue is dissected free of the corporal bodies easily with sharp and blunt dissection. The superficial dorsal vein is identified and ligated. Buck fascia is cleared and incised in the midline directly over the deep dorsal vein. The vein is dissected free of the tunica albuginea. Communicating circumflex and emissary veins branching off the deep dorsal vein can be controlled with bipolar cautery or 4-0 polyglactin sutures. Proximally, the vein is dissected until about 1 cm from the glans and ligated with 3-0 polyglactin ties. It is important to remain midline during this dissection to avoid injury to the dorsal artery and nerves. Distally, the vein is dissected up to the pubic bone and similarly ligated (Fig. 70.10).

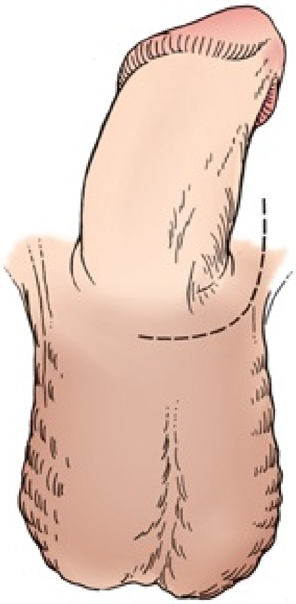

FIGURE 70.9 Parapenile incision (dashed line) for venous ligation.

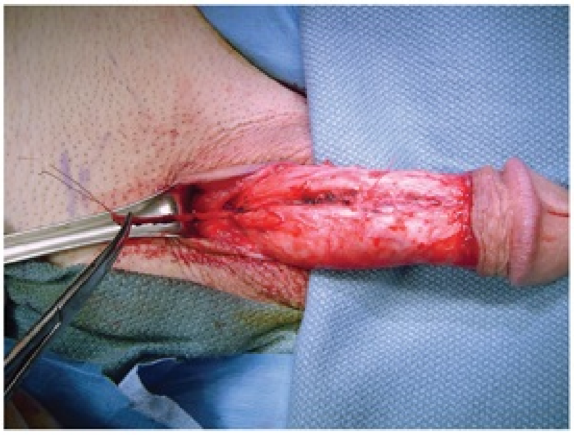

FIGURE 70.10 Dorsal vein ligation using a circumcising incision.

We do not routinely incise the suspensory ligament, but if this dissection is planned, the fundiform and suspensory ligament are both transected close to the underside of the pubic symphysis (Fig. 70.11). With the penis detached from the pubis, it is possible to dissect the dorsal vein more proximally into the hilum of the corpora. In this location, you may also divide the cavernosal veins if they are a significant source of venous leak. The cavernosal arteries and nerves in this area must be prospectively identified and preserved such that they are not injured if cavernosal vein ligation is performed.

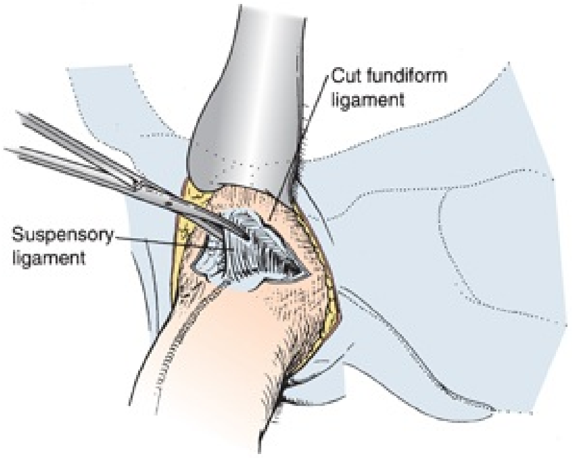

FIGURE 70.11 Ligation of the fundiform and suspensory ligaments.

The wound is closed in layers, and skin adhesive is used to dress the incision. A drain is not routinely left, although a TLS drain may be helpful for patients with significant bleeding during that case and who will be kept overnight. A compressive penile and scrotal dressing is not usually required. Most patients can be discharged on the day of surgery.

Crural banding can be performed in conjunction with dorsal vein ligation or as a standalone procedure. If performed at the same time as a dorsal vein ligation, a parapenile incision is usually simply extended further onto the scrotum for exposure. Otherwise, either a perineal or penoscrotal approach can be used, although a perineal incision is limited in its ability to ligate the crura proximally and may not be as useful in those patients with proximal or extensive crural venous leak. For the penoscrotal approach, a transverse scrotal incision is made, and the crura are identified and separated from the corpus spongiosum. A right-angle clamp can then be passed from medial to lateral around the crus on each side and cotton tape ligatures are used to ligate the crura. One or two ligatures can be used depending on the severity of the leak (Fig. 70.12).

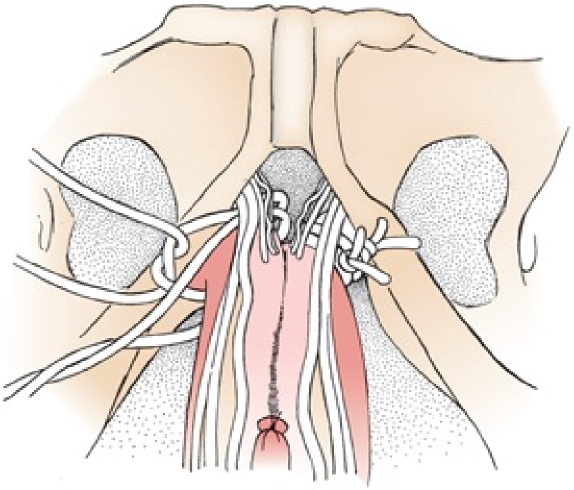

FIGURE 70.12 Crural banding following dorsal vein ligation.

Outcomes and Complications

Ideally, surgery for veno-occlusive dysfunction should be aimed at the prominent site of leakage found on cavernosography. For those patients with primary leak through the dorsal vein, treatment has been directed at superficial and deep dorsal vein ligation. Following introduction of dorsal vein ligation surgery, early results had been promising (36,37,38). Long-term outcomes, however, have consistently been less impressive, and this has not changed dramatically in more contemporary case series. Berardinucci and colleagues reported on 100 patients undergoing dorsal vein ligation for VED (39). They did not ligate cavernosal or crural veins. Defined as achieving an unaided erection sufficient for intercourse at least 50% of the time, they reported 3 months success rate of 62%. On telephone follow-up at average 45 months following surgery, however, success decreased to 31%. Complications were minimal, which they attributed to a more focused dissection and not incising the suspensory ligament. Given that the only other treatment option available to this group of patients is a penile prosthesis, they concluded that the procedure continues to be a reasonable option in select patients.

Similarly, Popken and associates reported their results on 122 patients who underwent venous ligation surgery for VED (40). In addition to the deep dorsal vein, they also ligated the crural vein in 38% and other ectopic veins in 26%. Unaided erections sufficient for intercourse were only found in 28% at 6 months and 14% at 70 months of follow-up. An additional 19% were able to achieve an erection with intracorporeal injections such that 33% of patients were considered to have benefited from the surgery. Complications in this series were 7% and mild in nature, with edema of the prepuce being the most common.

More recently, crural ligation procedures have been suggested to treat VED, especially for those patients with isolated corporal venous leak. These have been performed as standalone procedures or combined with vein ligations. Lue initially described the procedure, and in 2005, he reported on 11 patients undergoing crural banding in combination with dorsal vein ligation performed through a penoscrotal incision (41,42). Patients with diffuse or multifocal leak on cavernosography were excluded. The suspensory ligament was completely incised, but the tunica albuginea was reapproximated to the pubic bone prior to closure. Of the 11 patients, 9 noted marked improvement in their erectile function at a mean follow-up of 34 months. Penile shortening, which is a known complication following incision of the suspensory ligament, was not noted in any patient. This was thought to be secondary to reapproximation of the penis to the pubic bone with tunical fixation sutures.

In 2008, Cayan described his results using Lue's technique in 26 men found to have VED with a leak confirmed on cavernosography (43). Mean postoperative follow-up was 43.9 months. ED resolved completely in 42.3% of men. Increases in IIEF scores were seen from 6.7 preoperatively to 16.3 following surgery. No patient complained of penile shortening or numbness, but wound infections were noted in 7.7%. Similarly, Flores and colleagues performed corporal banding in 14 patients found to have isolated corporal leak and followed them with IIEF questionnaires (44). At an average of 16 months following surgery, the mean IIEF increased from 18 to 24 ($P = .01$). Sixty-six percent of the patients were able to have unassisted sexual intercourse.

There are a number of reasons why venous surgery might fail over time. Some of these patients likely have concomitant arterial disease, making the veno-occlusive function more tenuous. It has been theorized by some that collateralization of flow over time overcomes ligation procedures. Others refute this, suggesting that less complete dissections might lead to poorer outcomes (45). It is likely that a high rate of failures is seen because none of these procedures address diffuse corporal dysfunction that may be present in a portion of these patients. Inability of the sinusoidal spaces to expand secondary to atrophy or fibrosis and lack of rigidity within the tunica albuginea will prevent occlusion of the emissary veins no matter how meticulous or involved the surgical technique. Although crural banding appears to improve operative outcomes, durable success has only been reported in small case series. It is important to note, however, that patients not achieving spontaneous erections may still derive benefit through PDE5 inhibitor therapy. Nonresponders to PDE5 inhibition preoperatively who undergo venous surgery are more likely than patients who did not undergo surgery to respond to this class of medication and should rechallenged if spontaneous erections are not sufficient for intercourse (46). This fact and the portion of patients who enjoy a sustained response would suggest that these procedures still have a place in the management of VED.

CONCLUSION

ED affects a diversion population and is a common reason for presentation to urology practices. In the majority of patient, conservative treatments with PDE5 inhibitors, intracavernosal injections, or vacuum erection devices are sufficient treatments. Patients found to have either significant focal arterial insufficiency or veno-occlusive incompetence may benefit from surgical intervention.

CHAPTER 71 PENILE TRAUMA

JUDITH C. HAGEDORN AND DANIEL I. ROSENSTEIN

Trauma to the penis is an uncommon event. Because of the relatively protected position of the penis between the thighs and pubic bone, it is usually able to avoid direct injury from external forces. Nonetheless, penile trauma may arise from both blunt and penetrating injuries. Such injuries present unique and difficult management problems to the urologic surgeon, in particular regarding long-term cosmesis, voiding function, and future potency. Major blunt penile injuries include penile rupture and skin loss from strangulation or degloving injuries. Penetrating penile trauma is usually secondary to stab or gunshot wounds and thus seldom occurs in the absence of associated genital, urethral, or major organ injury, except in the event of bites and self-inflicted wounds. Due to the wide disparity in the causes, diagnosis, and treatment, this chapter is divided into three parts: penile rupture, penile skin loss, and penetrating penile trauma.

PENILE RUPTURE (PENILE FRACTURE)

The most common blunt injury involving the penis is rupture of the corpora cavernosa, or penile fracture. This almost invariably occurs when the erect penis is forced to bend in an irregular fashion, such as when it accidentally impinges on the pubis or perineum during sexual intercourse (1). The remainder of cases is caused by falls out of bed with an erect penis, masturbation, or manipulation of the erect penis. Recently, penile crush injury due to the accidental fall of a toilet seat has been described as an uncommon cause of genitourinary trauma (2). The patient often reports a cracking or popping noise at the time of injury, leading to immediate detumescence and rapid onset of discoloration and swelling over the site of injury. There is frequently a delay in presentation to the hospital—presumably secondary to patient embarrassment.

Diagnosis

The diagnosis of penile rupture is easily made by physical examination along with the appropriate history. Swelling and discoloration may or may not be limited to the penis, depending on the integrity of Buck fascia. If Buck fascia is intact, the hematoma will be contained and will not usually spread below the base of the penis, resulting in the typical “eggplant” deformity (Fig. 71.1).

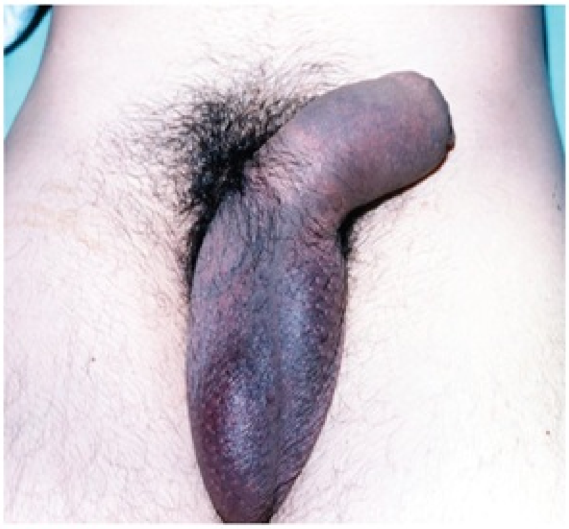

FIGURE 71.1 Fractured penis displaying the pathognomonic “eggplant” deformity with swelling and discoloration extending to the base of the shaft and, in this case, into the scrotum.

However, if the laceration in the tunica albuginea also lacerates through Buck fascia, extravasation will be contained by Colles fascia and ecchymosis will extend in a “butterfly” distribution over the perineum, scrotum, and lower abdomen. Examination may reveal angulation of the penis away from the side of rupture because of the mass effect of the hematoma. In addition, focal tenderness and a palpable defect in the tunica albuginea may help localize the fracture site. There is often a clot lying over or near the fracture site that corresponds to the site of cavernosal rupture. Imaging studies for the diagnosis of penile rupture are unnecessary after a thorough history and physical exam, but recent studies have described penile ultrasound as a low-cost supplement examination that can be easily performed and may be of value in identification of the rupture location (3). In addition, magnetic resonance imaging is a very accurate modality but of limited availability and practicality in this setting (4).

Penile rupture can occur anywhere along the shaft, including the base of the penis, where the corpora are fixed by the penile suspensory ligament. The fracture is typically transverse in orientation and located at the base of the penis, just proximal to the penoscrotal junction. However, longitudinal, distal fractures have been described in 30% of cases (4). In general, only one corporal body is injured, although both corpora and the corpus spongiosum can be affected depending on the severity of the injury. Most patients are able to urinate normally, but the urologist must maintain a high index of suspicion for urethral injury. Failure to void spontaneously may signify compression of the urethra by hematoma but should lead to evaluation of urethral injury by retrograde urethrography (RUG). Urethral injury occurs in up to one-third of cases and usually consists of partial disruption, although complete transection can result (4,5). RUG is mandatory in all patients with blood at the urethral meatus, hematuria of any extent, or inability to void (1). However, because RUG is easy to perform and provides reliable results, we perform it routinely in all cases of suspected penile rupture. Adjunctive imaging studies in penile fracture (including ultrasound, magnetic resonance imaging, and cavernosography) are usually unnecessary as the clinical picture is frequently adequate to initiate therapy (6).

Indications for Surgery

Although penile fractures can be managed nonoperatively, the literature shows a clear advantage to early operative repair (1,5). This approach results in faster recovery, shorter hospital stay, less morbidity, and less long-term penile curvature. The goals of acute exploration are evacuation of the hematoma and primary repair of the laceration and should be undertaken even in patients with delayed presentation (7). Of note, dorsal vein injury may mimic the presentation of penile rupture and may lead to a negative penile exploration (8).

Alternative Therapy

Conservative treatment consists of cool compression dressings, anti-inflammatory agents, and sedatives to reduce the frequency of erections. This results in eventual resorption of the hematoma and scar formation at the site of the tunical rupture. Conservative management is associated with significant complications in up to 50% of patients, including hematoma formation, corporal fibrosis and curvature, pseudoaneurysm of the corpora, and erectile dysfunction (8,9). Several studies have shown that surgical exploration and repair of the penile fracture leads to superior outcomes and therefore should be undertaken when the injury is suspected (10–12).

Surgical Technique

The patient is placed in a supine position and a Foley catheter is placed to facilitate identification of the urethra and urinary drainage. Exposure is usually obtained through a subcoronal circumferential incision, and the penile skin is degloved down to the base. The distal circumferential incision is favored because it allows both exposure of the ruptured corpus and adequate assessment of the contralateral corpus and corpus spongiosum. Alternatively, an incision may be made on the shaft directly over the fracture site. This approach is only useful if the fracture is palpable or seen on preoperative imaging, as the corporal bodies may not be easily explored through this incision. Further, the corpus spongiosum cannot be directly inspected via this approach.

Following the circumcising incision, the corpus spongiosum is carefully inspected to evaluate for potential urethral injury. Inspection of the fracture site usually reveals a transverse laceration, between 0.5 and 2.0 cm long, in the tunica albuginea of the proximal penile shaft (13). After evacuation of the hematoma and irrigation, minimal debridement of nonviable wound edges may be necessary before closure with interrupted 4-0 monofilament synthetic absorbable sutures (Fig. 71.2A and B).

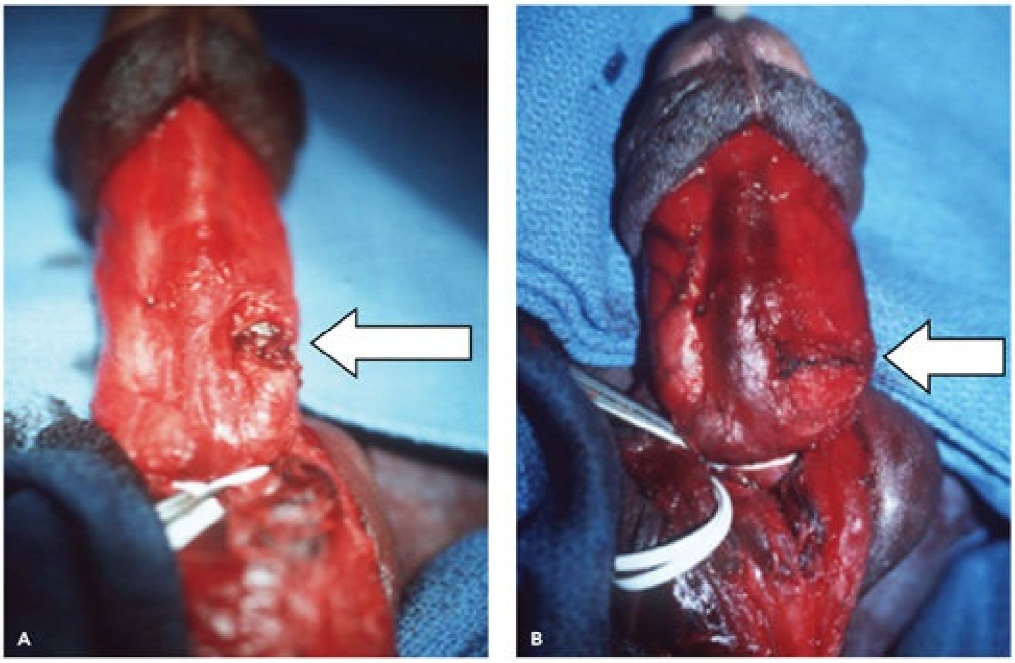

FIGURE 71.2 Identification and repair of penile fracture. A distal circumferential subcoronal incision is made and skin and soft tissue are mobilized off the underlying corporal bodies down to the base of the penis. Note that a white elastic tourniquet has been temporarily applied around the base of the penis. **A:** This maneuver exposes the transverse laceration in the tunica albuginea. *Arrow* points to site of corporal laceration. **B:** The laceration is repaired using interrupted 4-0 monofilament suture with the knots buried. *Arrow* points at laceration repair. Exposed corporal erectile tissue should not be probed or explored as this may cause troublesome bleeding.

The surgeon should not probe the exposed cavernous tissue unnecessarily as this may elicit troublesome bleeding. A tourniquet may be used intraoperatively to control hemorrhage. Lacerations may run directly under the dorsal neurovascular bundle located on the dorsal surface of the corpora at approximately the 10 and 2 o’clock positions (Fig. 71.3).

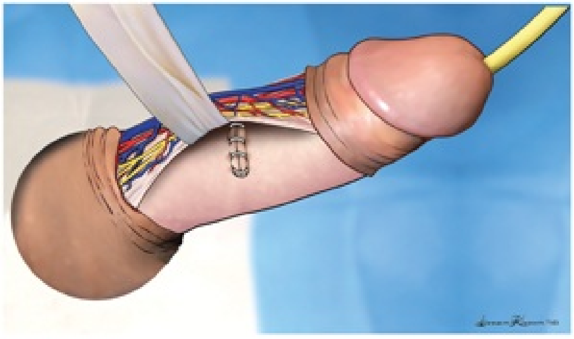

FIGURE 71.3 Penile fracture extending beneath dorsal neurovascular bundles. Elevation of the ipsilateral dorsal neurovascular bundle facilitates repair of lacerations and protects these structures from inadvertent injury.

This necessitates careful dissection of these structures off the corpora to allow a safe, watertight closure. Division of the deep dorsal vein facilitates unilateral dissection of the neurovascular bundle off the underlying corpus cavernosum. The penile skin is then replaced and the subcoronal incision is closed with interrupted 4-0 chromic sutures. If the patient is uncircumcised, the prepuce must be closely monitored for development of subcoronal edema. Postoperatively, a loose compression dressing (Coban) is gently placed, and the urethral catheter may be removed on postoperative day 1 (assuming no urethral repair was required). Systemic antibiotics, anti-inflammatory agents, and fibrinolytics are unnecessary. Most patients can be discharged home within 1 to 2 days of surgery. Sexual activity can be resumed at about 4 to 6 weeks. Painful erections may be present in the early postoperative period. Suppression of erections with benzodiazepines or amyl nitrate may provide symptomatic relief.

When urethral transection occurs in the context of penile rupture, we advocate primary repair with interrupted 5-0 or 6-0 synthetic, absorbable, monofilament sutures over a 16Fr silicone catheter. In cases of complete urethral transection, additional urinary diversion through a percutaneous suprapubic cystostomy tube may be prudent (1). A voiding cystourethrogram (VCUG) should be carried out at approximately 14 days postrepair to document adequate healing before catheter removal.

Outcomes

Complications

Penile fracture has potential complications, particularly when managed nonoperatively or with delayed repair. However, patients who undergo immediate surgical exploration may also develop some form of sexual dysfunction, such as painful erection, disabling curvature, or erectile dysfunction secondary to corporal veno-occlusive disease (8,14). Patients with a missed urethral injury associated with penile fracture are also at risk of periurethral abscess, stricture, and fistula formation.

Results

Patients who have operative repair within 48 hours of the injury have excellent functional results. In two relatively large studies, none of the patients with early operative repair experienced impotence, penile curvature on erection, or painful intercourse (1,13). Patients with delayed presentation of up to 7 days postinjury have acceptable postsurgical outcomes, even though the rate of chronic penile curvature is higher with delayed exploration (6,7).

PENILE SKIN LOSS

Diagnosis

Penile skin loss can occur from necrotizing infections, burns, constrictive bands, or degloving injuries from blunt or penetrating trauma, frequently resulting from farm machinery mishaps and motorcycle or bicycle accidents. Dog and human bites may also result in considerable penile skin loss and may lead to polymicrobial infection (6). When the skin loss is secondary to infection (e.g., Fournier’s gangrene), repeated debridement with antibiotics and moist dressing changes must be instituted to prepare the underlying tissue for delayed reconstruction (Fig. 71.4).

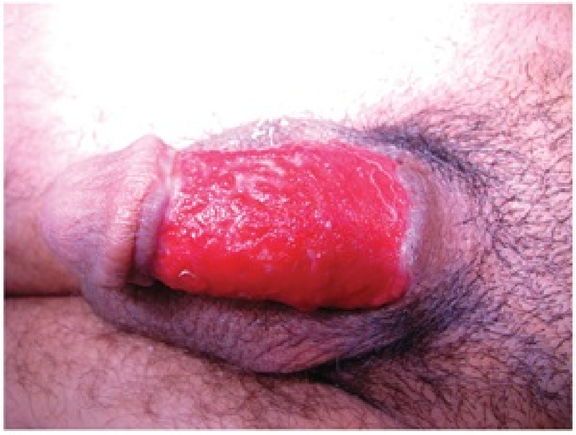

FIGURE 71.4 Debrided penile shaft in a patient who presented with Fournier gangrene of the penis. The penile shaft has healthy granulation tissue and no signs of infection after debridement and wet-to-dry dressing changes.

Avulsions are most often caused by power tool injuries or motor vehicle accidents, although this injury may rarely be self-inflicted secondary to insertion of the penis into vacuum cleaners and other suction devices (15). Because of the laxity of penile skin, the avulsion usually extends just to the subcutaneous dartos layer, leaving the corporal bodies uninvolved. Immediate repair is frequently possible and advised in cases of traumatic skin loss (6). If immediate closure is to be attempted, the wound edges must be clean and viable and hemostasis must be excellent to avoid delayed skin necrosis and sloughing.

Indications for Surgery

Partial penile skin loss, especially in the distal shaft, is best managed by rotational mobilization of a local skin flap. Primary closure may be appropriate if the defect is short and there is abundant remaining shaft skin. Extensive skin loss, whether from the injury itself or surgical debridement, usually requires tissue transfer for repair. In impotent patients, the penis can be buried under a scrotal flap with the glans left exposed to allow micturition (13). The penis may be liberated at a later date using the scrotal skin as a graft to cover the previously denuded area. This approach obviously results in significant cosmetic deformity.

In sexually active patients, a thick (0.016- to 0.018-inch), nonmeshed split-thickness skin graft is used. Thick split-thickness grafts are preferred because they are non–hair-bearing, have minimal contraction, and offer excellent cosmesis and viability. A thinner (0.014- to 0.016-inch) skin graft may be harvested and meshed especially if sexual function is not a concern. Recent literature has shown satisfactory outcomes in sexually active patients even with thinner unexpanded meshed skin grafts (16). The avulsed skin that is still attached on a viable pedicle can be gently washed and reapplied with the knowledge that it may need to be debrided at a later time. Completely avulsed penile skin will usually not survive as a free graft if reapplied to the denuded penile shaft.

Alternative Therapy

There are no alternatives to surgery for genital skin loss.

Surgical Technique

The patient is placed supine and both the genitals and a carefully chosen donor site are prepared into the field. The anterolateral thigh provides thickness, texture, and color resembling penile skin and is therefore the preferred donor site. Alternatively, the medial or posterior thigh or buttock may be used as a skin donor site. A Foley catheter is placed to prevent postoperative urinary contamination. The shaved donor site is coated with sterile mineral oil, and a pneumatic dermatome (10-cm wide strip) is used to harvest the graft in an approximately 0.016- to 0.018-inch thickness. The graft is then tailored to fit the defect on the shaft. The donor site may be dressed with fine mesh gauze under slight pressure to ensure adequate hemostasis. Placement of a biosynthetic, semipermeable silicone membrane (e.g., Biobrane) directly against the donor site helps reduce contamination. After about 24 hours, the silicone membrane is adherent to the donor site and the redundant edges may be trimmed. This dressing usually falls off spontaneously after 2 weeks.

To prepare the penile shaft for grafting, it must be sharply debrided of all devitalized tissue and any chronic granulation tissue. It is imperative to prepare the recipient site so that the graft will have adequate blood supply. Debridement of the glans should be avoided, but all nonviable skin, including the distal prepuce, should be excised up to the coronal sulcus. Native penile skin distal to the graft will become edematous because of disruption of native lymphatic and venous drainage along the shaft. Hemostasis in the graft bed is essential to prevent hematoma formation under the graft.

Once prepared, the penis is stretched and the graft applied circumferentially around the shaft. Some experts have recommended spraying a thin layer of diluted fibrin sealant onto the recipient site for better graft adherence and take (17). The graft seam is placed at the ventral aspect to simulate the appearance of the median raphe. The graft is sutured in place using interrupted 5-0 chromic sutures (Fig. 71.5).

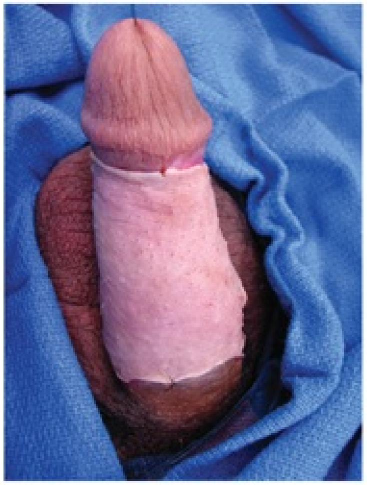

FIGURE 71.5 Penile nonmeshed split-thickness skin graft. A thick (0.016- to 0.018-inch) split-thickness skin graft is applied to the denuded penile shaft. The distal skin is discarded to just beneath the corona when a circumferential graft is indicated. The graft is placed with the seam in the midline ventrally and secured with 5-0 chromic sutures to itself and along the shaft.

Chordee formation has in general not been a problem because the graft will have minimal longitudinal contraction. The graft is secured to itself and along the shaft with interrupted 5-0 chromic sutures. Several 4-0 absorbable, synthetic, braided sutures are placed at the proximal and distal graft edges and left long to use as bolster tie-over sutures. A petroleum gauze nonadherent (e.g., Xeroform) dressing is placed directly on the graft. A bolster dressing is then fashioned using mineral oil–soaked cotton and fluffs (Fig. 71.6A). The whole dressing is secured in place using the bolster sutures, leaving the glans visible for inspection. To keep the penis in a vertical position, a padded plastic splint is placed around the bolster dressing. This housing may be fashioned out of a 500-mL sterile water container (Fig. 71.6B).

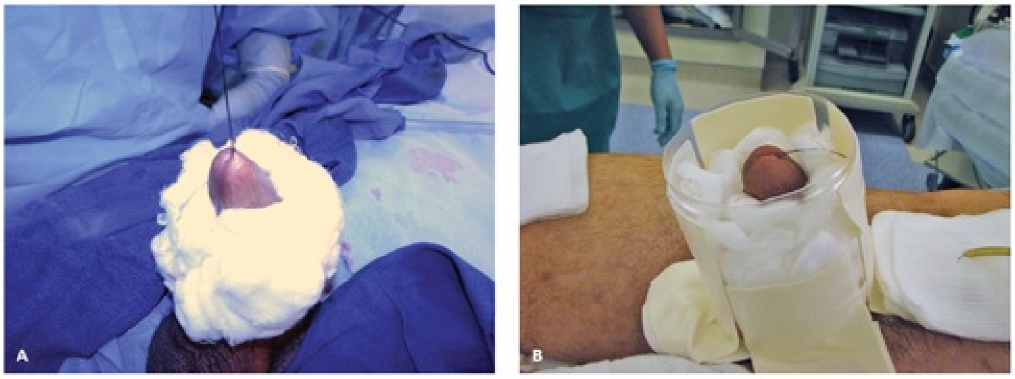

FIGURE 71.6 **A:** Mineral oil–soaked cotton is secured around the shaft. Several 4-0 absorbable sutures are placed at the proximal and distal graft edges and left long to use as bolster tie-over sutures. **B:** The penis is kept in a vertical position by a padded plastic splint fashioned out of a 500-mL sterile water container with the top and bottom cut off and secured to the patient with foam tape.

The use of topical negative pressure (vacuum-assisted closure) to split-thickness skin graft has mostly been described in the plastic surgery literature and has found a considerable advantage over traditional dressings in quality and quantity of graft take, including grafts to the penis and scrotum (Fig. 71.7) (18,19). The vacuum suction was set at 75 to 100 mm Hg and left in place for 4 to 5 days postoperatively with a graft take between 90% and 100% (19,20).

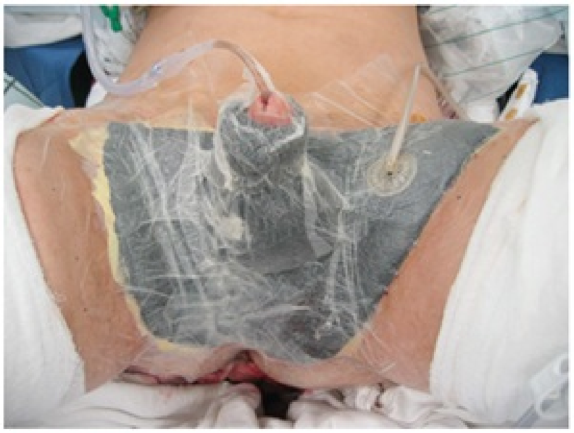

FIGURE 71.7 Vacuum-assisted closure (VAC) device on patient who has undergone skin graft resurfacing of penis, testes, and groins following debridement for Fournier's gangrene. The delicate grafts are further protected and adherent to the wound using the VAC device. (Reprinted by permission of Brandes SB, Morey AF. *Advanced Male Urethral and Genital Reconstructive Surgery*, 2nd ed. New York: Humana Press, 2013. Copyright 2014 Springer Science & Business Media.)

Postoperatively, the patient is kept at strict bedrest until the dressing is removed, usually after 5 days, when the Foley catheter is also removed. Immobilization of the penis in the extended position maintained by the bolster is critical for graft survival. Broad-spectrum antibiotics and administration of subcutaneous heparin for deep venous thrombosis prophylaxis are useful adjuncts. We do not routinely administer medications to reduce frequency of erections unless they are painful for the patient. Erections may provide natural tissue expansion, and the grafts usually slide easily along the loose areolar tissue superficial to the Buck fascia. Once the penile dressing is removed, twice-daily sitz baths can be started to enhance epithelialization and reduce bacterial contamination.

Outcomes

Complications

The common causes of early failure and loss of penile skin grafting are infection, graft separation, and underlying hematoma. It is imperative that the graft bed be free of infected granulation tissue and any necrotic tissue. Shearing forces disrupt the blood supply to the new graft and are prevented by the penile splint and bolster dressing, provided the patient is cooperative with strict bedrest for 5 days. It is critical that the penis be maintained in the extended position within the bolster dressing as this will prevent folding or telescoping of the fresh graft on the penile surface. Hematoma causes failure by creating poor contact between the graft and the recipient bed. It is prevented by ensuring meticulous hemostasis of the graft bed prior to laying the graft in place. Meshed grafts allow better dissipation of hematoma fluid and have recently shown to provide a satisfactory functional and cosmetic outcome, without the previously reported erectile dysfunction due to contraction (16).

Results

Long-term results of reconstruction have been excellent, with successful graft take exceeding 90%. Sensation remains absent in the grafted skin but is retained in the glans and in deeper structures. Potency is unaffected by this type of reconstruction. Most patients who were previously potent may have satisfactory intercourse after reconstruction.

PENETRATING PENILE TRAUMA

Penetrating trauma to the penis is most often caused by firearms but can also result from stab wounds, industrial accidents, self-mutilation attempts, and bites. In all cases, general principles of management include judicious debridement and hemostasis within the wound as well as careful exploration and repair of corporal and urethral injuries. Most civilian penile gunshot wounds are caused by low-velocity missiles, which cause damage only in the path of the bullet. Penetrating penile injuries are a more common genitourinary injury during wartime, possibly because of inadequate genital coverage by protective body armor and are a result of high-velocity missiles or explosive devices (20,21). Associated wounds of the thigh and pelvis are common and may require urgent exploration and repair. Successful treatment of penetrating penile injuries must address and preserve normal voiding, potency, and penile cosmesis.

Diagnosis

Genital injury is determined by careful physical examination, with special attention paid to the trajectory of the bullet and initial hemostasis. The finding of a palpable corporeal defect in combination with an expanding penile hematoma or significant bleeding from the entry/exit wound is highly predictive of corporeal injury and should prompt expedient exploration (22). The exam should include a vascular (glanular capillary refill) and penile sensory assessment (9). Urethral injury, which occurs in 25% to 40% of penetrating injuries to the penis, should be excluded with an RUG in all cases (23). The absence of blood at the meatus, absence of hematuria, and normal voiding suggests that there is no urethral injury; however, penetrating trauma can cause urethral injury without clinical signs of damage. Cystography, intravenous pyelography, and scrotal ultrasonography may be necessary to evaluate associated urologic injuries. Cavernosography is rarely indicated in this setting (9).

Indications for Surgery

Penetrating injury to the penis most often requires surgical exploration. In addition, patients with unstable major organ injury will be unable to undergo immediate exploration. In these cases, initial treatment consists of hemostasis and packing of major wounds. Penetrating injury causing major skin loss will require tissue transfer for satisfactory coverage, but associated corporal and urethral injuries must be repaired before the skin grafting. In addition, ballistic injuries need judicial tissue debridement prior to reconstruction, which may require several trips to the operating room as the nonviable tissue declares itself over time (20). Immediate primary closure or reconstruction should take place only with a clean wound that is in general less than 8 hours old.

Alternative Therapy

Single pellet wounds with small entrance sites and superficial stab wounds in which there is no active bleeding or hematoma may not require surgical exploration (3).

Surgical Technique

The operation consists of judicious debridement of devitalized tissue and hemostasis. The wound must be copiously irrigated to remove all foreign bodies, including powder from shotgun pellets and pieces of clothing. Bleeding almost always occurs from a lacerated corporal body but may also be from disrupted superficial veins. The primary objective of surgical exploration is control of corporal bleeding and repair of corporal defects. The corpora are well vascularized, and extensive debridement is usually unnecessary and will hinder future potency. We thus do not recommend extensive exploration of erectile or glanular tissue. Hemostasis is obtained by gentle compression and watertight closure of the tunica albuginea alone, usually with interrupted 4-0 synthetic, absorbable, monofilament sutures. Urethral injuries are repaired with 5-0 absorbable, synthetic, braided sutures over a silicone catheter. A devitalized urethra must be carefully debrided, and primary repair with a tension-free anastomosis can usually be accomplished (Fig. 71.8A and B).

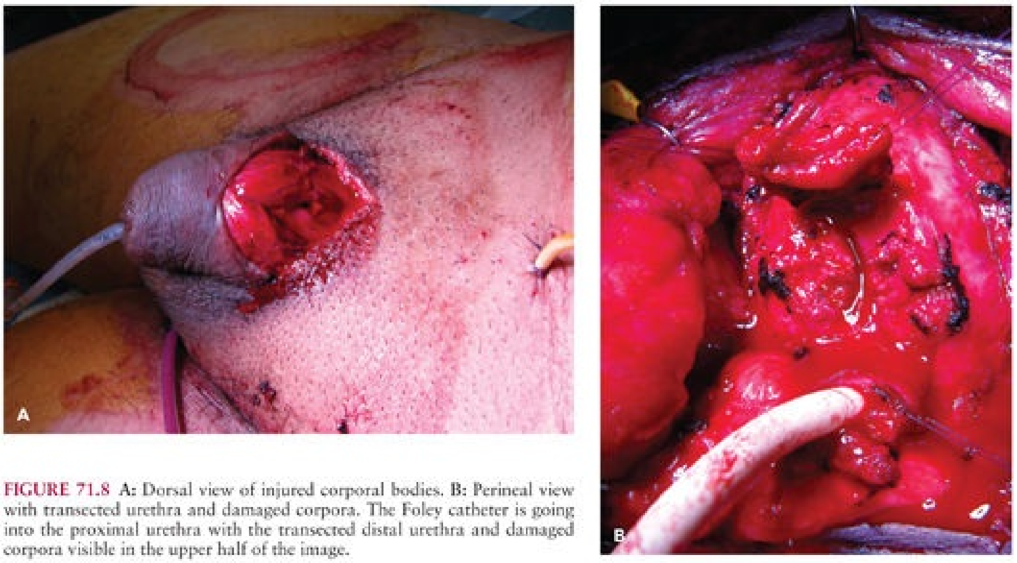

FIGURE 71.8 A: Dorsal view of injured corporal bodies. B: Perineal view with transected urethra and damaged corpora. The Foley catheter is going into the proximal urethra with the transected distal urethra and damaged corpora visible in the upper half of the image.

Associated scrotal and spermatic cord injuries are treated with debridement and, if necessary, orchiectomy or ligation of the vas deferens. The skin can be closed primarily unless viable skin edges cannot be approximated. In contaminated wounds or those encountered after 8 hours, immediate skin closure or grafting is not recommended and the wound is packed instead and managed with frequent wet-to-dry dressing changes. Once the wound is clean, delayed primary closure, staged reconstruction, or healing by secondary intention may be selected. An important contraindication to debridement and primary closure is the case of massive tissue destruction often associated with close-range shotgun blasts. These should be debrided and allowed to declare themselves in terms of the extent of injury. They may then be repaired in a staged fashion. It appears that longer range injuries due to shotgun blasts may create multiple low-velocity wounds with less significant blast effect. Carefully selected longer range shotgun injuries have been successfully managed with immediate debridement and primary repair (24).

Penile bites deserve special mention as they can rapidly progress to severe infection. Wounds should be copiously irrigated and all devitalized tissue debrided. All wounds should be left open and prophylactic antibiotics administered. Antibiotic treatment should cover gram-positive and gram-negative organisms as well as anaerobic gram-negative rods. The most common colonizing organisms in the mouth of a dog include *Pasteurella*, *Streptococcus*, and *Staphylococcus* species (25). Hospitalization with frequent wound inspection and intravenous antibiotics is necessary in those with delayed presentation or with increased risk factors such as steroid use, diabetes, or immunodeficiency syndromes. Close follow-up is mandatory in all outpatients.

Outcomes

Complications

Early complications of penetrating penile trauma include rebleeding and infection. Because the corpora are heavily vascularized, breakdown of repair in the tunica albuginea is rare. A small minority will report superficial sensory loss, pain with erection, and rapid detumescence. Complications attributable to the urethral injury include urethral stricture, periurethral abscess, and urethrocutaneous fistula.

Results

Excellent functional results can be expected except in those cases of high-velocity injuries where massive tissue destruction has occurred. Most patients report retained potency without penile curvature and with satisfactory cosmetic results (26,27). Patients who develop late penile curvature in the absence of palpable corporeal defects or plaques may have scarring and contraction of the underlying cavernosal tissues and the intercavernous septum (22).

CHAPTER 72 ■ PENILE REPLANTATION

JAIRAM R. ESWARA AND STEVEN B. BRANDES

Penile amputation is a rare condition that may be life-threatening if the bleeding is not controlled early. In addition to the physical injury, the psychological injury can be devastating. Phallic injuries have been reported in both children and adults and arise largely from attempts at self-emasculation among psychiatric patients, assault, workplace injury, circumcision, or during war (1–4).

The first penile replantation was described in 1929 by Ehrich (5) from Evansville, Indiana. He described a patient whose penis had been severed with a circular saw. The penis was reattached using no. 1 plain gut for the urethra and no. 1 chromic gut for the corpora cavernosa, and the patient had adequate erectile function at time of follow-up. The advent of microvascular techniques led to the first such repair by Cohen et al. (6) from Massachusetts General Hospital in 1977, and this is now the standard of care. Their technique involved approximating the urethra, corpora, and microsurgical anastomosis of the dorsal vein, arteries, and nerves. To date, there have been approximately 100 reports of penile replantation, both microsurgical and nonmicrosurgical, in the literature.

The largest single series of penile amputation injuries comes from Thailand, where 100 cases were reported, 18 of which underwent nonmicrosurgical anastomosis using the technique described by McRoberts (anastomosis over Foley catheter with scrotal tunneling of the denuded shaft) (7,8). Stabilizing the patient hemodynamically and psychiatrically is critical in the acute setting. The hemorrhage can be severe and has led to death in several instances; therefore, aggressive fluid resuscitation and blood transfusion may be necessary.

The physical diagnosis is obvious with complete loss of the distal penis. Given the high rate of command psychoses and severe personality disorders in this group, the surgery staff must work closely with a psychiatrist. Traumatic amputations either from an assault or industrial equipment will also likely have a postsurgical need for psychiatric evaluation.

The act of self-mutilation during psychosis is known as Klingsor syndrome after the magician who castrates himself in Wagner's opera *Parsifal*. Psychotic patients who carry out self-emasculation are typically schizophrenic. One study found that 87% of self-emasculating patients were psychotic at the time of injury (4). These patients are usually victims of command hallucinations that coerce the patient to mutilate his genitals. Nonpsychotic patients who self-emasculate are often diagnosed with severe personality disorders. These patients are more difficult to rehabilitate.

PRESERVATION OF SEVERED PENIS

The severed penis should be cleansed and gently debrided using normal saline. It should then be wrapped in damp saline dressings and kept cool by a separate ice compartment using the "bag-within-a-bag" technique. Placing the phallus directly on ice can lead to tissue edema and necrosis.

Technique

There are three ways to manage the amputated phallus: surgical replantation of the amputated penis, reconstruction of the remaining stump, and total phallic replacement. If the amputated penis is viable, penile replantation should be attempted. The penis should always be reimplanted because psychotic patients are typically remorseful after self-emasculation. If a patient experiencing psychosis refuses treatment, repair should still be attempted after competency has been determined.

Because penile tissue has a remarkable resistance to prolonged ischemia, all attempts to replant the penile remnant should be carried out unless the penis has been extremely mutilated. As successful replantation has been reported after 16 hours of cold ischemia and 6 hours of warm ischemia, penile replantation may be attempted up to 24 hours or longer after the injury (9).

Viable Penis for Replantation

To perform replantation, the initial surgical step is to obtain vascular control of the proximal edge of each corpus (Fig. 72.1). Depending on the extent of the bleeding, manual compression with gauze or a Penrose drain tourniquet may be necessary. After the bleeding is controlled, the tunica albuginea of the corpora cavernosa are reapproximated with 3-0 polyglactin (Vicryl) suture including suturing of the median septum for stabilization. The central cavernosal arteries do not need anastomosis because this is both technically very difficult and does not improve outcome (10). The proximal and distal urethral edges are mobilized off the corpora and the ends spatulated. The urethra is then anastomosed over a 16Fr silicone Foley catheter in the same manner as an anastomotic urethroplasty (Fig. 72.2). A two-layer closure is usually performed with interrupted 4-0 polydioxanone or Vicryl sutures soaked in mineral oil. A suprapubic tube is typically also placed to divert urine. In this way, the penile Foley may be capped.

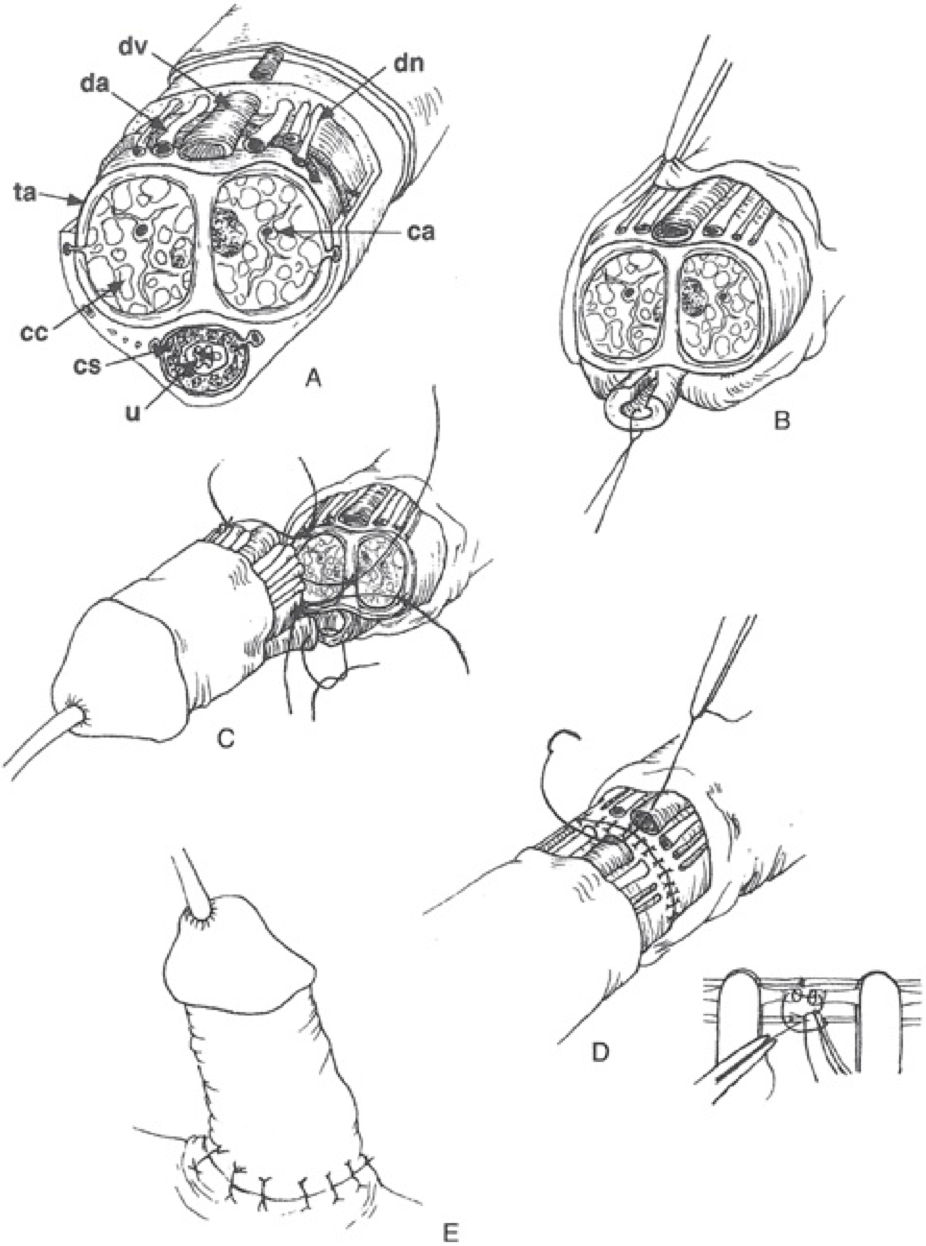

FIGURE 72.1 Penis amputation. **A:** Cross-sectional anatomy of penile stump. **B:** Exposure of the dorsal vessels/nerves and spatulation of the urethra. **C:** Reanastomosis of the corpora, median septum, and urethra. **D:** Microvascular repair of the dorsal vessels. **E:** Completed reattachment. *ca*, cavernous artery; *cc*, corpus cavernosum; *cs*, corpus spongiosum; *da*, dorsal artery; *dn*, dorsal nerve; *dv*, dorsal vein; *ta*, tunica albuginea; *u*, urethra. FIGURE 72.2 Repair of transected urethra by primary anastomosis (note interrupted sutures).

Once the penis is stabilized, microscopic anastomosis of the dorsal vessels and nerves is performed. First, the deep dorsal vein is anastomosed with 11-0 nylon or polypropylene (Prolene); this anastomosis must be patent to prevent glans and corporal edema. Second, one of the dorsal arteries, but preferably both, is reapproximated in the same manner as the vein. The arterial anastomosis restores blood flow to the subcutaneous tissues and helps prevent postoperative skin necrosis. Finally, the epineurium of the dorsal nerves is reapproximated with a simple 10-0 nylon or Prolene suture. The autonomic cavernous dorsal nerves do not demand repair. Reapproximation of the nerves is suggested to help preserve penile and skin sensation, however.

Depending on the state of the amputated penile skin, interrupted 4-0 chromic sutures may be used to reapproximate the skin edges. If the penile skin is unusable or extensively denuded, a nonmeshed, split-thickness skin graft is placed. Shaft skin should be preserved with minimal debridement because skin that initially appears dusky may improve during the postoperative period.

Nonsalvageable Amputated Penis

If the amputated penis is not viable or cannot be located, then the remaining penile stump is then assessed for functionality and possible reconstruction. The length of the residual penile stump will dictate the method of subsequent reconstruction. In general, we use the cutoff of 4 cm flaccid or 7.5 cm stretched length as the minimum length of penis needed to have satisfactory vaginal penetration intercourse. When the penile stump is of sufficient length, the denuded corpora are covered with a split-thickness skin graft, from the tip of the neoglans to the mobilized shaft skin and the distal urethral spatulated.

If the remaining penile stump is short (<4 cm), the penis can be advanced by dividing the suspensory ligament improving penile length by up to 2 to 3 cm. The mobilized penis is then resutured to the pubic bone with nonabsorbable braided suture (e.g., Ethibond). The residual shaft skin is then sutured to the proximal shaft, and the distal denuded corpora covered with a split-thickness skin graft. An alternative method for skin coverage is the transfer of superior lateral scrotal myocutaneous flaps or to bury the penis in a subcutaneous tunnel in the scrotum. This method leads to a suboptimal, hair-bearing, thick-skinned penile shaft and requires a second reconstructive surgery (8,11). Regardless of the method, covering the vascular anastomoses is important to prevent delayed vessel thrombosis and resulting replantation failure. Finally, the penis is wrapped in loose dressings and an external splint (a “penis house”) is fashioned to encourage venous and lymphatic drainage.

If a patient does not have access to a medical center with microsurgical capabilities, then reattachment involving simple reapproximation of the urethra and corpora can be attempted. Anastomosis of the deep dorsal vein alone is technically simpler than anastomosis of the dorsal arteries and leads to less glans hyperemia. Given its relative technical ease, this can be performed using loupes, and a microscope is not necessary (12). If penile replantation is not an option, then the penile stump can be closed as done for a standard elective partial penectomy (Figs. 72.3 and 72.4). A phalloplasty can be performed at a later date.

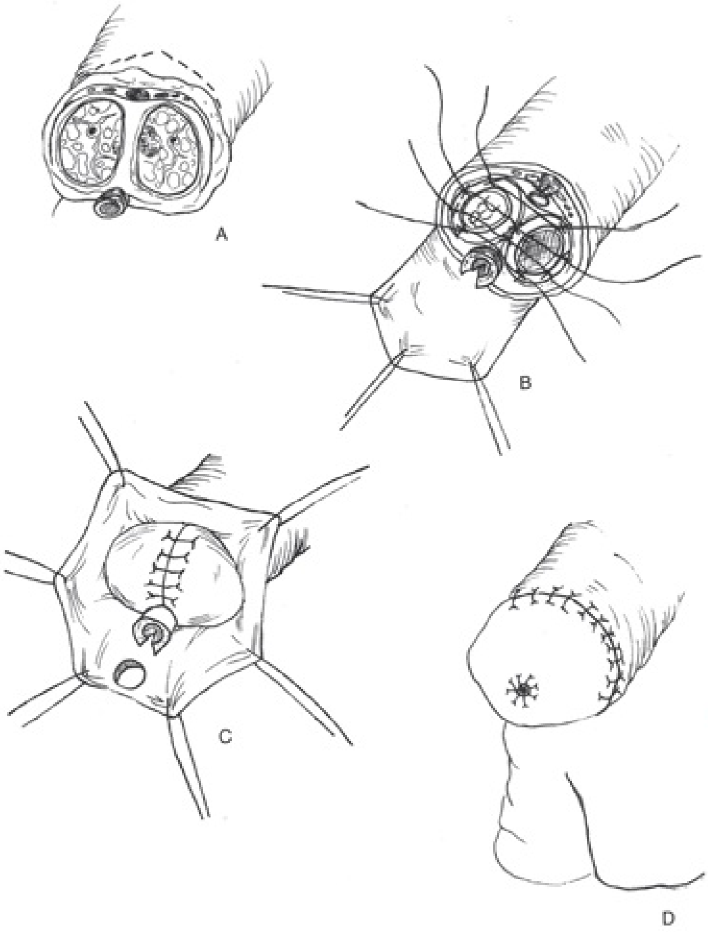

FIGURE 72.3 Amputation and loss of dismembered penis. **A:** Amputated penile stump. **B:** Closure of the corpora, ligation of the dorsal vessels, and spatulation of the urethra. **C:** Mobilization of the penile skin flap. **D:** Completed coverage of the partial penectomy and urethral anastomosis. Total phallic reconstruction may be considered in order to improve body image and psychosexual identity, particularly in younger men. Reports of phallic reconstruction after amputation are rare and typically employ a radial forearm free flap (13). The technical aspects of creating a neophallus after penile amputation are very similar to that for a female-to-male gender reassignment operation. Chang and Hwang (14) first described a forearm free flap based on the radial artery for phallic reconstruction. The major advantages of this flap are it is reliable, sensate, has a predictable anatomy, reliable vascular supply, and pliable skin (14,15). Major disadvantages are the donor site scar and deformity of the nondominant arm, complexity of the surgery, and the high complication rates, particularly urethral stricture.

POSTOPERATIVE MANAGEMENT

Postoperative management should include at least 2 to 5 days of bedrest, perioperative broad-spectrum antibiotics, and the use of Doppler ultrasonography to ensure graft survival. After 2 weeks of urethral stenting, the Foley may be removed after a pericatheter retrograde urethrogram performed to demonstrate no urethral leak. The suprapubic tube can be removed after a few days of normal voiding. Besides surgical management, psychiatric care must be ongoing. Genital self-mutilation is an irrational act, and there is a higher suicide rate among this population. Once the psychotic episode has been treated, most patients are remorseful and regret the act of self-mutilation. Of patients who have committed self-emasculation during psychosis, 31% will repeat this type of injury, typically after having discontinued medications (16).

OUTCOMES

Given the uniformly favorable results of microvascular penile replantation from both a cosmetic and functional perspective, this approach should be used if at all possible. If microsurgery is not feasible, macroscopic replantation should still be offered because this still offers reasonable success.

A recent systematic review was performed by Babaei and Safarinejad (17) in 2007. They found 50 cases of nonmicrosurgical replantation and 30 cases of microsurgical replantation after 1984. They reported a 90% (27/30) success rate among microsurgical repairs as defined by organ viability. They concluded that venous outflow was critical to long-term success.

Although the rate of erectile function after nonmicrosurgical repair, that is, anastomosis of only the deep dorsal vein, is approximately 80%, this technique is associated with a higher rate of fistula formation, urethral stenosis, glans and skin necrosis, loss of sensation, and erectile dysfunction (7).

COMPLICATIONS

The most common complications of penile replantation include skin sloughing, glans ischemia, erectile dysfunction, and urethral stricture and fistula (7,18). Although common, lymphedema and venous congestion are generally self-limiting. Microsurgical approaches have reduced the rates of these complications.

Partial or complete erections following microvascular replantation are common (19,20). Patients who fail to achieve adequate return of erections may still respond to vasodilatory pharmacologic therapy (e.g., prostaglandin E1 [Alprostadil], alprostadil/papaverine/phentolamine [Trimix]).

Once surgically reattached, adjuvant therapies have been reported to promote penile preservation. Leech therapy has been used with success, likely owing to improvement in decreased venous congestion (21,22). Hyperbaric oxygen has also been used in conjunction with microsurgical repair with successful outcomes (23).

CHAPTER 73 HYDROCELE AND SPERMATOCELE

ALI A. DABAJA AND CIGDEM TANRIKUT

HYDROCELE

Hydroceles were described as early as the 16th century by the French surgeon Ambroise Paré and refer to an abnormal collection of serous fluid between the parietal and visceral layers of the tunica vaginalis. They are the most common cause of painless, nonacute scrotal swelling, with an estimated incidence of 1% in the adult population (1) and are more commonly seen after the age of 40 years.

Embryology and Etiology

In order to understand how hydroceles form, one must understand the embryologic origin of the inguinal canal and the process of testicular descent. As the testis develops, it is anchored by two ligaments, the cranial and the caudal suspensory ligaments. The caudal suspensory ligament, also known as the gubernaculum, fixes the testis within the scrotum and directs its course during descent. At approximately the seventh week of development, shortening of the gubernaculum pulls the testis from the level of the 10th thoracic vertebra through the inguinal canal and toward the scrotum. As the gubernaculum shortens, its most ventral peritoneal cover invaginates to develop a semicircular blind-ending cavity, known as the processus vaginalis. The growth of the processus vaginalis is directed inferiorly and drags the various layers of the abdominal wall with it, leading to the formation of the inguinal canal (2).

Testicular descent is divided into two phases: the intra-abdominal phase and the inguinal-scrotal phase. During the intra-abdominal phase between the 7th and 12th weeks of gestation, the gubernaculum shortens and pulls the testis down to the level of the deep inguinal ring. The testis remains in the vicinity of the deep ring until the seventh month of gestation then, in response to multiple factors including hormonal changes, the inguinal-scrotal phase begins and the testis descends through the inguinal canal and into the scrotum by the ninth month of gestation. Just before term delivery, the testis has completely entered the scrotum, and the gubernaculum has atrophied to a ligament that attaches the lower pole of the testis to the scrotum.

As the testis descends and the processus vaginalis develops, each layer of the abdominal wall contributes to the spermatic cord. The first layer encountered by the processus vaginalis is the transversalis fascia—this layer will become the internal spermatic fascia of the spermatic cord. Because the transversus abdominis muscle is not completely developed near the inguinal canal, this layer does not contribute to any of the layers. Next, the processus vaginalis pulls the fascia of the internal oblique muscle with it, which becomes the cremasteric fascia of the spermatic cord. Finally, the processus vaginalis evaginates into a thin layer of external oblique muscle, which becomes the external spermatic fascia (3) (Fig. 73.1).

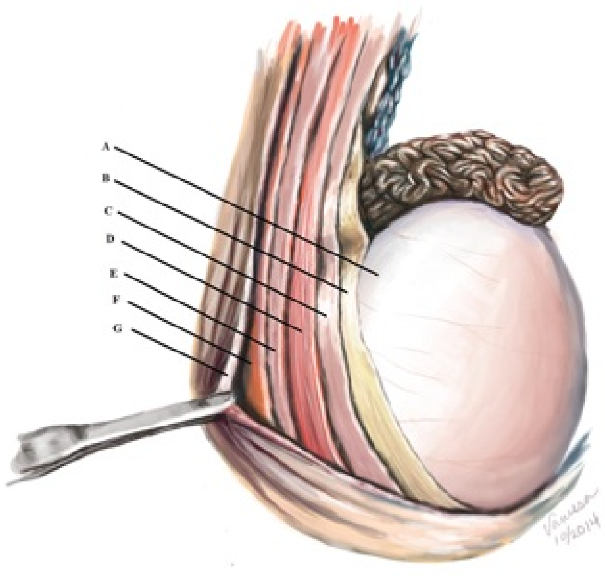

FIGURE 73.1 Anterior view of testis detailing the layers of the scrotum and their embryologic origins: (*A*) visceral tunica vaginalis, (*B*) parietal tunica vaginalis, (*C*) internal spermatic fascia, (*D*) cremaster muscle, (*E*) external spermatic fascia, (*F*) dartos layer, and (*G*) skin.

The processus vaginalis surrounds the testis to form the visceral and parietal layers. After testicular descent, the proximal end of the processus vaginalis located within the inguinal canal normally seals, leaving a small patent remnant surrounding the testis called the tunica vaginalis. If the proximal aspect fails to seal (patent processus vaginalis), communication between the tunica vaginalis and the abdominal cavity remains, and the tunica vaginalis will fill with serous fluid leading to formation of a communicating hydrocele. In some instances, the communication may be large enough to allow development of an indirect hernia (Fig. 73.2). A patent processus vaginalis is the most common cause of hydrocele in the pediatric population and usually resolves spontaneously by 18 to 24 months of age (4).

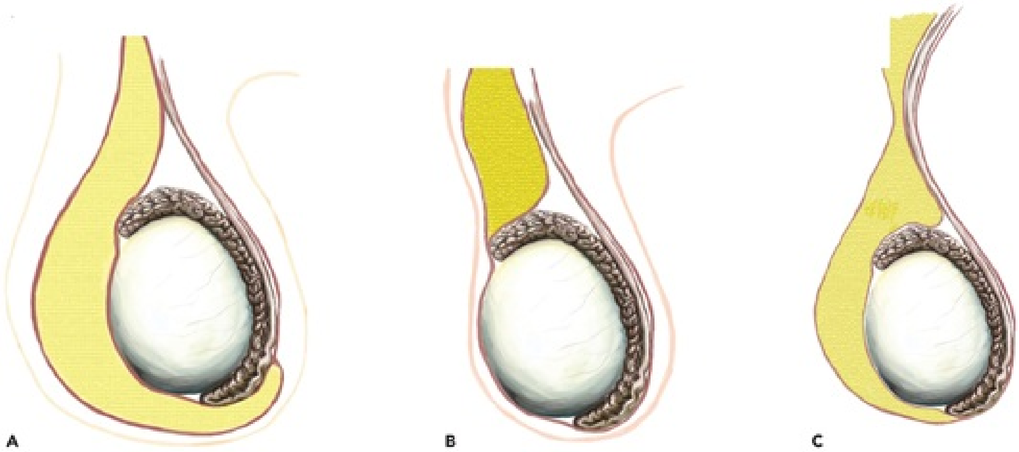

FIGURE 73.2 Types of hydrocele: (A) noncommunicating hydrocele, (B) hydrocele of the cord, and (C) communicating hydrocele.

Hydroceles in the adult population are generally acquired, noncommunicating hydroceles in which serous fluid accumulates within the tunica vaginalis. In the majority of cases, they are idiopathic (1), caused by either excess fluid production or inadequate drainage of fluid. Oversecretion of fluid may occur in response to infection or inflammation (e.g., orchitis), tumor (e.g., testicular cancer), obstructing testicular lymphatics, or trauma to the scrotum or inguinal canal. Inadequate drainage may develop as a result of prior inguinal or pelvic surgery. For example, one common cause of acquired hydrocele is nonmicrosurgical varicocelectomy (5) in which cord lymphatics, present in abundance within the sheath of the internal spermatic veins, are ligated along with the veins. Other surgical procedures such as inguinal hernia repair and renal transplant have been associated with hydrocele development. In addition, infection may cause lymphatic obstruction, such as in patients with the nematode parasitic infection *Wuchereria bancrofti* and, more commonly, severe or recurrent epididymitis or orchitis.

Diagnosis and Preoperative Patient Preparation

The normal scrotum contains 2 to 3 mL of fluid between the tunical layers with continuous production and drainage maintaining this volume at equilibrium. Sonographically detected hydroceles have been reported in as many as 65% of healthy men (6). The volume at which tunica vaginalis fluid becomes a hydrocele is not clearly defined. Even in cases of an obvious hydrocele on physical examination, the amount of fluid can be extremely variable among patients and may range from small and soft to large and tense.

Most commonly, patients present with complaints of painless swelling in one or both sides of the scrotum, occasionally reporting a vague scrotal pain or sensation of heaviness. Men may seek evaluation due to scrotal discomfort during intercourse or physical activity, anxiety in regard to the cosmetic appearance of the scrotum, concerns about damage to the reproductive organs, or fear of malignancy. Cases of painful and acute-onset hydrocele are usually secondary to trauma, infection, or testicular torsion and should be investigated promptly.

In the pediatric population, the parent may report that the degree of scrotal swelling fluctuates in size, often noting enlargement of scrotal swelling with increased abdominal pressures, such as during crying episodes. This finding usually suggests a patent processus vaginalis.

The diagnosis of hydrocele is made clinically by appreciating fluid around the testis, and one can usually transilluminate the scrotum. In patients with long-standing hydroceles in which the tunica vaginalis is thick, highly inflamed, and fibrotic, the fluid collection may fail to transilluminate. In all cases of suspected hydrocele, especially when the testis cannot be palpated due to the size of the hydrocele, an ultrasound is warranted to confirm the diagnosis and to rule out testicular lesions suspicious for malignancy (7). Additional investigations, such as complex imaging, are generally not required. It is important to assess for presence of a patent processus vaginalis or a concomitant inguinal hernia, as an inguinal approach would be appropriate for hydrocele repair in such circumstances. An inguinal approach is also necessary when neoplasm is suspected on scrotal ultrasound but not definitively diagnosed preoperatively.

Indications for Treatment

Hydroceles can cause discomfort and embarrassment due to size and may have a negative impact on work performance, sexual function, and daily activity, particularly in patients with advanced lymphedema and large hydrocele caused by lymphatic filariasis (8). Treatment is indicated when the patient complains of discomfort or disability due to size of the hydrocele. Data are scarce related to the possible effect of hydrocele on testicular function. It has been postulated that hydrocele may act as an insulator, leading to an increase in scrotal temperature with a possible subsequent negative impact on spermatogenesis (9). Tense hydroceles may cause pressure atrophy of the testis and increase the resistive index of the subcapsular artery (10).

Treatment

The basic principles of any hydrocele treatment are drainage of excess fluid and prevention of fluid reaccumulation (11). Surgery via a scrotal approach is the gold standard for repair of most adult hydroceles; fluid is drained after opening the tunica vaginalis and then the tunica is either excised, plicated, or inverted behind the cord in a bottleneck fashion. In the pediatric population, the presence of a patent processus vaginalis or an inguinal hernia will require an inguinal approach. An inguinal approach is also necessary when attendant neoplasm or hernia is suspected preoperatively. This allows for inspection of the testis to identify any potential testicular malignancy and to taking safe and appropriate action to manage such a situation, such as clamping the spermatic cord and carrying out testicular biopsy, if necessary. If the suspicious lesion is benign, the remaining testis is then reduced into the scrotum or, in the case of malignancy, a radical orchiectomy can be performed (12). Patients must be informed preoperatively of potential complications including scrotal hematoma, infection, testicular atrophy or injury, hydrocele recurrence, and fertility alterations.

Nonsurgical Repair

If the clinician believes that the hydrocele is due to an acute process and that the imbalance between fluid production and reabsorption may be temporary, as in an episode of orchitis, observation is a viable treatment option. Active surveillance is also recommended in children younger than the age of 2 years with a congenital hydrocele unless the patient has an accompanying hernia or if the diagnosis is uncertain, as many of these communicating hydroceles will resolve within the first 2 years of life if managed conservatively.

In patients who are poor surgical candidates, the hydrocele fluid can be aspirated percutaneously and sclerotherapy can be performed in an effort to eliminate the potential space. Hydrocele aspiration and sclerotherapy was first reported in 1975 as a nonsurgical outpatient treatment for acquired hydroceles as an attempt to address complications related to hydrocelectomy. Moloney (13) reported using a mixture of phenol, glucose, and glycerine as a sclerosing agent. Since then, multiple chemical and pharmacologic agents have been employed, including, but not limited to, 99.5% alcohol, antazoline, talc, ethanolamine oleate, tetracycline, fibrin glue, blood, phenol, and sodium tetradecyl sulfate (STDS). In addition to the many agents that have been used, various techniques have also been described, resulting in outcomes that are difficult to interpret and compare. In a recent trial, hydrocele aspiration and sclerotherapy with doxycycline corrected 84% of simple hydroceles within a single treatment. The use of doxycycline showed a better success rate as compared to other sclerosing agents and a similar outcome to the reported success rates of hydrocelectomy (14).

Aspiration and instillation with sclerosing agents should never be employed in men where future fertility may be a concern because obstruction of the epididymis is a significant risk of this technique (15). Furthermore, when this method fails, subsequent surgical hydrocelectomy is much more difficult due to adhesions and formation of multiple loculations.

Percutaneous aspiration and sclerotherapy can be performed in an outpatient office setting with local anesthesia. All patients are screened with a scrotal ultrasound to determine the nature of the hydrocele and to rule out scrotal abnormalities including testicular malignancy, spermatoceles, and septations. The hydrocele can be transilluminated with a light source, or ultrasound can be used to allow visualization of the hydrocele sac. Maintaining the hydrocele under pressure is important in an effort to avoid testicular injury. After initiation of a spermatic cord block, complete aspiration of the hydrocele can be performed using a 16- or a 19-gauge butterfly needle attached to a three-way stopcock; this allows the clinician to aspirate the hydrocele fluid then instill the sclerosing agent via the same puncture site. After complete drainage of the hydrocele fluid, the sclerosing solution is injected and a supportive dressing is applied (14,16).

Surgical Repair

Patient Preparation

There are several surgical approaches to accomplish hydrocelectomy. The procedure may be performed under general, spinal, or, less commonly, local anesthesia. Administration of preoperative antibiotics is appropriate, whereas postoperative antibiotics are generally not indicated. The scrotum and penis are shaved and the entire area is prepped and draped in a sterile fashion. The approach can be via either a median raphe incision, which gives ready access to both sides of the scrotum, or a transverse incision within the scrotal skin folds, avoiding the blood vessels (Fig. 73.3). The incision is carried down through the dartos fibers to the level of the tunica vaginalis where the characteristic “Robin egg blue” of the hydrocele is seen. At this point, one may select with which procedure to proceed.

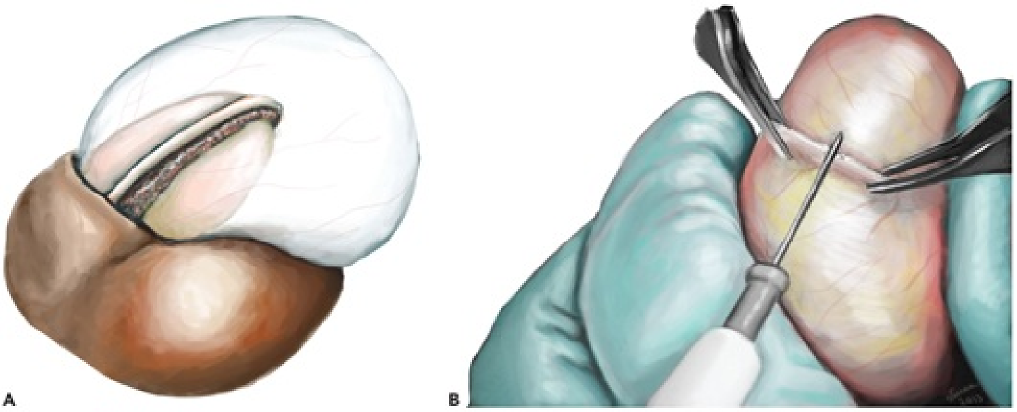

FIGURE 73.3 A: Testis within the hydrocele sac is exposed through a small skin incision. Depending on the repair technique employed, the tunica vaginalis is opened (B), and the testis and epididymis are delivered.

Jaboulay Procedure

Described by Mathieu Jaboulay in 1902 (17) (also called the Winkelmann procedure), this method involves making an incision in the tunica vaginalis through which the hydrocele fluid is drained. The testis is delivered through the incision and then most of the hydrocele sac is resected, leaving a small cuff along the borders of the testis and the epididymis. The remnant is everted posteriorly and the tunical edges are reapproximated in a running fashion (Fig. 73.4). Care must be taken to ensure that the closure is loose enough that the spermatic cord is not constricted (18). A modified version of this technique involves resecting the tunica vaginalis nearly flush with the testis and epididymis and either cauterizing the cut edges or oversewing them (Fig. 73.5). This approach runs an increased risk of injury to the epididymal and testicular blood supply. Use of loupes or, better yet, an operating microscope and leaving at least a 1-cm margin of sac minimizes the risk of epididymal vessel or testicular artery injury (19).

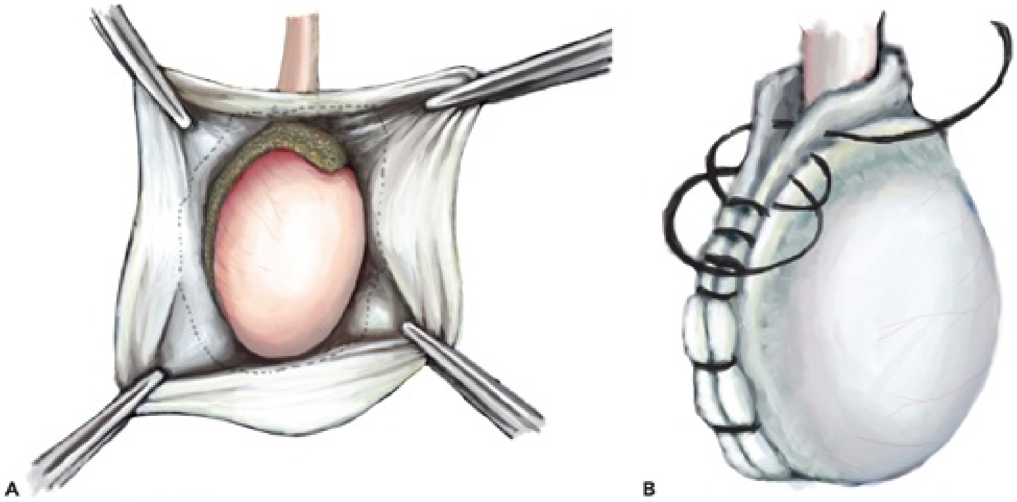

FIGURE 73.4 Jaboulay procedure. A: The hydrocele sac is resected, leaving a 1- to 2-cm cuff along the borders of the testis and epididymis. B: The edges are everted posteriorly around the cord and reapproximated by a running suture.

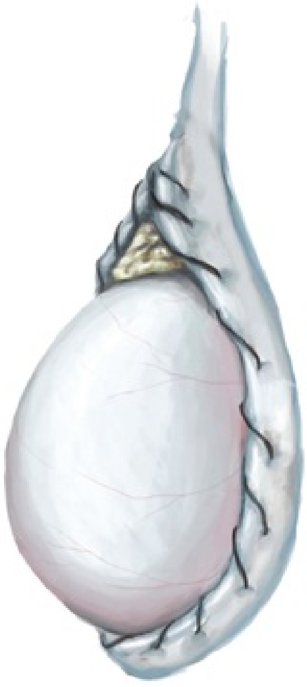

FIGURE 73.5 Modified Jaboulay: The tunica vaginalis is resected close to the edges of the testis and epididymis and the edges are oversewn.

The Jaboulay technique requires extensive dissection of the hydrocele sac that may lead to pain and scrotal edema. To minimize the dissection, a variant surgical procedure based on the same principle has been suggested (20): through a smaller (~15 mm) transverse scrotal incision, the tunica vaginalis is identified and grasped at the medial and lateral aspects of the incision. The sac is punctured to allow aspiration of the hydrocele fluid. Then, the tunica vaginalis is gently freed and delivered out of the small scrotal incision by applying gentle traction. After fully mobilizing and delivering the hydrocele sac, it is excised by electrocautery, and the wound is closed without the need to deliver the testis.

Andrews Procedure

This technique was described by E. Wyllys Andrews (21) in 1907 to improve the speed and the efficiency of the Jaboulay procedure. Andrews referred to this procedure in his original publications as the “bottle operation.” This works best with thin-walled, simple hydroceles without loculations. The testis is delivered through an anterior scrotal incision within the tunica vaginalis. The hydrocele sac is inspected and a vertical 2- to 3-cm incision is made in the anterior surface as it tapers into the cord. When the hydrocele fluid is drained, the empty sac takes on the shape of a bottle with an opening at its superior aspect. The testis is delivered through that superior tunical incision then the hydrocele sac is everted and the everted sac now surrounds the spermatic cord (Fig. 73.6). If there is any bleeding, the cut edge is sutured and appended around the cord. Otherwise, the everted edges of the sac can be left open without requirement of sutures.

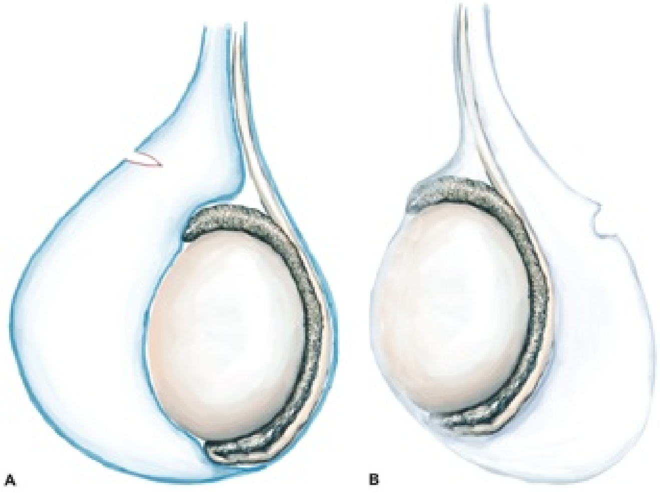

FIGURE 73.6 Andrews procedure. **A:** A 2- to 3-cm incision is made in the superior-anterior aspect of the hydrocele sac. **B:** The hydrocele sac is everted around the testicle resulting in relocation of the hydrocele incision posterior to the testis and around the cord; no sutures are required.

Lord Procedure

Peter Lord (22) devised a plication technique showing that several evenly spaced plicating sutures in the hydrocele sac can effectively obliterate the tunica vaginalis. As the plication technique includes minimal dissecting of the hydrocele sac, there may be relatively less bleeding intraoperatively and less scrotal swelling postoperatively as compared with other techniques. The hydrocele sac is opened, the fluid is drained, and the tunica vaginalis is minimally dissected off the dartos muscle. Allis clamps are used to hold the cut edges to visualize the testis and epididymis. After the hydrocele sac is completely opened, the edges are circumferentially plicated by placing interrupted sutures approximately 1 cm apart and 1 cm deep (Fig. 73.7). When tying these sutures, the hydrocele sac will fold onto itself, eliminating the sac. The suture placement for the Lord plication starts near the margin of the testis and the epididymis and thus carries an inherent risk of testicular or epididymal injury. When employing this for large, thick-walled hydroceles, considerable residual scrotal mass remains.

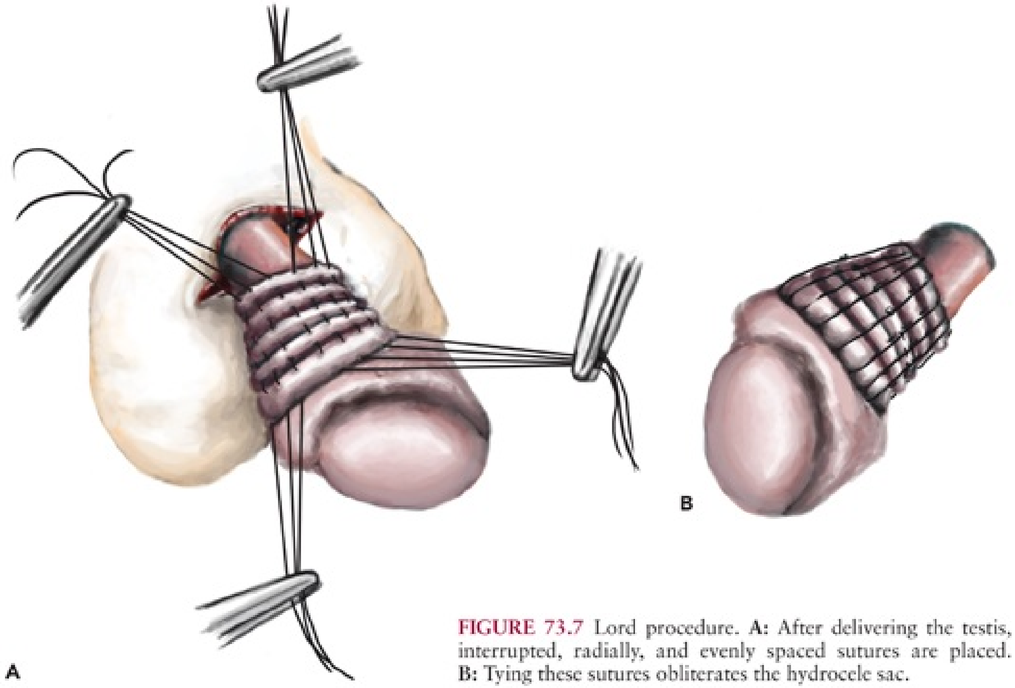

FIGURE 73.7 Lord procedure. **A:** After delivering the testis, interrupted, radially, and evenly spaced sutures are placed. **B:** Tying these sutures obliterates the hydrocele sac.

Recent publications describe combined plication and eversion techniques through a vertical incision on the scrotum. The hydrocele sac is dissected completely, the fluid is drained, and the hydrocele sac is everted. Using this modified technique, a plication suture of 3-0 chromic is placed 1 cm away from the testicular margin. The same suture is used to traverse posterior to the testis in order to plicate to the opposite edge of the sac at the same level, also about 1 cm away from the testicular margin. A maximum of three or four stitches are used, taken at different levels and placed about 1.5 cm away from each other. In this technique, fewer sutures are used as compared to Lord plication. These modifications make the procedure quicker and less likely to injure the epididymis (23).

Microsurgically Assisted Hydrocelectomy

This is now our preferred approach, especially in men where future fertility is an issue. Prior to surgery, a scrotal ultrasound should be performed to confirm absence of testis tumor. Through a transverse scrotal skin-fold incision, the hydrocele is delivered, and the spermatic cord and vas are identified and surrounded with a Penrose drain. An opening is made in the hydrocele sac, the hydrocele fluid drained, and the testis and epididymis delivered. Use of the operating microscope at the time of hydrocelectomy enables identification of the vas deferens, vassal vessels, and the epididymis, minimizing the possibility of iatrogenic injury. Transillumination of the opened hydrocele sac using the operating room lights can help identify the vas and epididymis, which may be splayed out within the walls of a thick and long-standing hydrocele sac and be difficult to otherwise identify. The vas should be dissected from the cord to the vasoepididymal junction. In cases where the margins of the epididymis are indistinct, the operating microscope is indispensable to assure that epididymal tubules are not transected during hydrocele sac excision. Redundant tunica vaginalis is resected, leaving a fingerbreadth margin of tunic around the epididymis. A bipolar cautery is used to control small bleeding vessels and larger ones are ligated or clipped. Although there is no published data available comparing the outcomes of microsurgical versus nonmicrosurgical hydrocelectomy, in our experience, microsurgical technique minimizes iatrogenic complications without significantly extending the operative time (24).

Wound Closure

After returning the testis to the scrotum in its proper anatomic orientation, an assessment of the surgical field for bleeding should be performed and meticulous hemostasis should be obtained. In large hydroceles, when the gubernacular has to be transected, the testis should be pexed with two or three interrupted sutures of 2-0 polydioxanone suture (PDS) from the cut edge of the hydrocele sac to the dartos to prevent torsion. Most hydrocelectomies may be performed without surgical drainage. However, it is important to note that the scrotal skin and fascial layers have little or no capacity to tamponade any bleeding. When hemostasis is difficult to obtain, a small Penrose drain should be placed through a separate stab incision in the dependent aspect of the scrotum and left overnight. The drain should be secured in place with 2-0 silk and a safety pin suture to prevent its migration into or out of the scrotum. The scrotal wound is closed in two layers using absorbable suture: the cut edges of the dartos muscle are closed with 3-0 Vicryl or Monocryl to prevent scrotal bleeding, then the skin is closed per the surgeon's preference (Fig. 73.8). Fluffed gauze held in place by an athletic supporter provides a supportive, compressive dressing. An ice pack helps diminish postoperative pain and swelling.

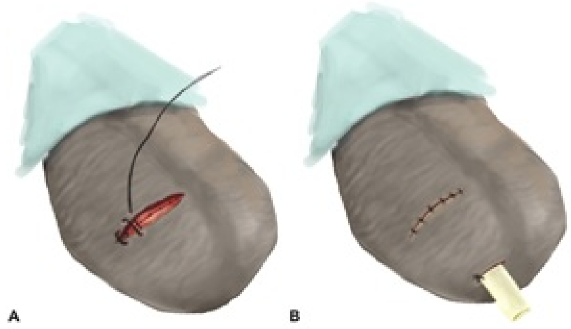

FIGURE 73.8 The testis is reduced into the scrotum and the incision is closed with two layers. A drain is placed in the dependent portion of the scrotum if hemostasis is not optimal.

Outcomes and Complications

The success rates of hydrocelectomy depend on the technique, ranging from 81% to 98% (25). Complications following hydrocelectomy include hematoma formation, infection, persistent or recurrent swelling, testis atrophy, reproductive tract obstruction, and chronic pain. Overall complications may be as high as 54% (25). One of the most detrimental complications to those patients who still seek fertility is the risk of epididymal injury, which may occur in up to 6% of patients who undergo hydrocelectomy (26). Epididymal injury can be avoided by considering the use of an operating microscope to optimize visualization of the epididymis and the vas deferens during resection of the hydrocele sac (19). Transillumination of thick-walled sacs after opening it often helps delineate the epididymis and vas, which can be between layers of the sac.

SPERMATOCELE

A spermatocele is a cystic dilatation of the efferent ductules, rete testis, or epididymal tubules (27). It is hard to differentiate between a spermatocele and an epididymal cyst clinically, although spermatoceles always arise from the cyst. Unlike spermatoceles, epididymal cysts do not arise from or communicate with efferent ductules. However, the approach for repair is the same for each entity. Definitive diagnosis of spermatocele is made intraoperatively by identifying sperm within the cyst fluid on a wet mount, whereas no sperm are identified with examination of fluid from an epididymal cyst. Spermatoceles/epididymal cysts have been identified in approximately 30% of asymptomatic patients undergoing scrotal ultrasound (28). Sonographic findings include a unilocular or, less commonly, multilocular, well-defined hypoechoic lesion, which sometimes demonstrates posterior acoustic enhancement. A spermatocele/epididymal cyst may contain low-level echogenic proteinaceous fluid, and cyst wall calcification may be present (29). The etiology of spermatocele is idiopathic, traumatic, or inflammatory. Epididymal duct obstruction, such as secondary to vasectomy, is thought to be associated with spermatocele formation, and spermatoceles are often associated with tubular ectasia of the rete testis.

Diagnosis and Presentation

Patients present with a discrete, usually asymptomatic, mass arising from the caput epididymis that is definitively outside of the testis. Diagnosis can be made with history and physical examination. Examination reveals a mass separate from and usually superior to the testis. When large enough, these cysts can be transilluminated. In most instances, imaging is not necessary; however, if the diagnosis is questionable, ultrasound can be used to confirm the diagnosis.

Indications for Treatment

Most spermatoceles do not require intervention but some spermatoceles can grow quite large leading to discomfort or cosmetic concerns. Occasionally, spermatoceles are associated with antisperm antibody formation, which can result in impaired fertility. Historically, spermatocelectomy was avoided in men desiring future fertility. However, use of an operative microscope during spermatocelectomy is an effective method to minimize risk of epididymal injury and resultant obstruction (30).

Surgical Technique

Patient preparation and surgical approach is identical to that for hydrocelectomy. A transverse incision within the scrotal skin folds and between the transverse scrotal blood vessel minimizes bleeding and results in a virtually invisible scar. The tunica vaginalis is opened with electrocautery away from the epididymis and the testis, epididymis, and spermatocele are delivered.

In patients who are concerned with future fertility, an operating microscope providing 6× to 25× magnification should be used for the remainder of the dissection (30). Careful sharp and blunt dissection is recommended to excise the spermatocele. The cystic structure should be excised from the epididymis without excessive mobilization of the epididymis and testis themselves so as to decrease the risk of vascular injury to these structures. Dissection down to the efferent ductule that the spermatocele arises from is performed under the microscope with a combination of gentle sharp and blunt dissection, taking great care to avoid entering the spermatocele before dissection is completed; they should be ligated using 5-0 or 6-0 absorbable sutures and the spermatocele removed intact (Fig. 73.9). Sampling of the fluid from the spermatocele and examination of the fluid under a 400 power provided by a bench microscope confirms the presence of sperm and diagnosis of spermatocele. If the patient does not have any interest in future fertility and the spermatocele is densely adherent to the surrounding structures resulting in a difficult dissection, partial or total epididymectomy may be considered as a treatment option (18). After the spermatocele is excised and hemostasis assured, the testis is reduced into the tunica vaginalis and the tunical edges are reapproximated in a running fashion using absorbable suture. The testis is then returned to the scrotum in its proper anatomic orientation and hemostasis of the surgical field is obtained. The rest of the wound closure is performed as described for hydrocelectomy.

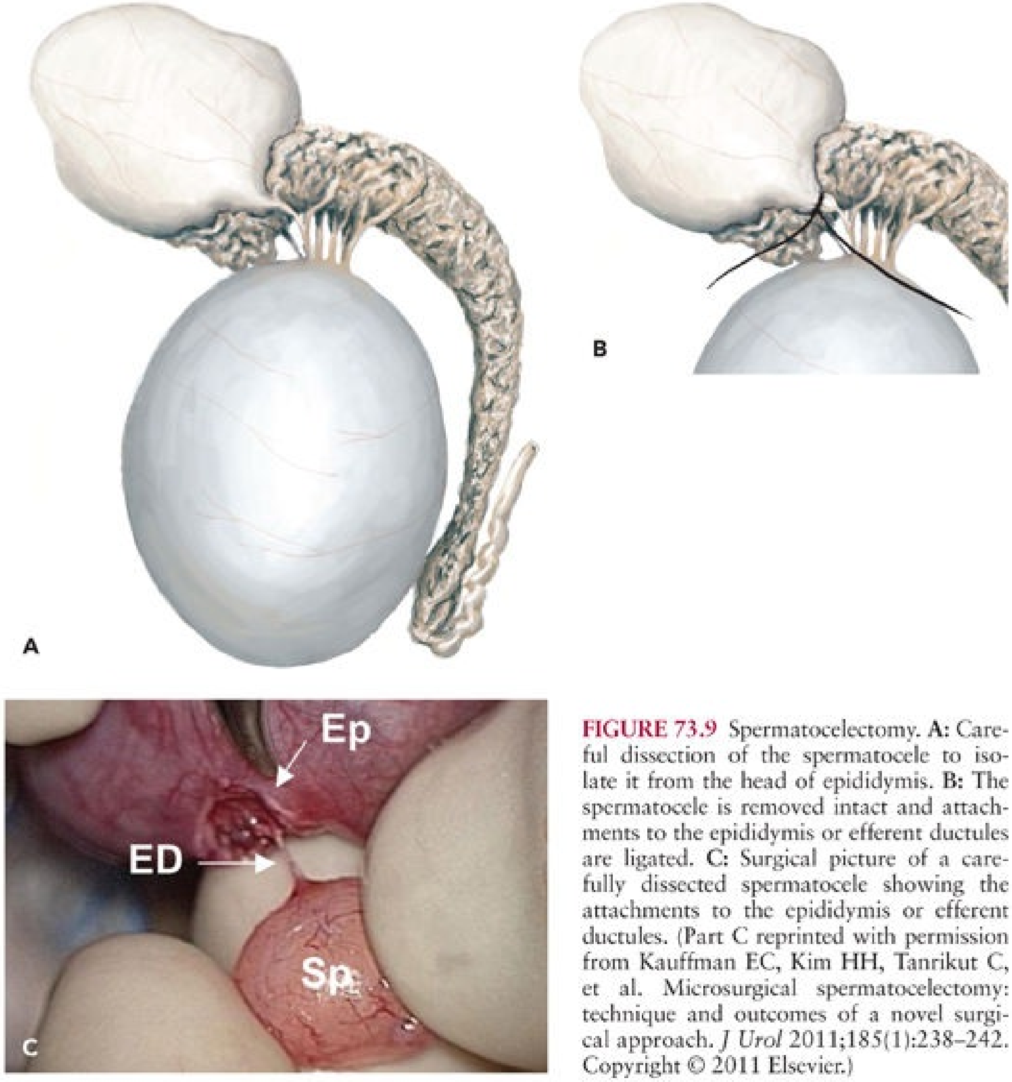

FIGURE 73.9 Spermatocelectomy. **A:** Careful dissection of the spermatocele to isolate it from the head of epididymis. **B:** The spermatocele is removed intact and attachments to the epididymis or efferent ductules are ligated. **C:** Surgical picture of a carefully dissected spermatocele showing the attachments to the epididymis or efferent ductules. Copyright © 2011 Elsevier.)

Outcomes and Complications

Of primary concern is epididymal injury leading to obstruction and compromised fertility. The incidence of epididymal injury during spermatocelectomy is 17% (26), and there is evidence of permanent postoperative changes on semen analyses in most patients who undergo spermatocelectomy (31). Prior studies report recurrence rates after spermatocelectomy of 5% to 10% (25). The use of the operating microscope to enhance visualization of the epididymis and efferent ductules reduces the incidence of iatrogenic epididymal obstruction with no change in postoperative sperm counts and a possible decrease in recurrence rates when performed by a skilled microsurgeon (30). Additional complications that are typical of other scrotal surgeries can be seen including hematoma, hydrocele, infection, and testicular atrophy due to vascular injury.

CHAPTER 74 CONGENITAL CURVATURE

ERIK GROSSGOLD AND JEREMY TONKIN

Patients with straight erections have normal and symmetrical expansion of all tissue layers of the penis. This requires normal tissue elasticity and compliance. During tumescence, the penis fills with blood and the tissues reach their limits of compliance. The limits of compliance of the tunica albuginea are especially important in rigidity; however, those with curvature may have an asymmetrical expansion of any one aspect of their penis. Thus, curvature can be due to decreased compliance of one aspect of the penis or foreshortening of one erectile body.

Penile curvature is described as either congenital or acquired. With regard to congenital curvature, there exists *congenital curvature* and *chordee without hypospadias*. Some use these terms interchangeably; however, they should not be thought of as synonymous.

Devine and Horton (1) proposed a classification system for congenital penile curvature consisting of five separate types of curvature. Types I to III can be collectively termed *chordee without hypospadias* (Fig. 74.1). This term in general refers to an abnormal development of ventral penile tissue in the presence of a normally placed meatus. For patients with type I, none of the surrounding layers are normal and there is malfusion of the corpus spongiosum. Patients with type II curvature have a dysgenic band of fibrous tissue lateral and dorsal to the urethra. This is believed to have formed from the mesenchyme that would have normally become the Buck and dartos fasciae. Type III congenital curvature exists in patients with a normally developed urethra, corpus spongiosum, and Buck fascia. The abnormality in these patients is in the dartos fascia, which has an elastic band that causes the penis to curve acutely. Not infrequently, these patients have a large and prominent mons pubis.

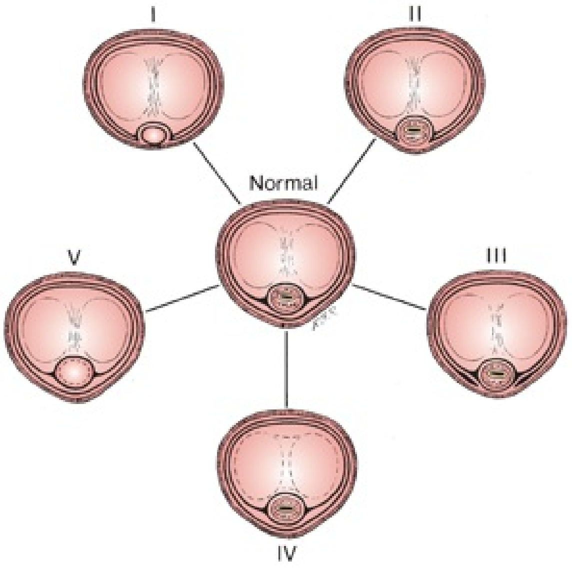

FIGURE 74.1 Cross section of the penis displaying the forms of congenital curvature of the penis. The normal penis is in the center. *Class I*: Epithelial urethra beneath the skin. Dysgenic tissue beneath it represents undeveloped corpus spongiosum, Buck fascia, and dartos fascia. *Class II*: Normal urethra and spongiosum but abnormal Buck and dartos fasciae. *Class III*: Abnormal dartos fascia only. *Class IV*: Normal urethra and fascial layers with abnormal corporocavernosal development. *Class V*: Congenital short urethra (rare). (Reprinted with permission from Devine CJ Jr, Horton CE. Bent penis. *Semin Urol* 1987;5:252. Copyright © 1987 Elsevier Inc.)

The authors refer to type IV curvature as congenital curvature of the penis. In type IV penile curvature, development of the urethra, fascial layers, and corpus spongiosum is normal. The defect is a relative shortness or inelastic area of the tunica albuginea. It is our experience that these patients have a penis of small or normal length when flaccid, but when erect, the penis may be larger than expected. This is thought to be due to hypercompliance of the tunica albuginea that allows hyperexpansion of the penis. Many of these patients will remember curvature prior to puberty, but this becomes more accentuated after pubescence and the penile growth spurt that occurs during adolescence.

Type V curvature is the rarest, and some have questioned whether it exists. This type is described as the congenitally short urethra. The short urethra is not elastic enough or of adequate length, leading to ventral curvature during erections.

DIAGNOSIS

Patients usually present in their late teens to early 30s. Most men cannot remember their penis ever being straight but may have assumed their curvature was normal. After puberty and the onset of sexual activity, they realize that their curvature impedes sexual relations. Some patients also attest that their curvature has worsened since puberty. Occasionally, a patient will present after the age of 30 years. This is due to either having been sexually active but found sex functionally or psychologically difficult or, less commonly, sexually inactive due to curvature and embarrassment issues.

All patients should undergo a complete history, including an extensive sexual history and physical examination. This should include time since onset and any prior traumatic events. Penile examination should focus on evidence of subclinical fracture or Peyronie disease, the latter being rare in this younger patient population. Patients at our institution are required to supply photographs of their erect penis for documentation of the curvature (Fig. 74.2). The photographs are also beneficial in distinguishing between congenital curvature and chordee without hypospadias. Psychological aspects of the disease also need to be addressed. On occasion, patients with significant psychological issues are evaluated preoperatively by a certified sex therapist and treated as needed.

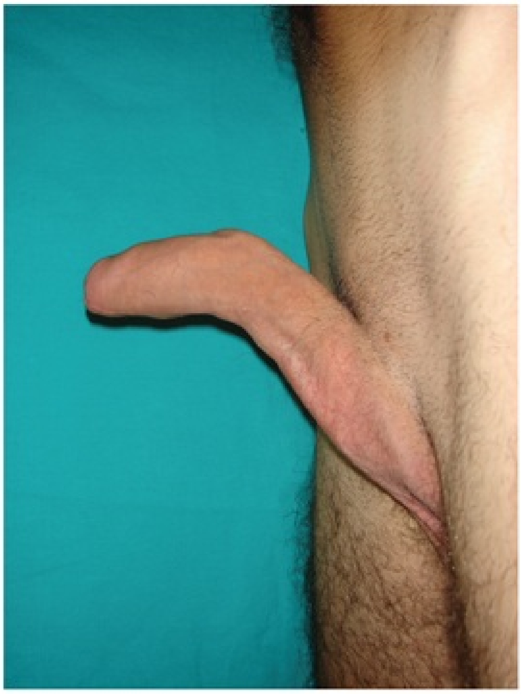

FIGURE 74.2 Preoperative photograph of an erect penis from a congenital curvature patient demonstrating a typical ventral curvature.

Patients with chordee without hypospadias usually present with a ventral or ventrolateral curvature (2) and usually have a penis that is normal or shorter than normal in length. As mentioned, these patients also recall penile curvature throughout their life but may note some progression of the curvature during or after puberty. Many of these patients have abnormalities of the ventral penile skin. This may be noted as a hooded prepuce or a high insertion of the penoscrotal skin (penoscrotal tethering). The deep ventral tissues of the penis may seem to be inelastic to examination and stretch. The inelastic tissue that is palpable is the dysgenic tissue that has replaced the Buck and dartos fasciae.

Some of these patients, because of their curvature and smaller-than-average length, have significant self-image issues. When identified, these are the patients who benefit from psychological counseling preoperatively.

INDICATIONS FOR SURGERY

Patients with congenital curvature usually have ventral or ventrolateral curvature. This can be poorly tolerated by the patient and/or their sexual partners. Patients who have significant enough curvature to impair their sexual function are candidates for surgery. Surgery for chordee without hypospadias is successful in this patient population, with most curvatures repaired in a single procedure. Many times, the curvature is corrected by excising the dysgenic tissue on the ventrum of the penis and mobilization of the corpus spongiosum. For patients with congenital curvature, many procedures have been described.

ALTERNATIVE THERAPY

There are no alternative therapies to surgery for this condition.

SURGICAL TECHNIQUE—CONGENITAL CURVATURE

There exists a wide variety of surgical procedures to repair congenital curvature, including incision and plication, incision with grafting, and penile disassembly. Most congenital curvatures are straightened completely with incision and plication alone.

Incision and Plication

In patients who have been previously circumcised, an incision is made through the circumcision scar. Due to the previous circumcision, the new patterns of lymphatic and venous drainage could lead to marked penile edema if an incision is made proximal or distal to the old scar. The incision is made down to the superficial layer of the Buck fascia. The penis is degloved in this plane. Once completely degloved, an artificial erection is created by introducing intravenous approved normal saline into the corporal space. Perineal pressure is needed initially to aid in storage, but prolonged pressure is not required because these patients have normal erectile function and will store the saline once initial tumescence is achieved. A tourniquet placed at the base of the penis is not recommended because this can mask or distort the proximal extent of curvature.

The artificial erection demonstrates the degree and location of maximal curvature. A layer of dysgenic tissue may be noted that includes the Buck and dartos fasciae. If so, this tissue is completely mobilized and excised. Care is taken not to injure the corpus spongiosum. In some cases, this will need to be detached from the glans to the penoscrotal junction. If injured, the urethra is closed primarily using a fine, absorbable suture. Patients who suffer from a differential elasticity between dorsal and ventral aspects of the corporal bodies may receive some benefit from the excision of the inelastic dysgenic tissue but are rarely straight and often require further maneuvers to straighten the penis. An artificial erection is repeated after this, and if straight, the skin is closed and the procedure is terminated (Fig. 74.3).

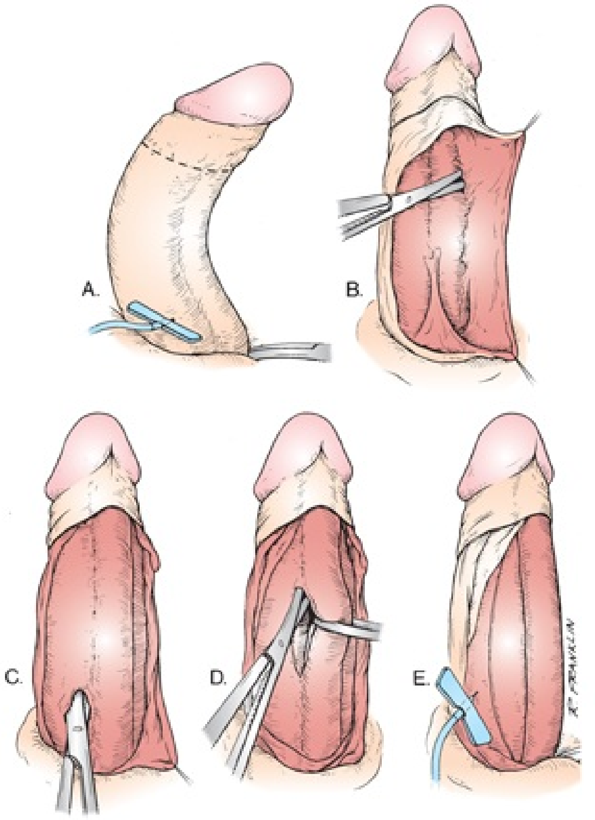

FIGURE 74.3 Surgery for chordee without hypospadias. A: Ventral curvature demonstrated with artificial erection. B: Dysgenic dartos fascia is elevated and will be excised. C: The dysgenic layer of the Buck fascia is undermined by spreading the scissors. D: The inelastic fascia is excised as the corpus spongiosum and urethra are mobilized. E: Artificial erection demonstrates correction of the curvature.

Further options to straighten the penis are to either lengthen the short side with incisions and grafts or to shorten the long side with excisions and/or incisions and plication. In many of these patients, penile length is not a major issue, and as such, we usually choose to excise and perform plications. The patients recover from plication procedures more quickly, and graft take is not an issue. Although rare, there is a possibility to induce veno-occlusive dysfunction with dermal grafts (Fig. 74.4).

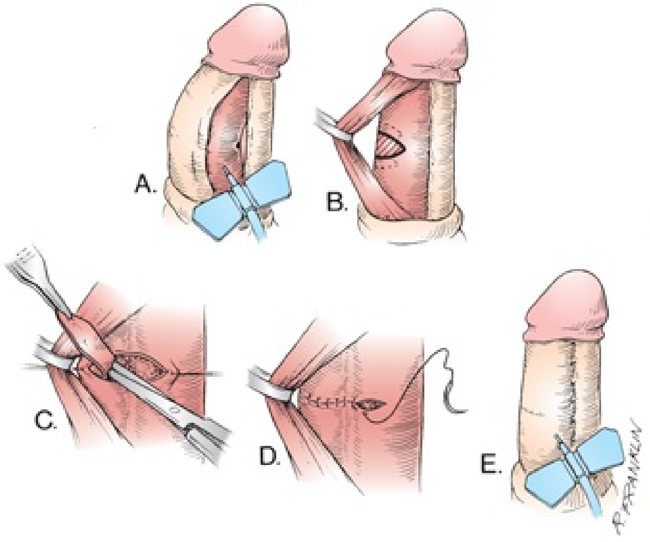

FIGURE 74.4 Surgery for chordee without hypospadias. A: A circumcision incision has been made and the urethra has been mobilized by resecting the dartos and Buck fasciae. The needle is in place for an artificial erection. The erection shows continuing chordee. The elastic urethra is not the cause of this curvature. The point of maximum concavity has been marked. B: An ellipse of tissue is outlined opposite the point of maximum concavity. As an alternative, two smaller ellipses are shown. C: Excision of the ellipse of tunica. Note the tips of the septal strands in the midline. D: Closure of the edges of the incision. E: Artificial erection revealing a straight penis. When the bend is more complex, ellipses must be excised in other locations. (Reprinted with permission from Devine CJ Jr, Horton CE. Bent penis. *Semin Urol* 1987;5:4. Copyright © 1987 Elsevier Inc.)

Once it has been determined to proceed with excision of tunica and dorsal plication, the Buck fascia is elevated, incorporating the neurovascular structures via one of two techniques. One approach is to start on the lateral aspect of the corpus spongiosum and carry the fascial elevation around to the dorsum of the penis. The alternative approach is to excise the deep dorsal vein and approach the tunica from the dorsal midline (Fig. 74.5). This approach requires excision of the dorsal vein and elevation of the inner layer of the Buck fascia off the tunica, including the dorsal neurovascular structures. This dissection is carried laterally and ventrally to the corpus spongiosum

(Fig. 74.6).

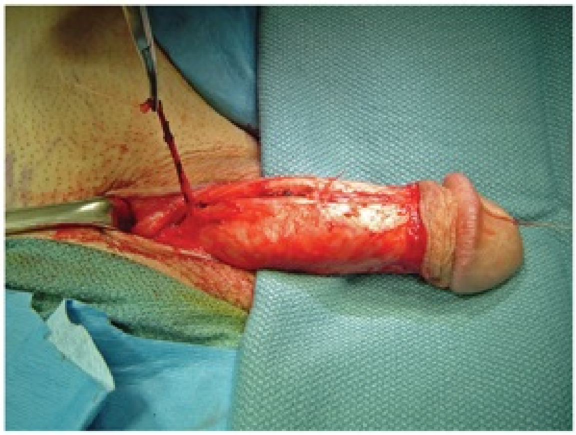

FIGURE 74.5 Dissection and ligation of the dorsal vein allows access to the plane between the tunica and the Buck fascia so that the dorsal neurovascular bundle may be mobilized.

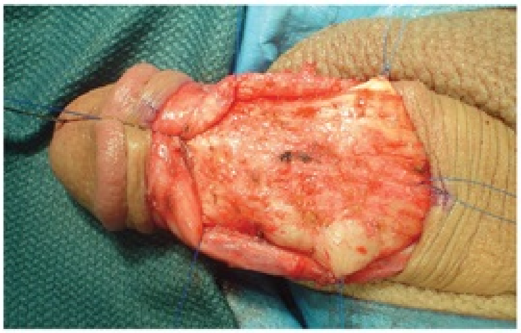

FIGURE 74.6 Dissection of the dorsal neurovascular bundles allows visualization of the tunica for straightening procedures. Stay sutures have been placed to elevate the tunica and retract the neurovascular bundles facilitating the excision and plication procedure.

After one of the earlier mentioned dissections is performed, an artificial erection is again performed and the point of maximal curvature identified. We mark this location with a suture that is later removed after penile straightening. The proposed areas of ellipse excision are identified and marked bilaterally. Matching excisions should be performed on each side unless lateral curvature is noted. In this case, excisions may need to be asymmetric. Edges of the planned ellipses are opposed with a 3-0 polypropylene (Prolene) suture or an Allis clamp, and a repeat artificial erection is performed. If this demonstrates adequate straightening, the edges are marked and the suture or clamp is removed. The ellipse of tunica is excised using a sharp no. 11 blade scalpel. The underlying erectile tissue is left undisturbed by staying in the space of Smith. Watertight closure is performed with interrupted 4-0 or 5-0 polydioxanone suture (PDS). An artificial erection is performed after each ellipse is excised and closed to determine results. If the penis is not straight, further ellipses are excised to straighten it. Many variations of the excision and plication procedure have been described. These include removing only the superficial layer of the tunica (3) or burying the tunical tissue instead of removing it (4).

Once straight, the Buck fascia is closed to prevent the dartos fascia from adhering to the tunica. Care should be taken not to entrap the dorsal neurovascular bundle with the closure sutures. Two small suction drains are placed. Usually, one drain is placed deep to and one superficial to the Buck fascia. The skin is reapproximated with a 4-0 Vicryl suture, and a small Foley catheter is placed overnight. A bio-occlusive dressing is placed. The Foley catheter is removed on postoperative day 1. One drain is removed in the morning as well, and if output is low, the other is removed that afternoon and the patient is discharged from the hospital.

Patients with lateral curvature usually have associated ventral curvature or rarely dorsal curvature. On occasion, patients with lateral curvature may have isolated lateral curvature, and in these patients, correction can be approached through a small incision at the maximal point of curvature. Preoperative pictures are extremely important in aiding detection of purely lateral curvature and when suspected an artificial erection prior to penile degloving will verify. After an artificial erection is obtained, the point of maximal curvature is identified and a small incision is made on the contralateral side of the maximal convexity. This allows for minimal dissection of the dorsal neurovascular structures. After 3-0 Prolene sutures or an Allis clamp are placed, an artificial erection is performed; if straight, ellipses are excised and closed as previously discussed (Fig. 74.7).

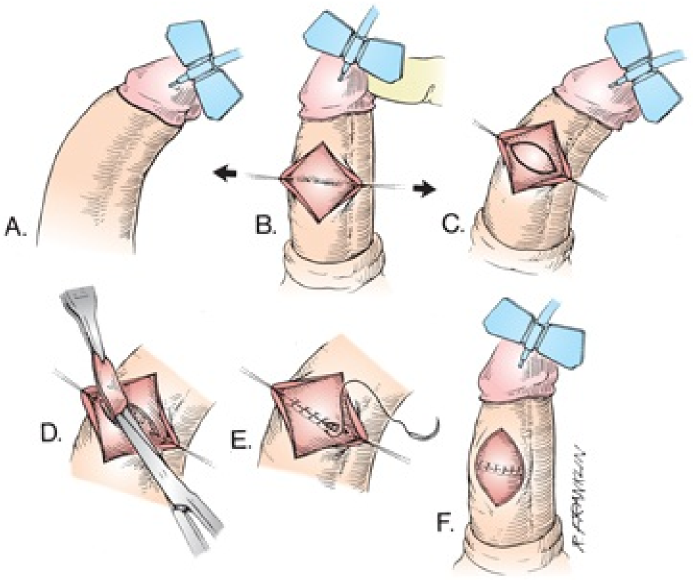

FIGURE 74.7 Congenital lateral curvature. A: An artificial erection reveals the curvature. The incision to gain access to the potential ellipse of tissue is marked. B: The tunica albuginea has been exposed by mobilizing the Buck fascia, and Prolene sutures have been placed at the dorsal and ventral tips of the potential ellipse. While maintaining the artificial erection, tension is established on the two sutures as the penile shaft is straightened. The fold produced in the tunica is marked. C: When the penis is relaxed, this mark defines the ellipse of tunica to be removed. D: The tunica is excised. E: The edges are approximated. F: The penis is straight. The Buck fascia and the skin are closed.

Although uncommon, congenital dorsal curvature is usually approached through a ventral midline incision. The corpus spongiosum is partially mobilized so that small incisions in the corpora can be placed just lateral to the ventral midline. The techniques used are those previously described, and the postoperative course is similar to that of the patient with ventral curve.

Although the use of absorbable and nonabsorbable suture has been described for penile straightening procedures, we prefer PDS as described earlier. This allows an absorbable suture that will also tolerate the pressure of any spontaneous postoperative erections. Although we routinely suppress postoperative erections using diazepam and amyl nitrate, this population usually has very good erectile function and spontaneous erections do occur. Avoidance of nonabsorbable suture may lessen the incidence of long-term palpable suture complaints (5).

Yachia Longitudinal Plication

Other techniques have been described for the repair of congenital curvature. Yachia (6,7) described a plication procedure using longitudinal incisions in the tunica albuginea that are closed transversely. This applies the Heineke-Mikulicz concept to penile curvature correction. The long side is therefore plicated without excising tunica. The procedure is similar to that previously described, with an incision through the previous circumcision scar and complete mobilization (Fig. 74.8).

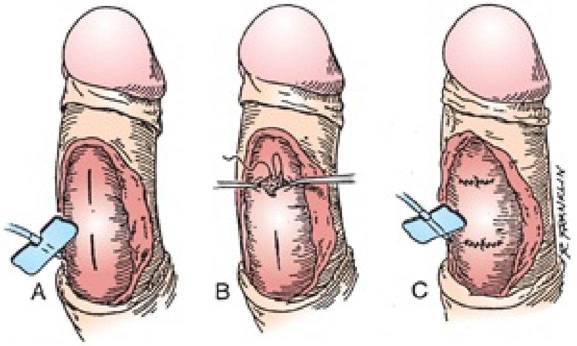

FIGURE 74.8 Technique after Yachia for correction of curvature, in this case, a patient with congenital lateral curvature. **A:** The Buck fascia is reflected, exposing the lateral tunica albuginea. **B:** Longitudinal incisions are created at the area of maximal curvature as demonstrated by artificial erection. **C:** The longitudinal closures are closed transversely, with artificial erection demonstrating good straightening of the penis.

Multiple Parallel Plication

Multiple parallel plication (MPP) is another technique described for the repair of congenital curvature of the penis without any tunical excision (8). In the original description, a pharmacologic agent is used to induce an erection. A circumcising incision is performed, the penis is degloved, and the dorsal vein and arteries are identified. The dorsal neurovascular bundle does not need to be dissected. Using four to six nonabsorbable 3-0 braided sutures, multiple deep plication sutures are placed into the tunica albuginea at the point of maximal curvature. These are placed between the deep dorsal artery and vein. Some of these sutures may not be fully tied down to prevent overcorrection. For patients with lateral or ventrolateral curvature, the sutures are placed more laterally using the same vertical orientation. When the patient has dorsal curvature, a midline ventral incision is made and the sutures are placed just lateral to the unmobilized corpus spongiosum.

Penile Disassembly

Perovic et al. (9) proposed a penile disassembly technique to avoid the penile shortening seen with the plication procedures. This technique requires complete disassembly of the penis into its component parts, these being the glans cap with its neurovascular bundle dorsally, the urethra ventrally, and the corporal bodies. Unfortunately, this technique only straightened the penis satisfactorily in 68% of patients, and on occasion, a plication procedure was still required.

Surgical Technique—Chordee without Hypospadias

The corpus spongiosum is rarely the limiting factor in these patients, even if they appear to have obvious abnormalities. The curvature in these patients is mainly due to the inelasticity of the ventral aspect of the corporal bodies. After the dysgenic tissue is excised, straightening is usually accomplished (10). After an artificial erection is obtained, any residual chordee can be corrected with a small incision in the ventral midline of the corporal bodies. The erectile tissue is not entered with this incision, and this allows the ventral tunica to move laterally, thus straightening the penis. If this is unsuccessful, the dorsal neurovascular structures are mobilized and a small ellipse of tunica is excised and closed as discussed earlier.

Some advocate the use of dermal grafts for patients with chordee without hypospadias, especially in those patients with severe chordee or those with a smaller-than-average penis. This approach avoids the shortening observed with the plication procedures but may increase the rate of complications. The major concern with placing a dermal graft is the risk of veno-occlusive dysfunction. Grafting the corpora cavernosa in any patient has the potential for creating erectile dysfunction and is a known complication when using dermis in adult patients with Peyronie disease. The majority of patients seeking surgery for congenital curvature are young adults, and the occurrence of erectile dysfunction can be devastating. It is thought that the pediatric patient may not develop veno-occlusive dysfunction because no tunica is excised and a much smaller graft is used than in the adult. No long-term studies have been published following these patients into adult life to determine the risk.

OUTCOMES

Complications

Surgical complications associated with congenital penile curvature surgery are relatively rare. This is in general a healthy population of patients. Some degree of penile ecchymosis is normal and is reduced by attention to hemostasis and the placement of suction drains. Complaints of penile shortening and penile irregularity from suture sites predominate. There are also complaints of suture granuloma and sometimes pain at the plication site. Temporary loss of glans sensation has been reported and can be expected due to traction on the neurovascular bundle. There is, however, one report of a patient with permanent loss of sensation. Postoperative erectile dysfunction is extremely rare because these patients usually have excellent preoperative erectile function. There is one reported case of penile necrosis secondary to a tourniquet which, as noted, we do not recommend using.

Results

The reported success rates of the Nesbitt, Yachia, and incision/ plication surgical procedures vary from 85% to 100% (11). Eight percent of MPP patients were satisfied with their correction, although two of the eight had to undergo a second procedure to correct a residual 15% curvature. All patients did notice the sutures, but only one considered them bothersome.

CHAPTER 75 ILEAL CONDUIT URINARY DIVERSION

SAMUEL C. HAYWOOD AND ERIC A. KLEIN

Despite the established role of continent catheterizable and orthotopic voiding urinary diversion techniques, the ileal conduit remains the most common form of urinary diversion performed worldwide. The operation, first popularized by Bricker, maintains this popularity in large part because of its applicability to a wide variety of urologic disorders, its tolerability in patients with often significant comorbidities, and its adaptability to almost all patients' anatomic constraints.

DIAGNOSIS

The ileal conduit may be constructed as part of a reconstruction following extirpative pelvic surgery, such as radical or simple cystectomy and pelvic exenteration, or as a diversion with the bladder left in situ, such as in cases of neuropathic bladder refractory to conservative management. The clinical evaluation in these patients is therefore directed to their specific bladder pathology.

INDICATIONS FOR SURGERY

Before choosing an ileal conduit, patients should be counseled on all forms of diversion. Comorbidities such as renal insufficiency (serum creatinine >1.5 mg per dL or glomerular filtration rate <50 mL per minute), bowel disease (inflammatory or malignant), extreme obesity, or neurologic illness that prevents the ability to perform self-catheterization may make incontinent diversion a wise choice. Although it was suggested in the past that patients with cardiovascular/pulmonary disease or advanced age may do better with the shorter, simpler conduit diversions, newer evidence suggests that perioperative morbidity is equivalent with conduit and continent diversions (1,2).

ALTERNATIVE THERAPY

Continent catheterizable or orthotopic voiding diversions are the most common alternatives to conduit diversion. In addition, choices exist within incontinent diversion with respect to bowel segment (ileum, jejunum, stomach, and colon) and/or the type of ureteroenteric anastomosis (refluxing versus nonrefluxing). Conduits from nonileal bowel may be associated with higher metabolic complications but may be the only option in some patients. Further, the ability to accommodate nonrefluxing anastomosis in colonic conduits may protect kidney function and be preferable in children or adults with long life expectancy. Additional types of diversion are described elsewhere in the text. Patients undergoing concurrent pelvic exenteration are presented with additional options, including sigmoid conduits with transverse colostomy to avoid bowel anastomosis or the use of the double-barrel wet colostomy to drain both the fecal and urinary streams through a single tract.

Other potential urinary diversions include an ileovesicostomy, which can be used in benign disease to avoid complications associated with ureteral mobilization and anastomosis. Finally, patients with limited life expectancy may be considered for percutaneous nephrostomy tubes.

SURGICAL TECHNIQUE

Traditionally, surgical pathways for ileal conduit diversion have included preoperative bowel preparation. More recently, however, studies have shown that omission of this step may be done without adverse outcomes, including gastrointestinal or infectious complications (3,4). Broad-spectrum antibiotics are given at the time of surgery. The stoma site should be selected after examining the patient in the supine, seated, and standing positions. To best accommodate an appliance, the site should not be too near the anterior superior iliac spine, costal margin, umbilicus, surgical scars, or skin folds. The usual ideal location is just medial to the linea semilunaris, approximately one-third of the distance on a line between the umbilicus and the anterior superior iliac spine.

Markedly obese patients may require a higher site to allow them to perform stoma care under direct vision. In instances where there is a question regarding the ideal stoma site, ambulatory trials of pouching candidate sites or preoperative consultation with enterostomal therapy (where available) can help determine the optimal location.

The increasing prevalence of laparoscopy and robotics in pelvic surgery has led to the development of techniques using these for creation of the ileal conduit. Traditionally, creation of the urinary diversion had occurred extracorporeally after completing the laparoscopic portion of the case (as in radical cystectomy), but improvements in technique have allowed creation of urinary diversions completely intracorporeally. Initial reports of intracorporeal ileal conduit creation demonstrated this procedure to be both reasonable and safe (5). More mature data has compared the intracorporeal and extracorporeal diversions (both continent and incontinent) with respect to patient outcomes. The data showed similar operative times and reoperation rates and further suggested decreased complication rates among patients with intracorporeal diversions (6). Despite this, it should be noted that open approach to urinary diversion remains the standard of care given the surgical expertise required as well as lack of prospective data evaluating the minimally invasive approach and as such will be the procedure described in the following text. Further, associated procedures such as radical cystectomy require a minilaparotomy incision for specimen extraction limiting the benefits of completely intracorporeal diversion. Detailed techniques for intracorporeal creation of ileal conduit exist in the literature (7).

A low midline incision extending from just below the umbilicus down to the symphysis pubica allows for exposure of the bladder for cystectomy as well as bowel exposure for the conduit portion of the procedure. The patient is positioned supine. A Bookwalter-type retractor may be used to retract the bowel from the cystectomy field, and then the blades may be repositioned on the abdominal wall for the conduit procedure. The posterior peritoneum is incised at the pelvic inlet above the iliac vessels, where the ureter can be found coursing over the vessels. The ureters are then dissected with care distally and transected as close to the bladder as possible. A lesser degree of proximal mobilization is also usually necessary. During mobilization of the ureter, care should be taken to maintain its blood supply by leaving a generous amount of periureteral soft tissue. The distal ends of the ureters may be clipped to allow dilatation while the ileal conduit is harvested and prepared.

The terminal ileum is then identified and examined. If signs of inflammatory bowel disease, radiation changes, or insufficient mesenteric length are not present, then this segment is in general preferred for conduit formation. The mesentery is examined by transillumination, and the watershed area between the ileocolic artery and the right colic artery is selected for the distal mesenteric incision. This is typically located 20 to 25 cm proximal from the ileocecal valve, and the preservation of this length of terminal ileum suffices to maintain bile salt and vitamin B_{12} absorption. The bowel incision is continued proximally into the mesentery to allow the distal end to reach the stoma site without tension. Figure 75.1 demonstrates the isolation of the ileal segment.

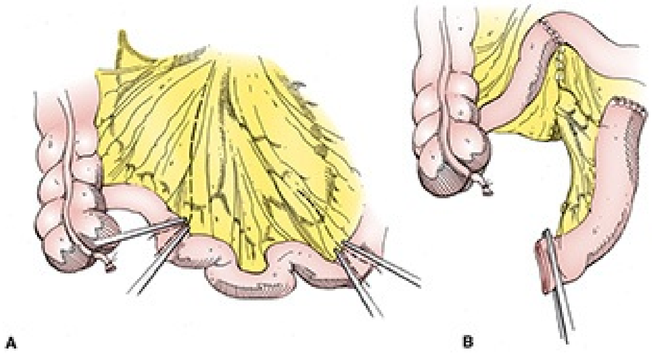

FIGURE 75.1 **A:** The ideal segment of bowel for the ileal conduit spares the terminal 10 to 20 cm of ileum and should require minimal ligation of mesenteric vessels to harvest. **B:** Once isolated, the conduit mesentery is positioned caudal to the bowel mesentery, which is reapproximated with a running silk suture.

The mesentery is again transilluminated, and a relatively avascular site is selected for the proximal incision. The optimal length of the conduit differs from patient to patient due to differences in body habitus and the degree of ureteral mobilization. The longest length of conduit should not exceed the distance between the sacral promontory and the stoma site; usually, if there is adequate left ureteral mobilization, a shorter length than this is optimal. If there is any question regarding the length, one should err on the longer side, as redundant conduit is much easier than insufficient conduit to treat intraoperatively. The conduit and its mesentery are positioned caudal to the rejoined bowel and its mesentery.

Standard hand-sewn or staple techniques are then performed to reestablish bowel continuity. The mesenteric window is also closed with a shallow running suture to prevent internal bowel herniation. Care should be taken during closure of the mesenteric window to avoid ligation of the ileal blood supply, which might compromise the healing of the anastomosis. Sterile towels are placed beneath the isolated ileal conduit, which is irrigated free of enteric contents with an antibiotic solution.

At this point in the procedure, either stoma formation or ureteroenteric anastomosis can be performed. This choice is based on surgeon preference. If ureteral stents are to be used, performing the ureteroileal anastomosis first allows for easier antegrade passage of the stent out of the distal end of the conduit. Creating the stoma first provides for more optimal localization of the ureteroileal anastomotic sites and helps direct the optimal level of the sigmoid mesentery through which the left ureter should be passed.

Construction of the stoma begins with the excision of a circular plug of skin around the preselected stoma site. Dissection is carried down to the anterior rectus sheath, and a cruciate incision is made in this layer. The posterior rectus sheath and rectus muscle are bluntly dissected after taking care to avoid the epigastric vessels. This dissection may be accomplished with a Kelly clamp, which then may be spread to create a hiatus for the conduit to pass through the abdominal wall. Traditionally, creating a hiatus approximately two fingerbreadths wide has been considered ideal to prevent compromise of mesenteric blood flow to the stoma. However, the rate of parastomal hernias in this population has been high, especially in obese patients (8). Ultimately, the size of the hiatus should depend intraoperatively on the width of the conduit. Creating a narrow passage will increase the risk of stomal stenosis, stomal retraction, or compromise of the blood supply. Conversely, a wide hiatus will predispose toward hernia and prolapse (9). To decrease the risk of parastomal hernia, the posterior rectus sheath is fixed with four separate sutures to the ileal conduit in order to prevent a sliding hernia.

In the standard end stoma (“rosebud”) technique, the efferent end of the conduit is grasped and pulled through the abdominal wall defect until the end is 2 to 3 cm above the skin surface. Each of the four tabs of the cruciate incision is then sutured to the bowel serosa, taking care not to pass sutures through the bowel mesentery. Absorbable sutures are then passed through the mucosal edge of the bowel, then the bowel serosa and muscularis deep to the skin edge, and finally through the dermal tissue just deep to the skin edge. Care is taken not to suture the bowel mucosa to the epidermis, as this can lead to mucosal rests that complicate pouching of the stoma. Figure 75.2 shows the technique of suture placement for the end stoma. Four quadrant sutures placed in this manner usually suffice to evert the stoma; additional sutures may be placed for reinforcement.

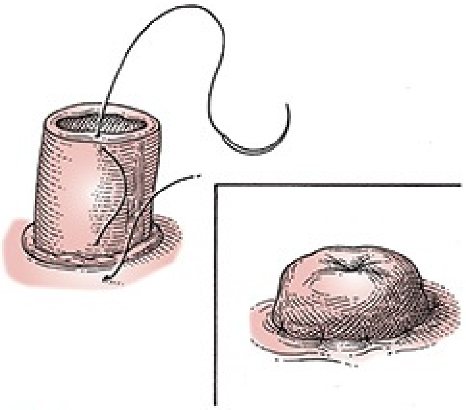

FIGURE 75.2 The end stoma (“rosebud”) is everted by passing sutures first through a full-thickness bite at the cut edge, then through the bowel serosa at the skin level, and finally through the dermis.

In obese patients or patients with a short mesentery, a Turnbull loop stoma should be considered. The distal end of the loop is closed with absorbable sutures (if the GIA stapler was used to harvest bowel, no additional closure is needed). An umbilical tape is passed through the mesentery at its border, with the ileum about 3 cm proximal to the end of the conduit. The tape is then grasped and pulled through the abdominal wall defect. A stomal rod is in general passed through the umbilical tape defect to prevent stomal retraction; this is then sutured in place and left in for 1 to 2 weeks. The blind end of the loop is positioned cephalad, and the loop is opened transversely nearer to the distal limb. The stoma is then matured using eversion sutures in the same manner described for the rosebud stoma. The technique for end-loop stoma formation is detailed in Figure 75.3.

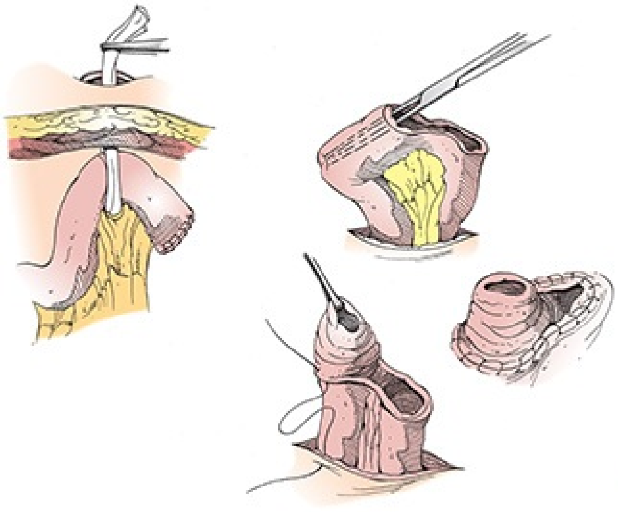

FIGURE 75.3 Creation of the end-loop stoma. The defunctionalized limb is positioned cephalad.

A long-term follow-up study comparing the results of loop versus end stoma revealed no major differences in outcome. Patients with an end stoma had slightly more ischemic complications, while those with the loop stoma required more frequent repair of parastomal hernias, presumably due to the need for a wider aperture in the abdominal wall (10).

Principles to consider in the creation of the ureteroenteric anastomoses include the maintenance of an adequate distal ureteral blood supply, the avoidance of tension on the anastomosis, the documentation of malignancy-free status in the distal ureter (if the diversion is performed for cancer), and the avoidance of ureteral kinking. Although more common with colonic anastomosis, nonrefluxing ureteroileal anastomoses have been described in the literature (11). The benefits of a nonrefluxing system have not been definitively shown, and the higher rate of anastomotic stricture and inability to use the loopogram study to evaluate the upper tracts limits the usefulness of this approach. Therefore, the freely refluxing end-to-side (Bricker) and conjoined end-to-end (Wallace) techniques remain the most commonly performed and recommended techniques.

In the Bricker technique, the proximal end of the conduit is either left closed if staples were used in the bowel harvest or closed in two layers with absorbable sutures. The left ureter is passed through a hole created in the sigmoid mesocolon. This hole is typically created at the level of the sacral promontory but may be moved cephalad or caudally to avoid ureteral kinking. A site on the conduit where the ureter lies naturally is incised down to the submucosal layer. The submucosa is grasped with forceps, and a small portion is excised along with its mucosa. The ureter is then spatulated, and a single-layer full-thickness anastomosis is performed with 4-0 or 5-0 interrupted absorbable sutures. Prior to closing the anastomosis, silicone ureteral stents may be placed; these can be guided in through the stoma using a Kelly clamp or a suction tip. Anchoring sutures through the ureteral adventitia and the bowel serosa may be placed 1 to 2 cm proximal to the anastomosis. Figure 75.4 demonstrates the ideal locations of the ureteroenteric anastomoses using the Bricker technique.

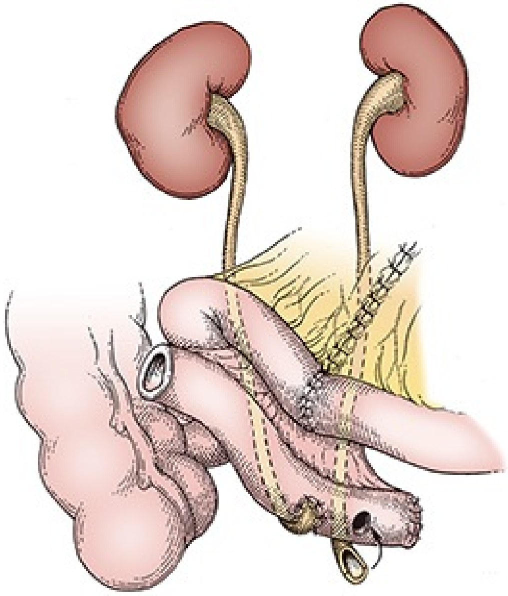

FIGURE 75.4 Ideal placement of the vesicoenteric anastomoses using the Bricker technique. The spatulated ureters should pass under the conduit and lie without tension or kinking.

The Wallace technique involves leaving the proximal end of the conduit open. The ureters are spatulated for a distance slightly greater than the conduit diameter. The posterior edges may be joined side-by-side or end-to-end using two running 4-0 absorbable sutures. One suture is then used to join the back walls of the conjoined ureters and the conduit, after which the anterior walls are closed. The side-to-side Wallace technique is detailed in Figure 75.5. Stents may be passed prior to closure of the anterior wall. This technique allows for the rapid creation of a widely patent ureteroileal anastomosis. However, disadvantages of this technique are that a process creating obstruction of one ureter (recurrent malignancy, anastomotic stricture) is more likely to cause bilateral obstruction and that retrograde investigations may be more difficult secondary to the right angle insertion of the ureters to the conduit. Further, a procedure to treat recurrent malignancy such as a nephroureterectomy requires additional anastomosis of the contralateral ureter.

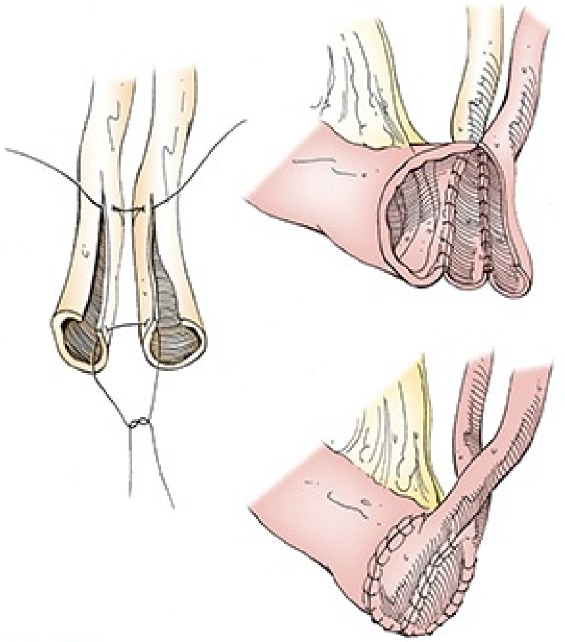

FIGURE 75.5 The side-to-side Wallace technique creates a widely patent vesicoenteric anastomosis at the "butt" end of the conduit.

After performing the ureteroileal anastomosis, the proximal end of the conduit is retroperitonealized by sewing the cut edges of the peritoneum to the conduit. Closed-suction drains (Jackson-Pratt type) are placed in the area of the ureteroileal anastomoses and maintained for the first few postoperative days.

The return of bowel function is the major determinant of the length of the postoperative hospital stay; this is evidenced by similar lengths of hospitalization for urinary diversion procedures with and without cystectomy. Most patients can expect a hospital stay of 4 to 7 days in centers with well-defined clinical pathways (12). Nasogastric decompression is optional. Some surgeons routinely use decompression for all postoperative patients, although more recent data suggests that early removal (13) or completely omitting nasogastric tube (14) may not prolong bowel recovery. The conduit also experiences an ileus, and its return of peristalsis parallels that of the small bowel; therefore, some surgeons advocate placement of a cut Foley or Rob-Nel catheter to promote conduit drainage in the first few postoperative days. There is no consensus regarding the need for ureteral stenting, although some reports suggest improved outcomes using stents (15). Timing of stent removal is left to the discretion of the surgeon, although it is recommended to remove them as early as possible after bowel function returns.

There is no consensus for the optimal length of ureteral stenting (if it is performed at all); the timing of stent removal is left to the discretion of the surgeon. Jackson-Pratt drains are left in place until the drainage is negligible; if drainage persists at high levels several days postoperatively, the drain fluid should be sent for creatinine analysis to rule out a urine leak. If a rod is left under the stoma, this may be removed prior to discharge.

Counseling and teaching by the enterostomal therapist should begin in the preoperative period and continue during the hospitalization. The patient or his or her caregivers should be competent in all aspects of stoma care prior to discharge. Ideally, the patient should be able to take care of the stoma personally to avoid undue dependency on caregivers. Follow-up care is tailored to the individual patient; in most cases, a periodic serum renal profile is indicated. The upper tracts can be assessed via a loopogram, avoiding the toxicity of intravenous contrast agents.

OUTCOMES

Complications

The mortality rates for cystectomy and diversion have steadily decreased since initial implementation. Nationwide, mortality averages approximately 2% (16), although in high-volume centers rates as low as 0.3% have been reported (17).

The most common morbidity causing prolonged hospital stay is ileus (17). This usually resolves quickly with nasogastric decompression; failure to do so after a few days should prompt a diagnostic workup for bowel obstruction. Urine leak at the ureteroileal anastomosis or from the conduit closure and urosepsis are the most common urologic complications of the procedure. Urine leaks can usually be managed successfully with placement of an abdominal drain and percutaneous nephrostomy diversion.

Late complications of ileal conduits are common but usually not severe. Stomal stenosis has been reported in 8% to 29% of ileal conduits (18,19); proper stoma construction can decrease this incidence. Flush stomas are more likely to shrink and become stenotic as compared to the rosebud technique. Definitive treatment includes removal or partial resection of conduit. Parastomal hernias have been reported in 14% of patients with obesity as an independent risk factor (8); stoma relocation may be superior to fascial repair in these cases. Hyperchloremic metabolic acidosis can occur but is rare in well-functioning conduit; the presence of more than a mild acidosis should prompt an evaluation for obstruction or redundancy of the conduit. Alkalinizing agents (sodium bicarbonate) or chloride transport blockers (chlorpromazine, nicotinic acid) can effectively treat this acidosis.

Ureteroileal anastomotic strictures are also uncommon (about 6% in older series); these can be successfully managed with endourologic balloon dilation or cold knife incision (about a 50% success rate), with open surgical repair (76% long-term success), or chronic ureteral stents (18). Notably, the use of minimally invasive techniques should be limited to short strictures; open repair should be used for longer strictures. Both the Wallace and Bricker style of anastomosis have acceptably low stricture rates; there has been some suggestion of lower stricture rate in the Wallace (20).

Acute pyelonephritis occurs commonly in patients with ileal conduits (18% of patients). Indeed, bacteriuria can be found in up to three-fourths of ileal conduit urine specimens (21). Most of these can be safely observed without treatment, as patients seem to tolerate this chronic colonization well, and few progress to acute pyelonephritis. Infections with *Proteus* or *Pseudomonas* are associated with deterioration of the upper tracts and should therefore be treated.

Deterioration in renal function occurs in a significant portion of patients undergoing conduit diversion; over the long term, 50% of patients have radiographic evidence of functional deterioration at 15-year follow-up, and up to 7% of patients can develop renal failure requiring dialysis (21). Renal function should be monitored periodically, and declines in function should alert the clinician to examine for correctable causes of renal dysfunction.

Results

The ileal conduit has provided reliable urinary diversion for patients with a variety of underlying illnesses for over 50 years. Continent catheterizable diversions and orthotopic neobladders continue to gain acceptance, and recent studies have focused on quality-of-life outcomes after continent and incontinent diversions. The existing evidence has not definitively shown superiority of continent diversion options over conduit diversion with respect to quality of life measures (22). Unfortunately, as younger, thinner, and healthier patients undergo continent diversion while older and more frail patients undergo ileal conduit, a real comparison of the quality of life after these procedures will likely never be possible. Still, it is clear that ileal conduit is a simple form of diversion that is well tolerated by most patients and has fewer contraindications than continent diversions. These factors make it likely that the ileal conduit will continue to play a major role in many urologists' practices.

SECTION VII ■ URINARY DIVERSION

Section Editor: URS E. STUDER

CHAPTER 76 ■ TRANSVERSE COLONIC CONDUIT

MICHAEL RINK AND MARGIT FISCH

J. H. Nelson was the first to describe the high rate of early and late complications using irradiated small intestine for urinary diversion. Subsequently, he described the technique of the transverse colonic conduit in 1969 for the first time (1). Since the first publication, the transverse colonic conduit has been more used with increasing frequency in patients with urologic or gynecologic malignancy who have been treated with radiotherapy (2–7). The anatomic origin of the transverse colon in the upper abdomen close to kidneys and renal pelvises distinguishes this bowel segment from the small intestine or other colonic segments elucidating its obvious advantages for certain urinary diversion indications. With its cranial position outside of the pelvic irradiation field, it fulfills the demand to be nonirradiated, which is of utmost importance for a segment to be used for urinary diversion. Nonirradiated bowel segments offer less risk for postoperative urinary leaks and small bowel complications associated with bowel and ureteral anastomoses (3).

Not only the transverse segment but also the ascending and descending colon can be used, which offers an adaptation to the individual patient's situation. The long mesentery enables individual adaptation with positioning of the stoma either to the left or right upper abdomen. There are no limitations with regard to short ureters. The segment offers the feasibility for nonrefluxing as well as refluxing ureteral implantation (8–10). Colonic stomas usually are also less prone to stoma stenosis compared to the ileum.

In patients with total damage of the ureters by irradiation or retroperitoneal fibrosis and in patients with recurrent urothelial tumors (11), a direct anastomosis of the conduit to the renal pelvis represents an option (pyelotransverse pyelocutaneostomy) (12).

INDICATIONS

Indications for Surgery

The foremost indication for transverse colonic conduit is urinary diversion in patients with urologic/gynecologic malignancies and irradiation damage of bowel and distal ureters. Further indications comprise urinary incontinence in patients with radiation cystitis, complex vesicovaginal and rectovesicovaginal fistulae after irradiation, recurrent retroperitoneal fibrosis, Crohn disease, and unsuccessful primary urinary diversion requiring conversion. Complex cases of prostate cancer with a history of irradiation or brachytherapy and recurrent stenosis of the posterior urethra and/or fistula formation in addition to a small bladder capacity represent a rare indication. In patients with recurrent urothelial tumors of the ureters, a direct anastomosis of a conduit to the renal pelvises allows direct endoscopic access to the calices.

Contraindications for Surgery

Absolute contraindications for the transverse colonic conduit are irradiation of the upper abdomen, status post extensive colon resection, and ulcerative colitis. In addition, the use of colonic bowel segments should be considered carefully in patients with inflammatory large bowel disease and chronic diarrhea.

DIAGNOSIS

Preoperative Examinations

For upper urinary tract evaluation, an intravenous urography should be performed preoperatively. Nowadays, intravenous urography often is replaced by computerized tomography (CT) with urographic imaging. However, intravenous urography offers the advantage of being diagnostic and functional and may be considered in addition to CT.

Bowel imaging with water-soluble contrast media or colonoscopy should be performed preoperatively to exclude polyps or diverticula.

Patient Preparation

Nowadays, bowel preparation before urinary diversion is debatable, particularly in ileal diversions. For elective colorectal surgery, mechanical bowel preparation has been practiced as a clinical routine for many decades. However, contemporary randomized clinical trials and meta-analyses found no strong evidence supporting the use mechanical bowel preparation for elective colorectal surgery (13). Yet, the authors of this chapter recommend some type of bowel preparation prior to elective colonic surgery to reduce the stool burden. This may facilitate surgery and potentially avoid postoperative complications.

Finding the best localization of the stoma is an integral part of the preoperative preparation and of critical importance regarding avoidance of postoperative difficulties with stoma accessories, thus improving the patients' quality of life. Marking the site of the stoma should be done in cooperation between urologists and stoma therapists. To achieve best results, the stoma should be placed in an area free of scars or skin folds. The best position is in the epigastric region; the attached stoma plate has to be checked in sitting, lying, and standing positions of the patient. The patient should wear the stoma bag for several hours up to a day prior to surgery to figure out difficulties with the marked and designated location.

Intraoperatively, broad-spectrum antibiotics such as cephalosporins often in combination with metronidazole are usually given.

ALTERNATIVE THERAPY

A continent, cutaneous colon transverse pouch represents an alternative in young and healthy patients capable for catheterization (14).

SURGICAL TECHNIQUE

Instruments required include a basic kidney set with additional instruments for intra-abdominal surgery, an abdominal retractor, suction, and a basin containing prepared iodine solution for disinfection. As suture material, absorbable monofilament sutures such as polyglycolic acid 4-0 are used for closure of the conduit and intestinal anastomosis to reestablish bowel continuity as well as creation of the stoma. The ureters are implanted using 5-0 and 6-0 sutures. Intraoperatively, a gastric tube (alternatively gastrostomy) and a central venous catheter are placed.

Access is gained by median laparotomy. Both ureters are identified as they cross over the iliac vessels and dissected in the cranial direction. The dissection toward the bladder descends until the irradiated level is reached. The ureters are cut above the irradiated field where they show good vascularization. There should be capillary arterial bleeding from the ureteral wall and spontaneous urine efflux. The ureteral stump is ligated, and the cranial end is marked by a stay suture. Depending on the remaining length of the ureters, it is decided which one can be brought to the opposite side by a retromesenteric pull-through. The retromesenteric entrance should be wide enough, and the path of the ureter slightly curved in order not to angle or compress it.

A bowel segment of approximately 15 cm in length in patients with normal weight is selected respecting the course of the vessels (Fig. 76.1). The length of the segment depends on the thickness of abdominal wall. Stay sutures outline the segment. Bowel mobilization differs depending on the segment chosen: If the ascending segment is selected, the right colonic flexure is mobilized. The greater omentum is separated from the transverse colon over a distance of 10 to 15 cm starting at the right side. When the descending colon is chosen, the left colonic flexure has to be mobilized and the left part of the omentum has to be separated from the transverse colon. The selection of a transverse colonic segment makes mobilization of both the right and left flexure necessary as well as a complete separation of the greater omentum from the transverse colon.

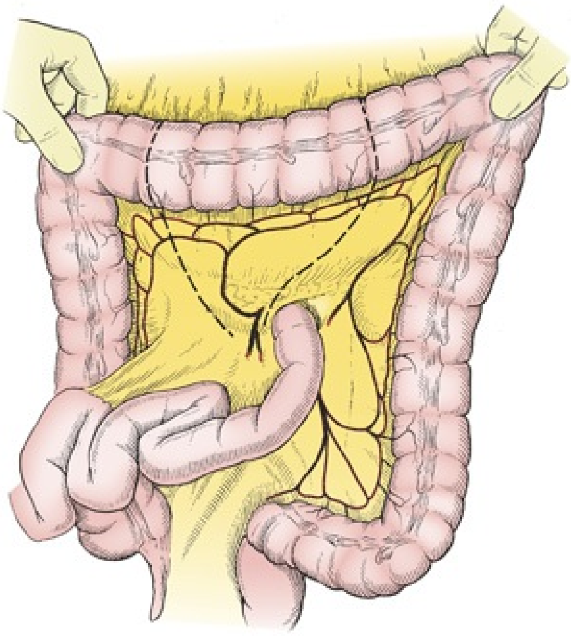

FIGURE 76.1 A bowel segment of approximately 15 cm in length in patients with normal weight is selected, respecting the course of the vessels.

The mesentery of the selected segment is incised lateral to the supplying artery, and the arcade is divided between mosquito clamps and ligated. The fat is dissected from the seromuscularis of the bowel in the area where the segment will be cut and bleeding vessels are coagulated. The segment is isolated without the use of clamps with the result that the bleeding out of the ends can be seen. The segment is cleaned using moist sponges. Bowel continuity is reestablished by a one-layer seromuscular suture using polyglycolic acid 4-0, and the mesenteric slit is closed by running suture

(Fig. 76.2).

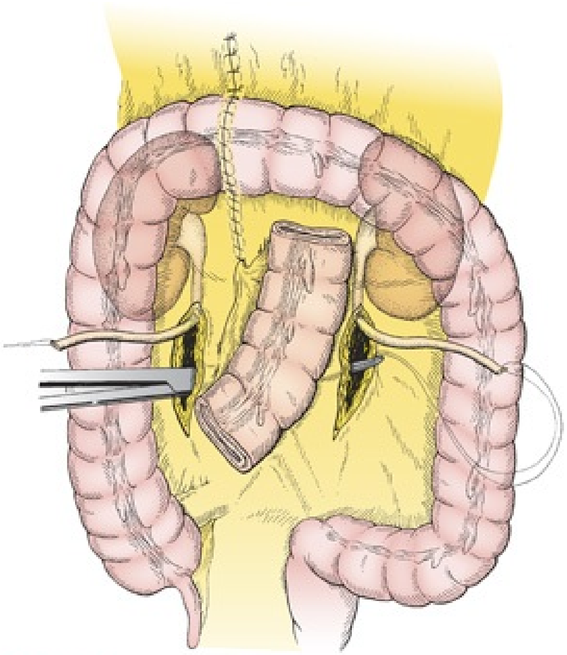

FIGURE 76.2 Bowel continuity is reestablished by a one-layer seromuscular suture using polyglycolic acid 4-0, and the mesenteric slit is closed by running suture.

One option for ureteral reimplantation is the refluxing Wallace technique (15). Both ureters are resected to an adequate length and spatulated over a distance of 3 cm. A stay suture is placed at the 6 o'clock position and a ureteral stent inserted. The first suture for anastomosis of the medial margins of the ureters is placed at the 12 o'clock position and tied later. The anastomosis is performed by a running suture with polyglycolic acid 5-0. The ureteral stents are fixed to the ureteral mucosa (polyglactin 4-0 with short reabsorption time) and subsequently brought out through the conduit. The ureteral plate is then anastomosed to the oral end of the conduit by two running sutures of polyglycolic acid 5-0 (Fig. 76.3A). When the conduit is positioned on the right side and the left ureter is relatively short, it can be implanted antidromic to the right ureter (like the "crossed hands of a ballerina"; Fig. 76.3B).

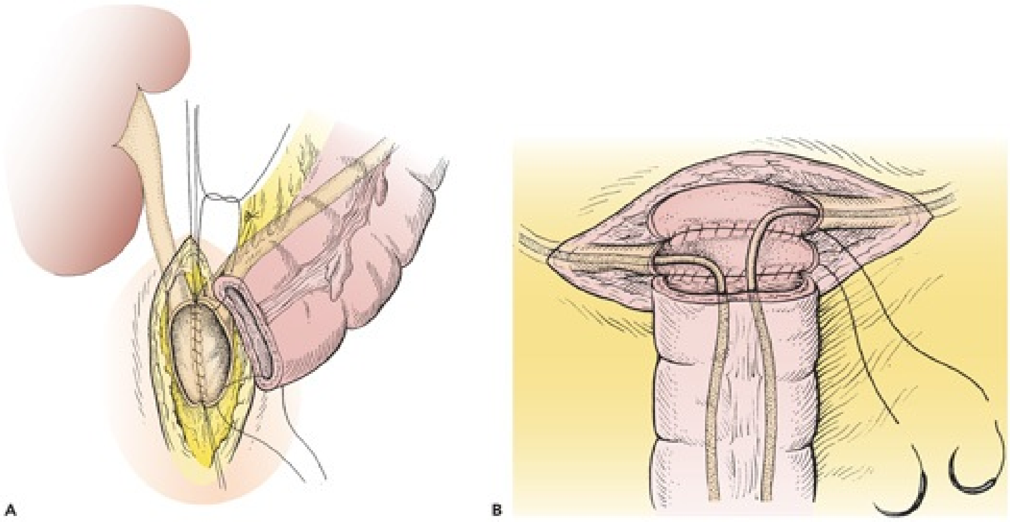

FIGURE 76.3 The ureteral plate is then anastomosed to the oral end of the conduit by two running sutures of polyglycolic acid 5-0. A: Classical implantation. B: Implantation with left ureter in opposite direction to the right.

An alternative method of refluxing ureteral reimplantation is a direct implantation using a "buttonhole" technique. The conduit is longitudinally opened in the area of the taenia libera over a length of 3 to 4 cm starting at the oral end. Two stay sutures are placed at the back wall of the conduit. The mucosa in between is excised and the seromuscular layer incised to create an entrance for the ureter. The ureter is pulled through and implanted by two anchor sutures at the 5 and 7 o'clock positions (polyglycolic acid 4-0) and mucomucous sutures (polyglycolic acid 5-0). A stent is inserted, fixed, and led out through the conduit (Fig. 76.4). The contralateral ureter is implanted in the same manner and the conduit closed.

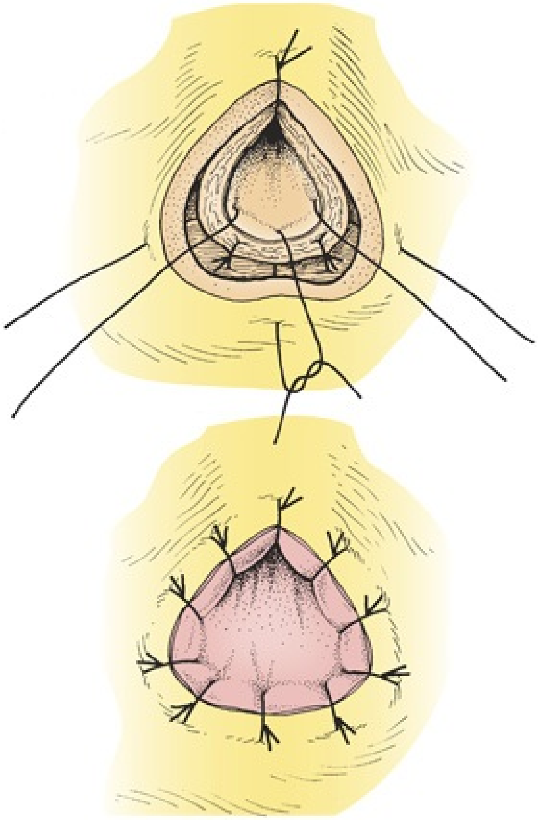

FIGURE 76.4 The mucosa in between is excised, and the seromuscular layer incised to create an entrance for the ureter.

An antirefluxive ureteral implantation can be performed using the Goodwin–Hohenfellner technique (16). The conduit is longitudinally opened over a length of approximately 4 cm starting from the end chosen for ureteral implantation (proximal end preferable). Four stay sutures are placed to facilitate ureteral implantation. A submucosal tunnel is dissected starting from the end of the conduit (tunnel length, 3 to 4 cm). The bowel mucosa at the end of the tunnel is incised, and the ureter is pulled through the respective submucosal tunnel. After spatulation and resection of the ureter to an adequate length, implantation is performed by one anchor suture at the 6 o'clock position, grasping the seromuscularis of the bowel and all layers of the ureter (polyglycolic acid 5-0). The anastomosis is completed by mucomucous single sutures (polyglycolic acid 6-0).

To secure the ureteral implantation, a 6Fr ureteral stent is inserted in each ureter and fixed to the bowel mucosa (polyglactin 4-0 with short reabsorption time). For implantation of the second ureter, a second tunnel is prepared beside and parallel to the first; the implantation is done in the same way (Fig. 76.5). Both ureteral stents are led out through the aboral end of the conduit. The proximal end of the conduit and of the incision line in the area of the taenia libera are closed (single seromuscular sutures, polyglycolic acid 4-0).

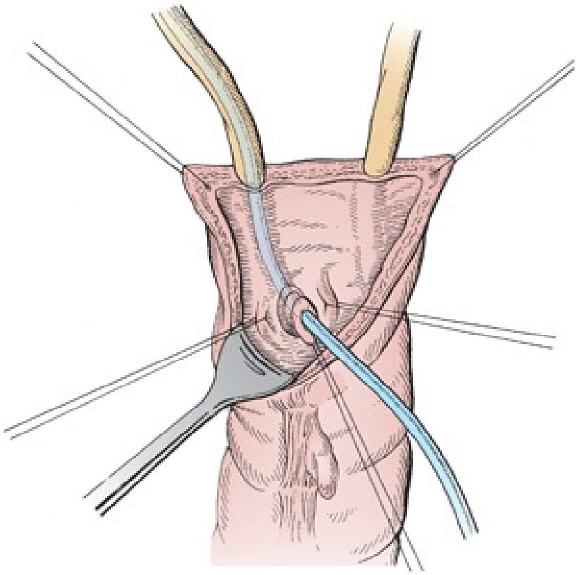

FIGURE 76.5 For implantation of the second ureter, a second tunnel is prepared beside and parallel to the first; the implantation is done in the same way.

A circular area of the skin (approximately 3 cm in diameter) is excised. The abdominal fascia is crosslike incised, and the conduit is pulled through the fascial and the skin opening, together with the ureteral stents, by means of two Allis clamps after having freed the distal end of the conduit of fat and epiploic appendages. The seromuscularis of the conduit is fixed to the abdominal fascia by circular single stitches of polyglycolic acid 3-0, and the conduit is anastomosed to the skin by circular single stitches of polyglycolic acid 5-0 everting the stoma (Fig. 76.6). An option may be passing the stoma through the rectus muscle in order to minimize the risk of parastomal hernia. However, stomal compression with compromised urine output may be a disadvantage.

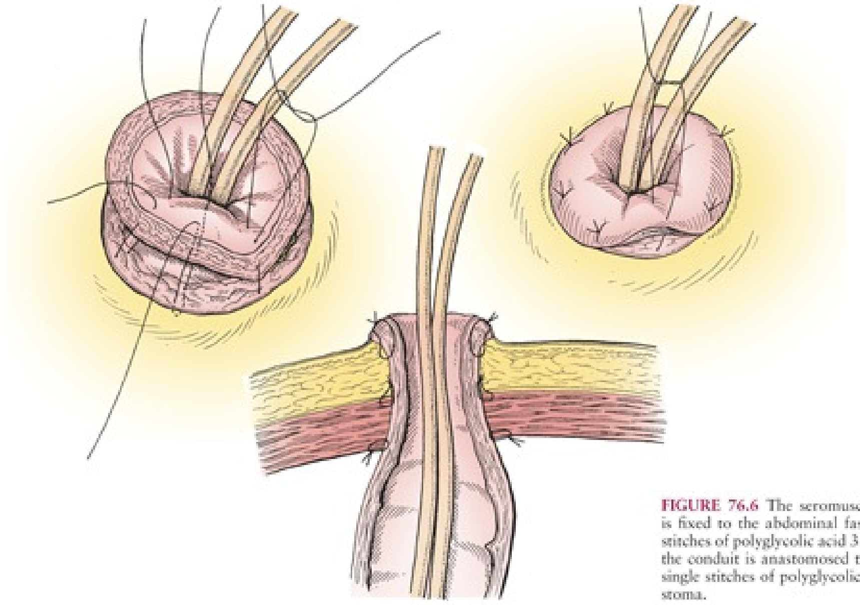

FIGURE 76.6 The seromuscularis of the conduit is fixed to the abdominal fascia by circular single stitches of polyglycolic acid 3-0, and the oral end of the conduit is anastomosed to the skin by circular single stitches of polyglycolic acid 5-0 everting the stoma.

Pyelotransverse Pyelocutaneostomy

An extensive bowel mobilization is necessary including cecum, root of the mesentery, Treitz ligament, and the right and left colonic flexures (Fig. 76.7A). The omentum majus is completely dissected from the transverse colon, and the bursa omentalis is opened. The bowel is exteriorized out of the abdomen. The ureters are cut at the ureteropelvic junction, and the renal pelvis is longitudinally spatulated. A transverse colon segment with a length of 25 to 30 cm and an adequate blood supply is isolated (Fig. 76.7B). After having placed a ureteral stent in a calyx of the right kidney and fixed the stent inside the renal pelvis (polyglactin 4-0 with short reabsorption time), an end-to-end anastomosis of the right renal pelvis and the distal end of the conduit is performed using two running sutures of polyglycolic acid 5-0. The ureteral stent is led out through the conduit before the anastomosis is completed. The conduit is brought to the left renal pelvis without tension (Fig. 76.7C). Likewise on this side, a stent is inserted into the kidney, fixed, and led out through the conduit later. For anastomosis of the renal pelvis with the conduit, the wall of the conduit is incised at the taenia libera over an adequate length and an end-to-side anastomosis of the renal pelvis and the conduit done by two running sutures of polyglycolic acid 5-0 (Fig. 76.7D). The stoma formation is identical to the standard technique. In patients with a single kidney, the technique is more simple: A direct anastomosis of the spatulated renal pelvis and the oral end of the isolated bowel segment is performed, and the aboral end led out through an abdominal stoma created as described earlier.

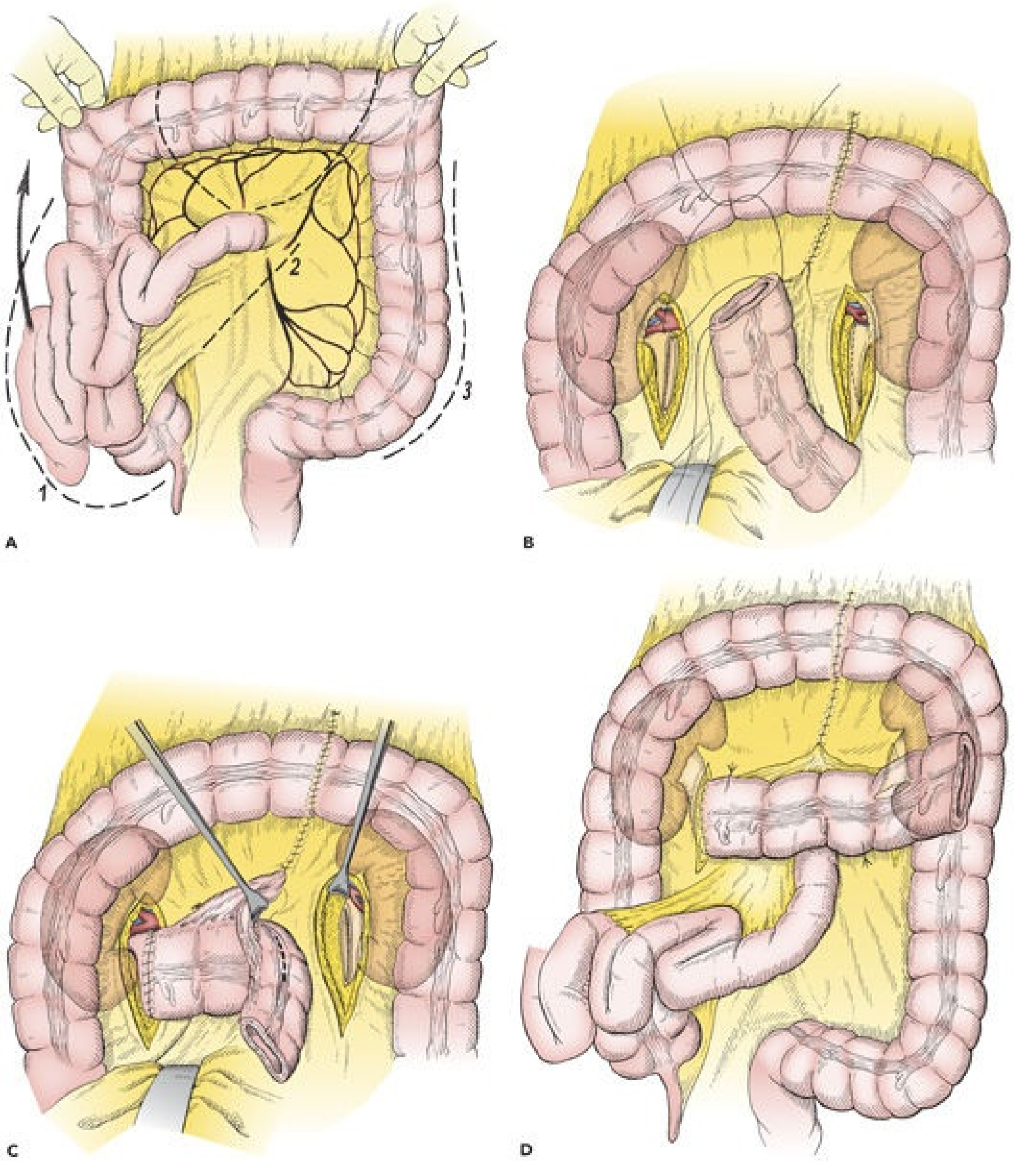

FIGURE 76.7 A–D: An extensive bowel mobilization is necessary including cecum, root of the mesentery, the Treitz ligament, and the right and left colonic flexures.

Surgical Tips

Transilluminating the mesentery by a fiberoptic light source visualizes the vessels and facilitates the selection of the segment as well as the preparation of the mesenteric slits. When the conduit is positioned on the right side and the left ureter is relatively short, it can be implanted directly to the right ureter (like the crossed hands of a ballerina). This is applicable for the Goodwin–Hohenfellner as well as the Wallace technique. The colonic conduit can be performed so that the urine flow is peristaltic and antiperistaltic so that the stoma can be alternatively positioned in the right or left upper abdominal quadrant. For an antiperistaltic application, an extensive mobilization of the Treitz ligament and the descending part of the duodenum becomes necessary; otherwise, compression of the duodenum by the conduit may result. If an isoperistaltic application is preferred, either the right or left colonic flexure can be used for conduit creation. An extraperitonealization of the conduit facilitates revisional surgery, and this can be done through a flank incision. Thereby, a transabdominal approach with the need for adhesiolysis can be avoided.

POSTOPERATIVE CARE

Antibiotics are given for 5 days. Originally as standard of postoperative care, parenteral nutrition was continued until bowel contractions appear and then gradually reduced. The gastric tube was removed starting from postoperative day 3 after clamping. The rectal tube stayed for 3 days. Nowadays, fast track regimens with early removal of the gastric tube and early oral nutrition are increasingly implemented. Ureteral stents are loosened after day 9 and removed after day 10, beginning on one side with a check of the kidney by ultrasonography on day 11. Then, the second stent is removed. An intravenous urography demonstrates regular kidney function after stent removal.

The acid-base balance should be checked before the patient is discharged. The patient should be taught about all aspects of stoma care.

OUTCOME

Results

Transverse colonic conduits offer reasonable short- and long-term results with low complication rates. The reported perioperative mortality rates range from 0% to 4%, with decreasing mortality rates in more contemporary series (5,6). The majority of patients show stable renal function in the early postoperative period (6). At a 10-year long-term follow-up, Schmidt et al. (7) found that upper urinary tracts and renal function remained stable or improved in 88% and 95% of patients, respectively; however, the study cohort was small. Transverse colonic conduit recipients who survived their underlying disease did well during long-term follow-up (7).

Complications

Contemporary data on peri- and postoperative complications are lacking. In older reports, immediate postoperative complication rates of 25% (17) and long-term complication rates of 13% to 37% (5,7,17) have been reported. Ureterocolonic insufficiency represents a specific early complication, whereas febrile urinary tract infection and ureter/implantation stenosis are common long-term complications (18). Electrolyte deterioration can be monitored by venous blood gas analysis. During long-term follow-up, approximately 10% of patients experience a temporary drop of the base excess under 2.5 mmol/L, but almost no patient with colonic conduit develops clinical acidosis or a decrease in blood pH and serum electrolyte disturbances. Nevertheless, some patients with colonic conduit receive prophylactic alkali substitution (19). Stoma stenoses are less prone compared to ileal conduit urinary diversion. Increased complication rates were observed in transverse colon conduit patients who were previously treated with very high dose pelvic irradiation (5). Therefore, a major goal of transverse colon conduit urinary diversion is the use of nonirradiated bowel and ureters for diversion.

CHAPTER 77 ■ MANAGING THE PATIENT WITH ORTHOTOPIC BLADDER SUBSTITUTION

GIANLUCA GIANNARINI AND URS E. STUDER

Orthotopic bladder substitution has become the preferred method of urinary diversion, usually following radical cystectomy for malignant disease, in both male and female patients, provided that certain criteria are satisfied (1). The goal of this type of lower urinary tract reconstruction is to substitute the original bladder in both location and function by creating a reservoir that provides a safe and continent means to store and void urine through the urethra. This allows patients to preserve their body image, avoiding the need for a stoma and to recover an almost completely normal and socially integrated lifestyle.

Several types of bladder substitution have been developed over the past decades, each with its own specific advantages and disadvantages. However, regardless of the type of bladder substitute, optimal outcomes are achieved when a low-pressure, high-compliance reservoir is made of detubularized and cross-folded bowel segments with a preserved sphincter competence and no mechanical/obstructive outlet resistance. Good long-term results with any bladder substitute are not only dependent on surgical technique but equally importantly on a thorough preoperative assessment, meticulous active postoperative management, and lifelong patient follow-up.

PREOPERATIVE MANAGEMENT

Patient Selection

A thorough preoperative assessment requires that the following factors be evaluated when determining candidacy for orthotopic bladder substitution (Table 77.1).

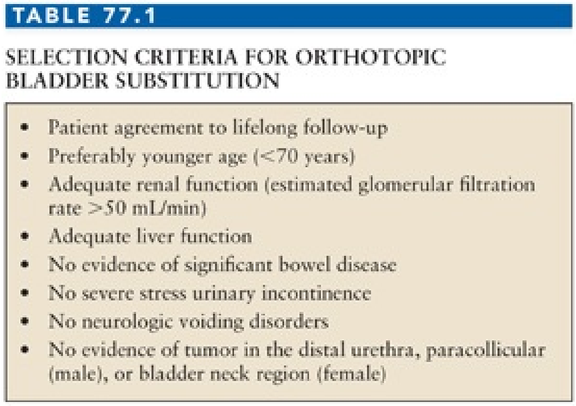

TABLE 77.1

SELECTION CRITERIA FOR ORTHOTOPIC BLADDER SUBSTITUTION

- Patient agreement to lifelong follow-up
- Preferably younger age (<70 years)
- Adequate renal function (estimated glomerular filtration rate >50 mL/min)
- Adequate liver function
- No evidence of significant bowel disease
- No severe stress urinary incontinence
- No neurologic voiding disorders
- No evidence of tumor in the distal urethra, paracollicular (male), or bladder neck region (female)

Patient Motivation and Mental Status

Perhaps the single most important factor contributing to a successful bladder substitute is patient motivation and willingness to comply with an indefinite follow-up. A thorough understanding of how one’s bladder substitute works is mandatory. Within this context, a dedicated specialized nurse can facilitate the preoperative assessment and postoperative education, as well as be a useful resource when patients have problems with their bladder substitute, by providing continuous and long-term educational reinforcement.

It is, however, the responsibility of the treating surgeon to thoroughly inform patients before surgery on all possible forms of urinary diversion and their relative benefits and risks should an orthotopic bladder substitution be not possible at the time of surgery. Alternative forms of urinary diversion to be discussed are continent cutaneous diversion, ureterosigmoidostomy, and incontinent cutaneous diversion (ileal conduit, ureterostomy, and percutaneous nephrostomy).

Patients should also be informed that the choice of a particular form of urinary diversion is primarily a quality-of-life decision with no or little impact on the course of the disease necessitating bladder substitution. Having this background in mind, patients are prepared to make a truly informed decision.

Adequate intellectual skills and physical dexterity, should intermittent self-catheterization become necessary, are currently relative criteria. Recent data has, in fact, shown that in men, the need to self-catheterize is rare, provided the reservoir has no outlet obstruction or this is promptly treated when it occurs (2). The problem remains for female patients in whom urinary retention may occur in up to 50% within 5 years postoperatively (1).

Age

Chronologic age should not be a criterion for offering orthotopic bladder substitution. However, in general, elderly patients (particularly octogenarians) have prolonged recovery of urinary continence and increased risk of long-term urinary incontinence (particularly nighttime) as compared to their younger counterparts (3,4).

Renal Function

The most frequent postoperative complications are metabolic acidosis and electrolyte abnormalities. The type and severity of these disorders depend on type and length of bowel segment used, time of urine contact with bowel mucosa, and compensatory renal reserve. An absolute contraindication to continent urinary diversion is a compromised renal function as a result of chronic renal failure or long-standing ureteral obstruction. Some patients with preexisting renal failure due to ureteral obstruction caused by their primary bladder cancer may recover sufficient renal function to allow for continent diversion once the obstruction is relieved. Placement of a percutaneous nephrostomy tube before surgery in these patients may provide a more accurate estimate of the true renal function. Currently, an estimated glomerular filtration rate of 50 mL/min is considered the lower limit so as to prevent the need for lifelong alkaline supplementation.

Liver Function

Adequate preoperative liver function is also mandatory. The continuous contact of urine with bladder substitute wall allows ammonium to shift through the bowel mucosa into circulation. A urinary tract infection caused by a urease-splitting organism will further increase this ammonium load. If baseline liver function is impaired, a hyperammonemia state will occur, which can lead to severe neurologic decompensation and eventual coma.

Bowel Function

Because bowel is needed for a bladder substitute, the impact of a prior bowel resection and diseased (e.g., Crohn disease) or irradiated bowel needs to be considered as it relates to malabsorption or diarrhea. The bowel segment used for the bladder substitute itself needs to be free of any pathology. Patients with compromised bowel function are better served by an ileal conduit.

Urinary Continence Status

Urinary incontinence, especially in female patients, may reflect a poorly functioning sphincter. These patients require preoperative urodynamic evaluation including a urethral pressure profile because this may identify an etiology and thereby potential treatment options. Severe stress urinary incontinence and neurologic voiding disorders are contraindications to an orthotopic bladder substitution.

Paracollicular and Bladder Neck Biopsy

Positive biopsies from the paracollicular region in the prostatic urethra or the bladder neck/proximal urethra in women indicate a high likelihood of a urethral recurrence. These patients should undergo a primary urethrectomy in conjunction with radical cystectomy and be considered for an alternative form of urinary diversion. Prostatic infiltration (superficial or stromal) proximal to the paracollicular region as well as carcinoma in situ and/or multifocal cancer of the bladder confer a higher risk of urethral recurrence but are not absolute contraindications for an orthotopic bladder substitution.

PREPARATION BEFORE SURGERY

The type of bowel preparation depends on the bowel segment used for the construction of the bladder substitute. If small bowel is used, a limited preparation with two enemas late in the afternoon before surgery is sufficient. Antegrade rinses and neomycin-erythromycin preparations are avoided. In addition, such preparations may increase the risk of fluid imbalances. In the elderly patient, this can produce cardiovascular instability due to intravascular volume depletion as well as potentially place the patient in a catabolic state prior to surgery. If large bowel is used, this must be freed from feces by antegrade irrigation or laxatives. A full mechanical bowel preparation is no longer required for colorectal surgery (5).

Subcutaneous deep venous thrombosis prophylaxis is started the evening before surgery and continued postoperatively. It is administered in the upper extremity so as to prevent a pelvic lymphocele. All patients receive perioperative antibiotic prophylaxis. Also, patients wear stockings and are taught appropriate exercises by a physiotherapist in order to prevent a deep venous thrombosis of the lower extremities or bronchopneumonia.

INTRAOPERATIVE MANAGEMENT

There are certain critical surgical steps that, if adhered to during radical cystectomy, will allow for optimal functional results of the bladder substitute.

Preservation of Pelvic Innervation

In general, nerve sparing should be performed on the non–tumor-bearing side and extensive resection on the tumor-bearing side of the bladder (Fig. 77.1). It has been shown that attempted nerve sparing during radical cystectomy in bladder substitute patients does not only increase the chance to maintain erectile function but also have a positive impact on daytime and nighttime urinary continence (3).

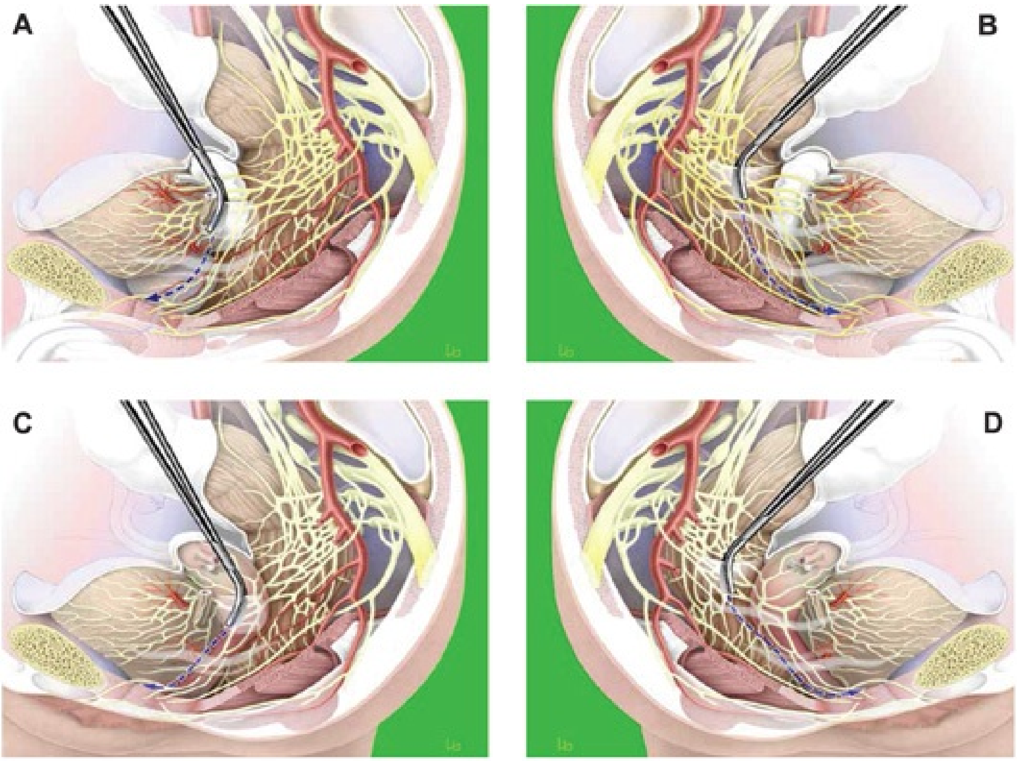

FIGURE 77.1 Dissection line for nerve sparing on the non–tumor-bearing side and for extensive resection on the tumor-bearing side of the bladder in male (**A and B**) and female (**C and D**) patients.

For nerve-sparing cystectomy in men, the nerve fibers in the dorsomedial pedicles lateral to the seminal vesicles as well as the periprostatic neurovascular bundle have to be spared. The pelvic plexus can be preserved by sectioning the dorsomedial pedicle along its ventral aspect, anterolateral to the seminal vesicles, and terminating the dissection at the base of the prostate. A nerve-sparing prostatectomy must also be performed which requires a lateral approach with incision of the endopelvic and periprostatic fascia and bunching of Santorini plexus at the level of the prostate and not distal to it. The dorsolateral neurovascular bundle can be separated from the prostatic capsule. The prostatic apex needs to be approached laterally directly along the prostatic capsule, and the membranous urethra is delivered sharply out of the donut-shaped prostatic apex to avoid nerve damage on the dorsolateral side of the urethra (6).

For nerve-sparing cystectomy in women, the vaginal wall dissection at the cervical level is in the anteroventral plane of the vagina, that is, at the 2 or 10 o'clock position. An empty sponge-holding forceps in the vagina helps facilitate dissection along the whitish vaginal wall. It is important to remain in close contact with the whitish wall of the vagina, thereby ensuring that the paravaginal venous plexus is hemostatically controlled and resected with the dorsomedial bladder pedicle. The endopelvic fascia is only incised cephalad to the bladder neck to minimize damage to the sphincter, its innervation, and to the intrapelvic branch of the pudendal nerve, which also contributes to urethral innervation (7).

Atraumatic Dissection of the Urethra

To obtain a maximum length of competent urethra, sharp and atraumatic dissection of the urethra with minimal use of electrocautery at the prostatic apex in men is used with preservation of the distal puboprostatic ligaments, which cover the membranous urethra. In female patients, the endopelvic fascia is not incised at its deepest point but along the bladder neck. This, together with the preservation of the pubourethral ligaments, will allow for urethral stability and improved urinary continence.

Ureters

Ureters need to be resected at a safe oncologic distance from the bladder, allowing for removal of periureteral lymphatics that may harbor micrometastases. In addition, by removing the distal ureter, the risk of ureteral ischemia and subsequent stricture formation is decreased. Furthermore, when mobilizing the ureters, the periureteral tissue must be preserved in order to ensure good blood supply to the anastomotic area, again in order to prevent anastomotic strictures. The left ureter is transposed without tension to the right side of the abdomen retroperitoneally by crossing the aorta above the inferior mesenteric artery. An antireflux ureterointestinal anastomosis (8) or other antireflux mechanisms (9) are not required in low-pressure bladder substitutes, rather they may be detrimental to the renal function. A long, spatulated, end-to-side anastomosis according to the refluxing Nesbit technique using a water tight running suture should, instead, be performed. Traction on the anastomosis can be avoided by placing interrupted sutures between the periureteral tissue and the bowel wall. Although stenting of the ureterointestinal anastomosis apparently does not lower the stricture rate, it may improve the recovery of bowel function and decrease the risk of metabolic disturbances in the early postoperative period (10). If ureteral stents are placed, they should be passed through the bowel wall where their exit sites are covered with mesenteric fat, so as to prevent urine leakage once they are removed.

Bladder Substitute

Several segments of bowel have been used over the past years for the construction of a bladder substitute. A comparison of the various segments has shown an advantage for ileum over any other segment (gastric, ileocolic, right colic, and sigmoid) with regard to capacity at first and at maximum contraction, involuntary contractions, elasticity, incidence of metabolic disorders, and long-term adaptation of mucosa from absorption to storage (11–13).

The most common segments currently used are ileum and colon. If ileum is used, the terminal ileum (i.e., the most distal 25 cm) needs to be preserved in order to minimize vitamin B12 deficiency and bile acid–induced diarrhea. The ileocecal valve should be preserved as well if possible or consideration should be given to its reconstruction (14). The ileocecal valve, in fact, controls the rate of delivery of ileal contents and prevents the migration of bacteria from colon into ileum. Ileal segments of up to 60 cm can be resected in healthy individuals without any significant consequences, provided the ileocecal valve is left intact. When more than 60 cm of bowel is resected, the risk of malabsorption increases and becomes inevitable if greater than 100 cm is used.

Resection of a considerable length of colon in isolation is possible without detrimental effect on absorption if the right colon remains intact. The right colon, in fact, retains solid residue for up to 8 hours determining the recovery of salt and water, whereas the left and rectosigmoid colon mainly function as a conduit. The right colon is particularly important in patients with ileal resection, in whom the severity of diarrhea increases as the length of any associated colonic resection increases (15,16). The severity of diarrhea depends more on length for contiguous colonic than ileal resection. Therefore, it may be best to avoid contiguous colonic and distal ileal resection in the formation of a continent urinary reservoir.

One hour prior to bladder substitute construction, administration of anesthetics via the epidural catheter is stopped. This prevents increased smooth muscle tone and activity of the ileum, which would, otherwise, result in a functional shortening of bowel with the risk of removing more bowel than is necessary for reservoir construction.

The reservoir should be spherical in order to achieve maximum capacity and minimal pressure for the given surface of bowel used. As dictated by Laplace law (pressure = tension/radius), intraluminal pressure is low for a given tension because conversion of a tubular structure into a spherical reservoir increases the radius. Furthermore, the spherical shape obtains maximal capacity, whereas the surface/volume ratio limits the reabsorbing surface and therefore minimizes associated metabolic disturbances.

It is mandatory that the anastomosis between the bladder substitute outlet and the urethra is not to the funnel-shaped end of the reservoir. This error would increase the risk of kinking and obstruction at the anastomotic site, especially when the reservoir is full. To obtain optimal voiding, the anastomosis should sit broadly on the pelvic floor (Fig. 77.2). In addition, all suture material should be absorbable, thereby eliminating any potential nidus for stone formation.

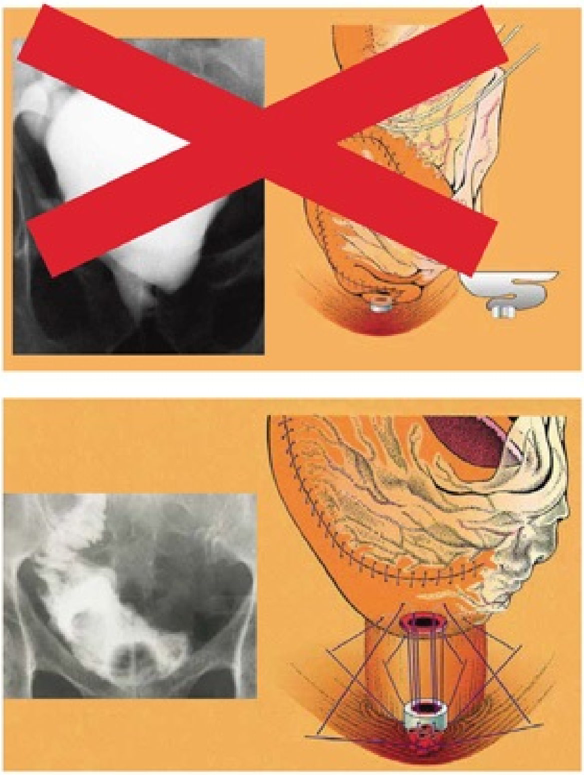

FIGURE 77.2 A funnel-shaped reservoir to urethra anastomosis must be avoided because of the risk of subsequent kinking and outlet obstruction.

POSTOPERATIVE MANAGEMENT

During the postoperative period, fluid and electrolyte management predominates; however, it is also important to use this time to educate and encourage patients to become comfortable with their bladder substitute (Table 77.2).

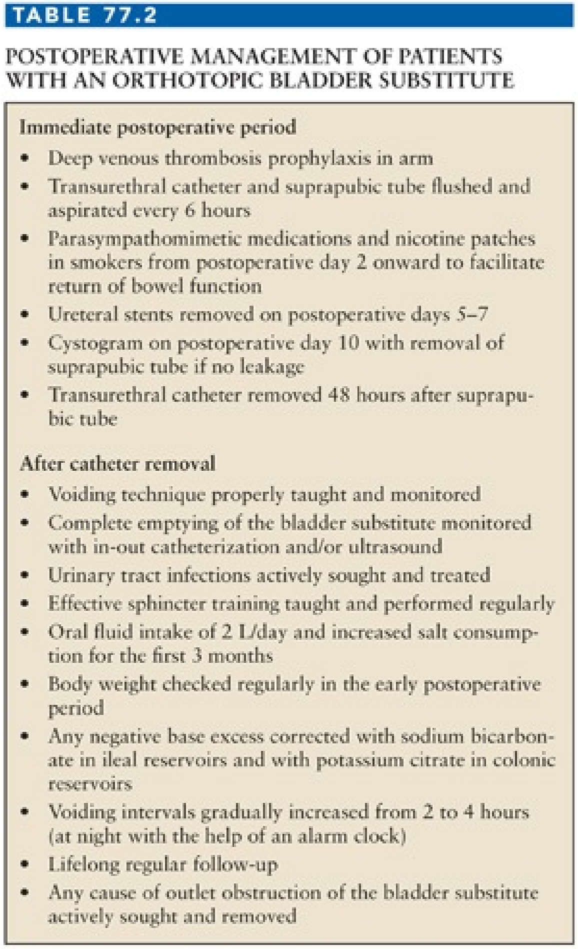

TABLE 77.2

POSTOPERATIVE MANAGEMENT OF PATIENTS WITH AN ORTHOTOPIC BLADDER SUBSTITUTE

Immediate postoperative period

- Deep venous thrombosis prophylaxis in arm
- Transurethral catheter and suprapubic tube flushed and aspirated every 6 hours
- Parasympathomimetic medications and nicotine patches in smokers from postoperative day 2 onward to facilitate return of bowel function
- Ureteral stents removed on postoperative days 5–7
- Cystogram on postoperative day 10 with removal of suprapubic tube if no leakage
- Transurethral catheter removed 48 hours after suprapubic tube

After catheter removal

- Voiding technique properly taught and monitored
- Complete emptying of the bladder substitute monitored with in-out catheterization and/or ultrasound
- Urinary tract infections actively sought and treated
- Effective sphincter training taught and performed regularly
- Oral fluid intake of 2 L/day and increased salt consumption for the first 3 months
- Body weight checked regularly in the early postoperative period
- Any negative base excess corrected with sodium bicarbonate in ileal reservoirs and with potassium citrate in colonic reservoirs
- Voiding intervals gradually increased from 2 to 4 hours (at night with the help of an alarm clock)
- Lifelong regular follow-up
- Any cause of outlet obstruction of the bladder substitute actively sought and removed

Immediate Postoperative Period

The suprapubic tube and transurethral catheter must be flushed and aspirated with saline 0.9% every 6 hours. This is needed to prevent mucus buildup, which can block catheters and result in rupture of the bladder substitute. This complication is greatest when bowel activity has resumed with the catheter still in situ. To prevent abdominal distension and accelerate return of bowel function, parasympathomimetic medications (e.g., neostigmine methylsulfate 0.5 mg three to six times a day subcutaneously) and nicotine patches (in smokers) are started 2 days after surgery. The ureteral stents should be removed between postoperative days 5 and 7 after the bowel function resumes.

On postoperative day 10, the suprapubic tube can be removed, provided a cystogram rules out urinary extravasation. The transurethral Foley catheter remains in place for an additional 2 days to provide enough time for the suprapubic tube exit site to heal.

Management after Catheter Removal

After all catheters and drains are removed, any bacteriuria should be managed with antibiotics until the urine is sterile. Infected urine can cause reservoir instability with subsequent urinary incontinence as well as increased mucus production, which can lead to increased postvoid urine residual and even urinary retention (17).

Voiding and Urinary Continence

Patients must be carefully instructed on how to void. Initially, they are taught to empty the bladder substitute every 2 hours during the daytime in a sitting position by relaxing the pelvic floor and, if necessary, by also slightly increasing their intra-abdominal pressure. At night, they should use an alarm clock to void every 3 hours. The adequacy of emptying needs to be monitored with in-out catheterization and/or ultrasound of the reservoir after voiding.

Patients without or after compensation of metabolic disturbances are instructed to retain urine thereafter for 3 hours and later for 4 hours in order to expand their bladder capacity. During this exercise, increased bladder substitute pressures may cause incontinence, but the elevated pressures are required to increase the reservoir's capacity. Therefore, patients are advised not to void when they experience such urinary leakage; otherwise, the bladder substitute will never achieve the desired capacity. It is essential to increase the capacity to approximately 500 mL in order to have low end-fill pressures to ensure urinary continence. With increasing capacity, nighttime continence will improve, but, on the other hand, a bladder substitute capacity of >500 mL should be prevented. Overdistension of the reservoir will result in a "floppy bag" unable to adequately empty with increased residual urine and the potential for urinary retention.

A postvoid urinary dribble incontinence can be prevented by instructing the patient to milk the urethra at the end of each void (18). Time required to achieve urinary continence depends on diligent sphincter training, patient age, as well as achieving intraoperative nerve preservation to the urethra and pelvic floor (if oncologically safe).

Urethral length, especially if the sphincter is damaged, is also important in the genesis of urinary incontinence as demonstrated by the formula: urinary continence = urethral length × closing urethral pressure (19). Using the female sheep model, Strasser et al. (20) showed that maximal urethral closure pressure was markedly decreased in sheep with denervated urethra (18 cm H_2O compared to baseline of 49 cm H_2O). If the autonomic nerves are damaged, closing urethral pressure cannot compensate for a shortened urethral length. Theoretically, therefore, after resection of the proximal urethra, patients may not leak with increased intra-abdominal pressure because of the intact pudendal nerve pathway but may leak when walking, particularly with a full bladder substitute, because of reduced functional urethral length or decreased closing pressure at rest. Also, sensory innervations of the proximal urethra may influence urinary continence. Division of these nerves may result in loss of the afferent limb of the external sphincter guarding reflex stimulated by urinary leakage into the proximal urethra. Nerve sparing may also be beneficial to preserving the function of the other pelvic organs. In a further experimental setting using a male canine model, Zehnder et al. (21) showed that not only smooth urethral sphincter function but also cavernosal body and smooth rectal sphincter function was preserved significantly better after a nerve sparing compared to a non–nerve-sparing cystoprostatectomy.

When adhering to all these principles, daytime continence rates of up to 90% and nighttime continence rates of up to 80% at 12 months can be achieved (4,22).

Urinary retention tends to be a problem primarily in female patients with bladder substitute. Having an unobstructed outlet with prevention of kinking of the urethra or reservoir can help avoid this eventuality (Fig. 77.2). The contribution of the intrapelvic pudendal somatic nerves and autonomic branches of the pelvic plexus to sphincter function has not been fully established, but animal studies have demonstrated a pressure increase in the distal urethra after pudendal nerve stimulation and in the proximal urethra after stimulation of the pelvic plexus. This suggests that nerve sparing has functional significance for both continence and voiding ability. In female sheep, Strasser et al. (20) found marked degeneration of the smooth muscle cells of the proximal urethra after bilateral denervation of an isolated urethra, which reflects the situation in bladder substitute patients. Thereby complete autonomic denervation of the urethra in patients undergoing cystectomy and bladder substitute may result in long-term smooth muscle dysfunction. Absence of the tonus-regulating function of the autonomic nerves may lead to a dilation or rigidity of the urethra resulting in intrinsic sphincter deficiency. A denervated proximal urethra may result in ineffective active relaxation and/or kinking during voiding and, thus, incomplete emptying which necessitates intermittent self-catheterization.

Metabolic Acidosis

After catheter removal, the patient is at an increased risk for metabolic acidosis. Both the urologist and the patient should be aware of the symptoms that may arise with a metabolic acidosis, such as lack of appetite, fatigue, weakness, weight loss, dyspepsia, heartburn, nausea, and ultimately vomiting. The base excess should be monitored with regular venous blood gas analysis, and a negative base excess needs to be corrected.

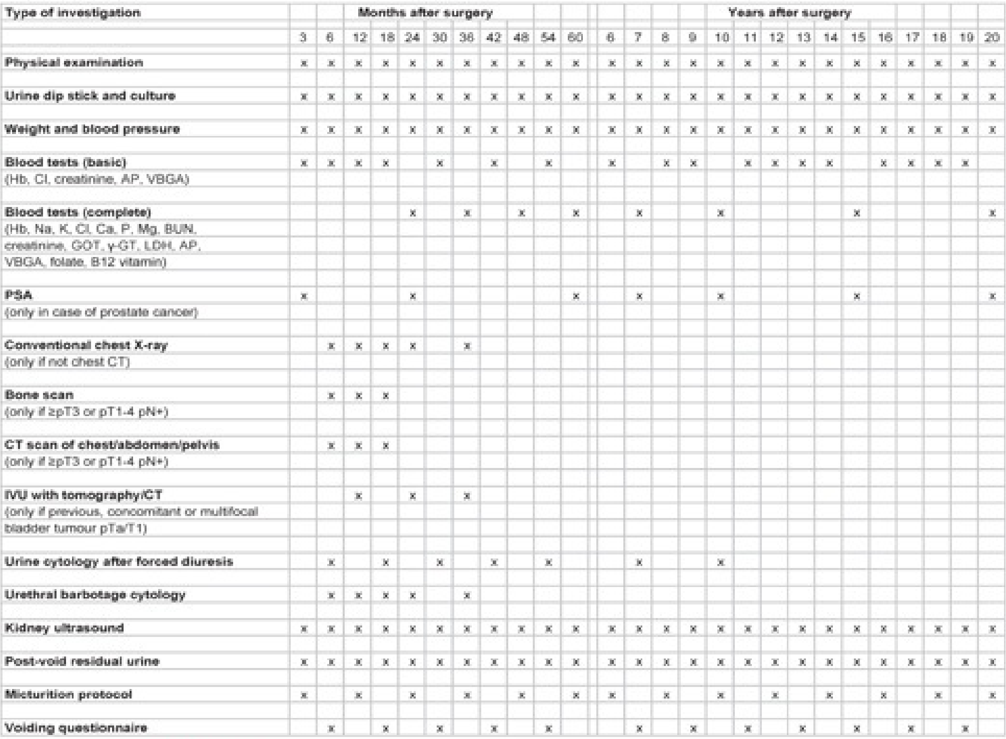
Because the main goal of any intestinal segment is to produce isosmotic contents, the bladder substitute has the ability to rapidly absorb or secrete sodium and chloride ions in response to the osmolarity of its contents (14):

1. If small bowel is used in the initial postoperative period, when the urine is hypo-osmolar, the bladder substitute will secrete sodium chloride resulting in a salt-losing syndrome, hypovolemia, and metabolic acidosis. The resultant dehydration and anorexia may lead to a rapid decrease in body weight and, therefore, daily postoperative body weight assessment is essential. To prevent this metabolic cascade, patients should increase their salt intake, primarily because they are also encouraged to consume 2 to 3 L of fluids a day to prevent metabolic acidosis resulting from highly concentrated acidotic urine. They also receive sodium bicarbonate supplementation (2 to 6 g) to maintain a positive base excess. With time, the villi will atrophy and this syndrome will become less pronounced.
2. Because the main absorptive function of large bowel is water recovery through active sodium and chloride reabsorption, its use for urinary reservoirs may lead to serum hyperosmolarity and subsequent decreased aldosterone release with increased antidiuretic hormone release. This metabolic disturbance results in highly concentrated urine from which the colonic mucosa will absorb more sodium and chloride. Typically, all these patients with close scrutiny have at least a mild degree of hyperchloremic metabolic acidosis. This can be treated with alkalizing agents and/or blockers of chloride transport. Hypokalemia and total body depletion of potassium may be more frequently seen with colonic diversion because ileal segments absorb more potassium. Therefore, treatment with potassium citrate is the most appropriate form of substitution for patients with large bowel reservoirs.

Comparative studies of ileal and colonic reservoirs are limited, as the absorptive surface areas are difficult to calculate. However, in the colon, chloride absorption and bicarbonate excretion are more pronounced, and there is evidence to suggest that inherent chloride absorption is maintained when in contact with urine. Metabolic acidosis is encountered in up to half of patients with an ileal bladder substitute soon after surgery, particularly in those with previous renal impairment or ongoing urinary infection, but most patients do not require sodium bicarbonate supplementation for >3 months (22). Conversely, up to more than one-third of patients with ileocecal bladder substitute require a lifelong substitution with potassium citrate (23). Therefore, it may be preferable to use ileum rather than colon for bladder reconstruction to reduce the risk of hyperchloremic acidosis, particularly in the presence of preoperative renal impairment.

Long-Term Follow-up

Meticulous and lifelong follow-up is essential for optimal reservoir function and prevention of long-term complications (22,24,25). The ideal bladder substitute should have no incontinence, no relevant postvoid residual urine, no urinary infection, no impairment of renal function, and no metabolic disturbances (e.g., acidosis, vitamin B_{12} deficiency, osteopenia). These points, together with screening for metastases, upper tract, or urethral recurrence, should be routine because without a regular follow-up, serious, if not life-threatening, complications, such as urosepsis, are likely to occur. A suggested protocol is illustrated in Figure 77.3.



Type of investigation	Months after surgery											Years after surgery														
	3	6	12	18	24	30	36	42	48	54	60	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20

FIGURE 77.3 Proposed protocol incorporating oncologic, functional, and metabolic investigations for regular follow-up of patients undergoing radical cystectomy with extended pelvic lymph node dissection for bladder cancer and ileal orthotopic bladder substitution. AP, alkaline phosphatase; BUN, blood urea nitrogen; Ca, calcium; Cl, chloride; CT, computed tomography; GOT, glutamic oxaloacetic transaminase; Hb, hemoglobin; IVU, intravenous urography; K, potassium; LDH, lactate dehydrogenase; Mg, magnesium; Na, sodium; P, phosphorus; PSA, prostate-specific antigen; VBGA, venous blood gas analysis; γ-GT, gamma-glutamyltransferase.

Prevention of kinking at the reservoir outlet at the time of surgery and removal of any cause of outlet obstruction (such as urethral strictures, protrusion of ileal mucosa into the urethra or residual prostatic tissue) postoperatively in the case residual infected urine is noted, is preferable to lifelong clean intermittent catheterization. An early sign for incomplete voiding is infected urine, which, especially if recurrent, should prompt the treating physician to investigate possible causes primarily by endoscopy. If this active monitoring is accomplished, spontaneous voiding at 10 years postoperatively can be achieved in as high as 96% of patients with a bladder substitute (2).

CHAPTER 78 ORTHOTOPIC URINARY DIVERSION USING AN ILEAL LOW-PRESSURE RESERVOIR WITH AN AFFERENT TUBULAR SEGMENT

FIONA BURKHARD AND URS E. STUDER

An ileal low-pressure orthotopic bladder substitute offers several significant advantages over other forms of orthotopic urinary diversion. One is the ease of surgery, as the operation can be performed by any urologist experienced in performing radical prostatectomy or cystectomy with an ileal conduit (1). The short ileal segment, approximately 55 cm, which is used to construct this bladder substitute, minimizes the risk of intestinal malabsorption. Both the terminal ileum and the ileocecal valve are preserved. The reservoir is constructed as a sphere, thus achieving a maximum volume-to-surface area ratio and maximum capacity from the selected bowel segment (2). Another advantage is the isoperistaltic afferent tubular segment with the end-to-side ureteroileal anastomosis at its proximal end. This allows resection of the distal ureters, including the paraureteral lymphatics, at a safe distance from the cancerous lesion in the bladder and reduces the risk of leaving distal ureters behind that may contain carcinoma in situ. Furthermore, the shorter the remaining ureters are, the better the blood supply at their distal end and the lower the risk of ischemic stricturing of the distal ureter. The peristalsis of the afferent ileal segment acts as a dynamic antireflux mechanism, and in cases of complicated urethral strictures or urethral tumor recurrence, the afferent tubular segment can easily be transformed into an ileal conduit. By slightly modifying this reservoir, it can be applied for bladder augmentation following subtotal cystectomy in patients with benign bladder pathologies.

SELECTION CRITERIA

Patients undergoing orthotopic bladder substitution will generally receive the diversion after cystectomy for bladder cancer. A full workup to stage the cancer is important as well as a cystoscopy to determine the extent of the cancer and exclude involvement of the urethra (negative preoperative biopsies from the prostatic urethra [male]/ bladder neck [female]). As is true for all bladder substitutes, specific selection criteria need to be adhered to. In general, metastatic disease should be ruled out. Adequate renal function defined by a glomerular filtration rate >50 $mL/min/m^2$ precludes the need for lifelong bicarbonate supplementation and liver function should be normal (aspartate aminotransferase, alanine aminotransferase). Patients should not have active inflammatory bowel disease or have undergone previous extensive bowel resection (malabsorption). It is important that patients have the mental and physical ability to learn to live with a bladder substitute (comply with voiding intervals, mobility to get to toilet also at night). They also have to be willing to comply with routine follow-up.

INDICATIONS FOR SURGERY

Orthotopic diversion represents the procedure of choice in the properly selected patient undergoing cystectomy. However, as with all bladder substitutes, oncologic outcome and complete resection of the cancer must in no way be compromised by the orthotopic reconstruction. In addition, the external rhabdosphincter and internal lissosphincter complex and their corresponding innervation must remain functionally intact. The ileal orthotopic bladder substitute is particularly well suited for patients in whom the sequelae of ileocecal resection should be avoided.

ALTERNATIVE THERAPIES

Alternatives to the ileal orthotopic bladder include other forms of diversion, including ileal and colon conduits, continent urinary diversions, and other orthotopic diversions.

SURGICAL TECHNIQUE

Cystectomy

Pelvic lymphadenectomy and cystectomy are performed according to standard technique, with slight modifications (3). The external iliac vessels, the obturator fossa, and the hypogastric vessels are completely freed of all lymphatic, fatty, and connective tissue on both the medial and lateral side. After dividing the dorsolateral bladder pedicles, which contain the superior and inferior vesical vessels, close to the hypogastric arteries, the pelvic floor fascia is incised and the Santorini plexus is ligated. The prostatic vessels should be preserved on the non–tumor-bearing side to ensure adequate blood supply to the pelvic plexus and neurovascular bundle.

The ureters are divided where they cross the iliac vessels. This allows en bloc removal of the distal ureters and paraureteral lymphatic vessels, together with the cystectomy specimen. The dorsomedial pedicle is resected along the pararectal-presacral plane on the tumor-bearing side. Whenever possible, care is taken to preserve the hypogastric nerve fibers and the pelvic plexus, which are situated dorsolateral to the seminal vesicles, on the contralateral non–tumor-bearing side. On this side, the dissection along the dorsolateral wall of the seminal vesicles is stopped at the base of the prostate. The neurovascular bundle is then detached from the prostatic capsule in a retrograde fashion. The Santorini plexus is then divided, and the membranous urethra is transected as close as possible to the apex of the prostate by excavating it out of the donut-shaped apex.

Preparation of the Ileum Segment for the Bladder Substitute

For construction of the reservoir, an approximately 55-cm long ileal segment is isolated 25 cm proximal to the ileocecal valve (Fig. 78.1). The length of the ileal segment is measured with a ruler in portions of 10 cm along the border of the mesoileum without stretching the bowel. Irritation of the bowel as well as epidural anesthesia with local anesthetics should be avoided because this can increase smooth muscle tone and activity and thereby "shorten" the bowel, resulting in a measured segment which will be too long after muscle relaxation.

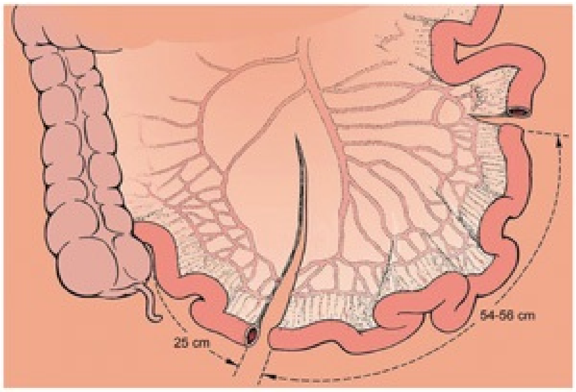

FIGURE 78.1 An approximately 55-cm long ileal segment for the bladder substitute is isolated 25 cm proximal to the ileocecal valve. Note the long incision distally (eases reanastomosis of the ileum and mobilization of the reservoir) and the short incision in the mesoileum proximally (preserves blood supply to the reservoir).

The incision of the mesoileum at the distal or aboral end of the ileal segment is long and transects the communicating vessels between branches of the superior mesenteric artery and the ileocecal artery. In contrast, the proximal incision must be short in order to preserve the main vessels perfusing the future reservoir segment. Bowel continuity is restored with a 4-0 running polyglycolic acid suture incorporating only the seromuscular layer. The mesoileum borders are adapted with a running suture (2-0 polyglycolic acid) in which the mesoileum of the bladder substitute is included (Fig. 78.2). The sutures must be applied superficially, taking care to preserve the blood supply to the bladder substitute. Both ends of the isolated ileal segment are closed by seromuscular running sutures (4-0 polyglycolic acid). The distal end of the ileal segment, approximately 40 to 45 cm long, is opened along its antimesenteric border (see Fig. 78.2), leaving a 10- to 12-cm afferent tubular limb into which the ureters are implanted.

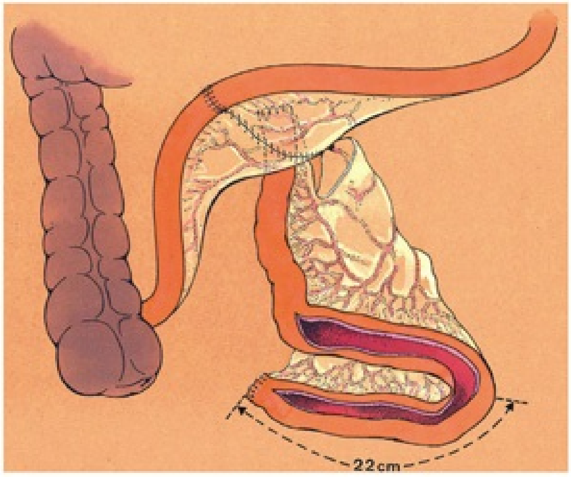

FIGURE 78.2 Bowel continuity is restored with a continuous end-to-end suture incorporating only the seromuscular layer. The incision in the mesoileum is closed; deep sutures are avoided in order not to compromise circulation. Both ends of the isolated ileal segment are closed by seromuscular running sutures. The distal two-thirds of the ileal segment are opened along its antimesenteric border.

Ureteroileal End-to-Side Anastomosis

The left ureter is mobilized up to the lower pole of the kidney, with care taken to maintain its surrounding blood supply and thereby prevent ischemia. It is then brought without tension to the right side of the abdomen retroperitoneally by crossing the aorta slightly above the inferior mesenteric artery. Note: If the ureters need to be resected close to the kidney (e.g., if there is carcinoma in situ, compromised vascular supply, or previous radiation history), a longer afferent ileal segment can be harvested to bridge the necessary distance. Transpose the opened part of the ileal segment onto the patient’s upper abdominal wall, with the proximal end of the afferent tubular segment hanging into the abdominal cavity at the level of the common iliac vessels (Fig. 78.3). The ureters are spatulated over a length of 1.5 to 2.0 cm. Incisions (2 cm) are made in the most proximal portion of the afferent tubular ileal segment along the paramedian antimesenteric border. The spatulated ureters are implanted using the Nesbit technique in an open end-to-side fashion using running sutures (Fig. 78.4). To prevent bowel ischemia between the ureteral anastomoses, the right ureter is placed approximately 1 cm distal to the left ureter.

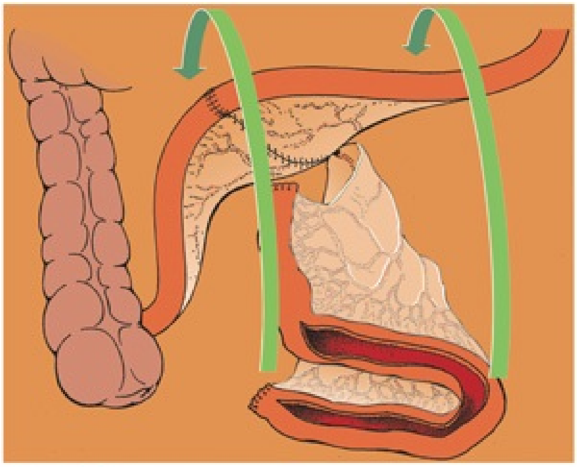

FIGURE 78.3 Transpose the divided ileum for the reservoir onto the upper abdomen as shown by the *arrows*. The proximal part for the afferent tubular segment remains in the abdominal cavity.

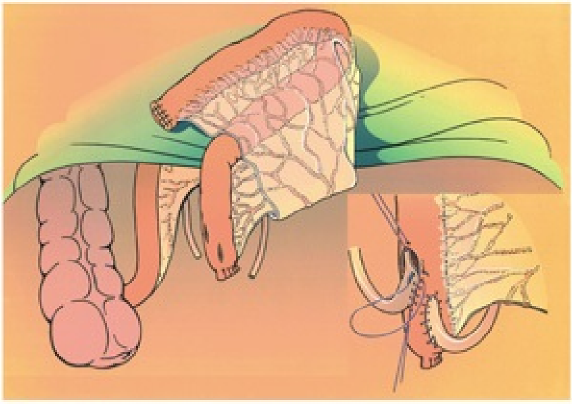

FIGURE 78.4 Two slightly staggered incisions (2 cm) are made in the most proximal portion of the afferent tubular ileal segment along the paramedian antimesenteric border. The ureters are spatulated over a length of 1.5 to 2.0 cm. A ureteroileal anastomosis using an end-to-side Nesbit technique with a 4-0 running suture ensures a low stricture rate.

The ureters are stented with 7Fr or 8Fr catheters. To prevent dislocation of the catheters, a rapidly absorbable suture (5-0 polyglycolic acid) is placed through both the ureter and the catheter 3 to 4 cm proximal to the anastomosis. It is tied loosely to avoid compromising the ureteral blood supply. The most distal periureteral tissue is sutured to the afferent ileal segment to both relieve tension on the anastomosis and to cover it. The ureteral catheters are passed through the wall of the most distal end of the afferent tubular segment, where it is covered by some mesoileum. This provides a "covered" channel in the reservoir wall when withdrawing the ureteric catheters 4 to 7 days postoperatively.

Construction of the Bladder Substitute and Anastomosis to the Urethra

To construct the reservoir itself, the two medial borders of the opened U-shaped distal part of the ileal reservoir are folded to form a U and sewn together with a single continuous seromuscular layer of 2-0 polyglycolic acid suture (Fig. 78.5). The bottom of the U is then folded up between the two ends of the U (see Fig. 78.5), resulting in a spherical reservoir consisting of four cross-folded ileal segments. After closure of the lower half of the anterior wall and part of the upper half (Fig. 78.6), the surgeon's finger is introduced through the remaining opening to determine the most caudal part of the reservoir. At this point, a hole of 8 to 10 mm in diameter is cut out of the pouch wall, outside the suture line (Fig. 78.7). Importantly, although it may appear easier to perform, it is imperative that the anastomosis of the urethra to the neobladder is not to the funnel-shaped end of the reservoir. This increases the risk of kinking and obstruction at the anastomotic site when the reservoir is full (Fig. 78.8). To achieve optimal voiding, the anastomosis must sit broadly on the pelvic floor. After placement of a silicone 18Fr Foley urethral catheter, six 2-0 Vicryl sutures anastomose the previously made hole in the bladder substitute with the urethra (Fig. 78.9). Two posterior sutures are placed medial to the neurovascular bundles including a generous portion of Denonvilliers fascia, and two anterolaterally to these through the lateral portion of the urethra, and two anteriorly, taking only a small part of the urethra but including the ligated Santorini plexus and the puboprostatic ligaments (Fig. 78.10). When the urethral sutures are placed, the needle incorporates 3 to 4 mm of the sphincter but exits at the mucosal edge, thereby bringing them close to the mucosal edges of the reservoir. The aim is to anchor the reservoir to Denonvilliers fascia and the puboprostatic ligaments thereby minimizing tension on the anastomosis and avoiding shortening of the urethral length. Adherence to these steps also reduces the incidence of anastomotic strictures. The following maneuvers can be applied to help bring the reservoir down to the pelvic floor without tension: Place the mesoileum in the upper abdomen, pull the sigma upward to make space for the reservoir, and gently pull the mesoileum of the reservoir down toward the pelvic floor (Fig. 78.11). If necessary, the operating table is now flexed to reduce the distance between the bladder substitute and the urethra. By tying the anterior stitches of the ileourethral anastomosis first and then the lateral sutures and finishing with the posterior sutures, the reservoir is anchored anteriorly and tension on the posterior sutures is reduced. Sutures are tied loosely to prevent cutting, ischemia, and stenosis. If necessary and this is seldom the case, two stitches can be placed lateral to the urethra to fix the bladder substitute to the pelvic floor thereby preventing undue traction on the anastomosis.

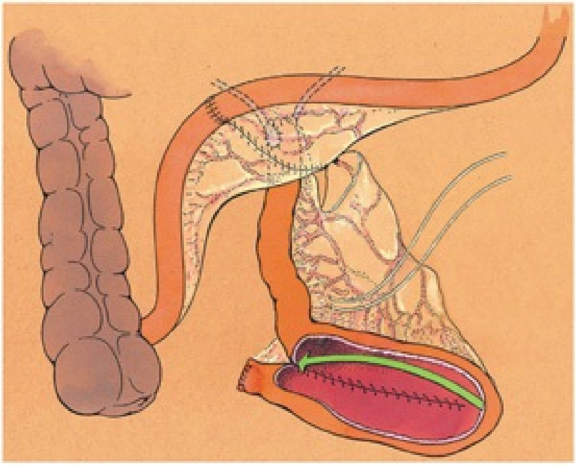

FIGURE 78.5 The two medial borders of the antimesenteric opened U-shaped distal ileum segment are oversewn with a single-layer seromuscular running suture. The bottom of the U is folded back to the two ends of the U to form a sphere as shown by the *arrow*. Note placement of the ureteral stents through the mesoileum.

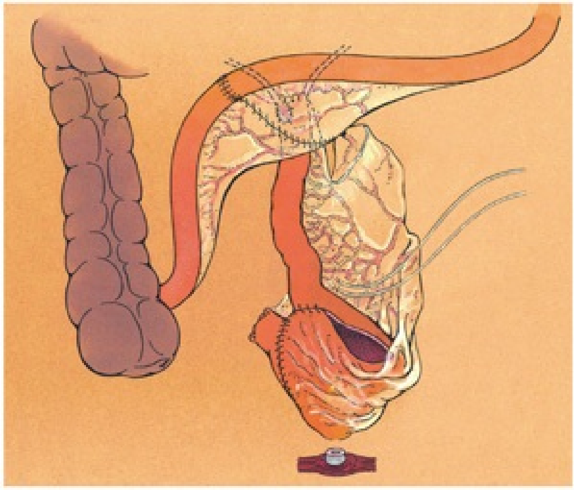

FIGURE 78.6 The caudal half of the remaining reservoir opening is closed completely, and the cranial half partially by a running seromuscular suture.

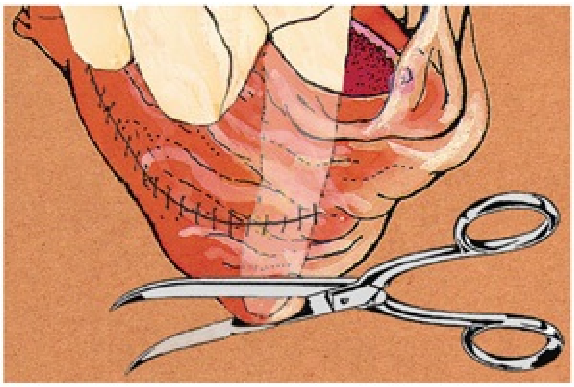

FIGURE 78.7 The surgeon's finger is introduced to determine the most dependent part of the reservoir, and an 8- to 10-mm diameter hole is excised.

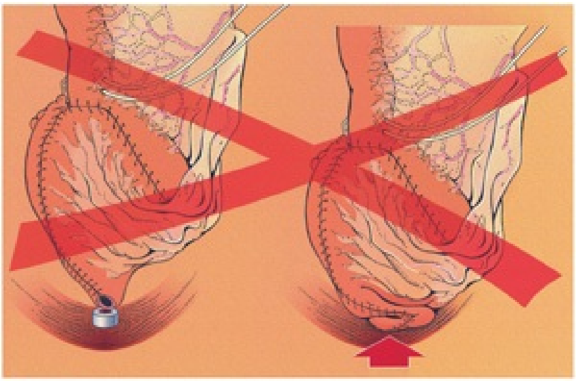

FIGURE 78.8 Anastomosis of the neobladder to the urethra is not made using the funnel-shaped end of the reservoir, as this leads to kinking and outlet obstruction (as shown by the arrow).

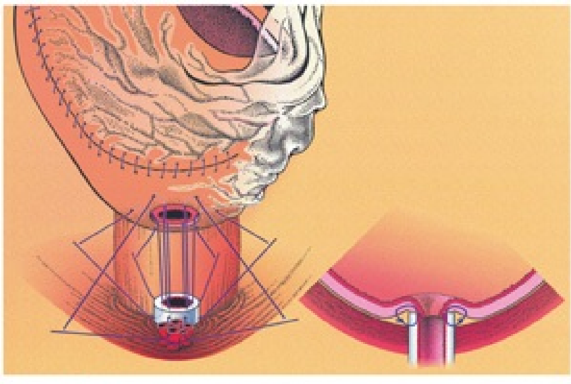

FIGURE 78.9 Six 2-0 Vicryl sutures anastomose the previously made hole in the bladder substitute to the urethra.

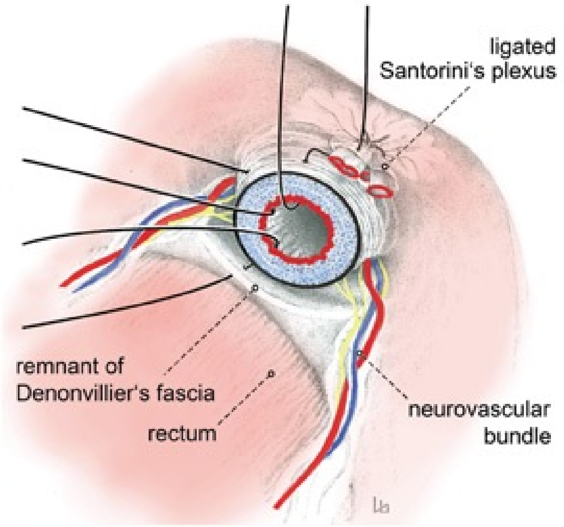

FIGURE 78.10 Two posterior sutures are placed medial to the neurovascular bundles including a generous portion of Denonvilliers fascia, two anterolaterally thereof through the lateral portion of the urethra, and two anteriorly, taking only a small part of the urethra but including the ligated Santorini plexus and the puboprostatic ligaments.

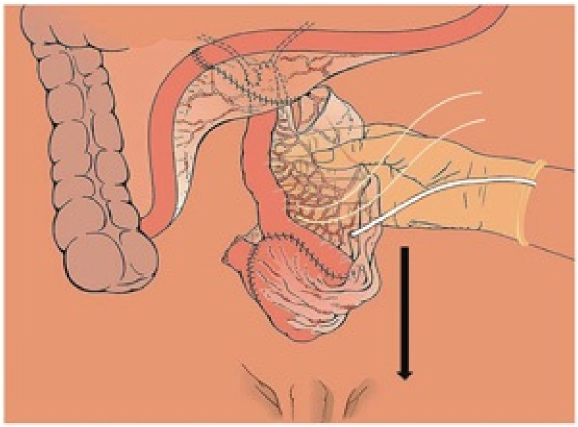

FIGURE 78.11 To aid bringing the bladder substitute down to the pelvic floor, gently pull on the root of the mesoileum of the bladder substitute.

Before complete closure of the reservoir, a cystostomy tube is passed through the wall of the bladder substitute and positioned so that its exit site is covered with mesenteric fat (Fig. 78.12).

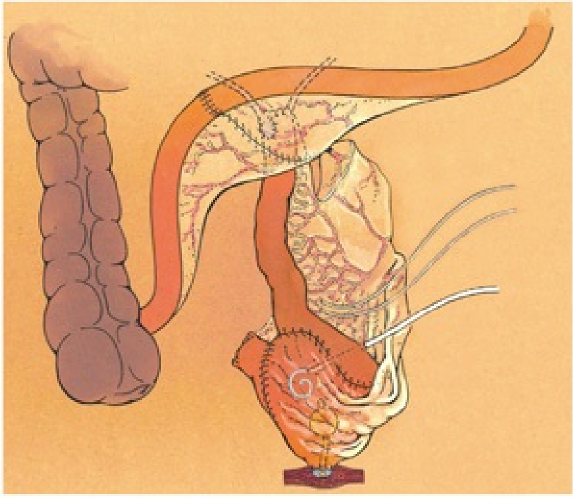

FIGURE 78.12 After insertion of a 10Fr cystostomy tube, the reservoir is closed completely.

Surgical Modifications for Obese Patients

An ileal neobladder can successfully be constructed and brought down into the pelvis of obese patients. A measure of whether the reservoir will work in obese patients is if the bowel 12 cm from the distal end of the harvested segment is able to reach the base of the penis. To ensure this will happen, the following steps should be employed. First, extend the distal mesenteric incision deeper into the mesentery; this will provide for increased mobility. If necessary, the serosa can be incised transversely at different levels, the incision has to be very superficial to avoid damaging the vessels (Fig. 78.13). In the case of obese patients, limit the amount of ileum used for construction of the reservoir as cross-folding of the thick mesoileum can be difficult. To decrease the thickness, fatty tissue between the distal vascular arcades can be removed.

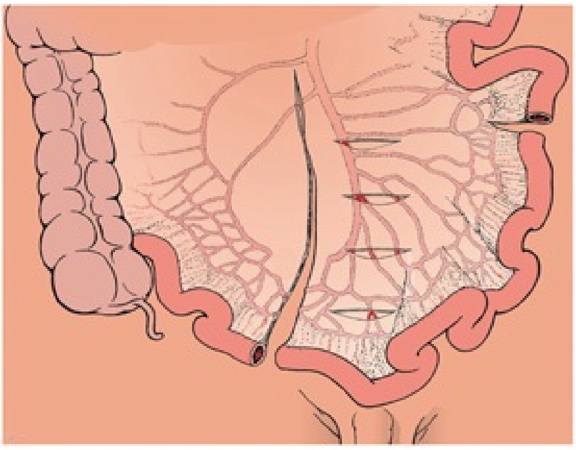

FIGURE 78.13 The distal mesenteric incision can be extended deeper into the mesentery and superficial transverse incisions of the serosa can be made to achieve more length.

Postoperative Care

Critical components to good long-term results include the ability to create a high-compliance, low-pressure reservoir with an effectual continence mechanism, as well as patient compliance and meticulous postoperative care. Ureteral stents are removed after bowel activity has resumed about 5 to 7 days after surgery. At 8 to 10 days postoperatively and after pouchography documents no evidence of urinary leakage, the cystostomy tube is removed. The Foley catheter remains for an additional 2 days to provide adequate time for closure of the cystostomy channel in the reservoir wall. Although our patients are on antibiotics, all drains are removed as early as possible to prevent infections. After the patient is drain-free, any bacteriuria is treated with antibiotics until the urine is sterile.

Patients are carefully instructed on how to void. Initially, they are instructed to empty the pouch every 2 hours during the daytime in a sitting position by relaxing the pelvic floor and increasing intra-abdominal pressure. At night, they are told to use an alarm clock to void every 3 hours. In the early phase, the urine is often hypo-osmolar; consequently, the bladder substitute will secrete sodium chloride, resulting in a salt-losing syndrome and therefore hypovolemia and metabolic acidosis. To prevent this series of metabolic events, patients are instructed to consume at least 2 L of liquid a day and to increase salt intake. They are prophylactically placed on sodium bicarbonate (2 to 6 g per day) after ureteral stent removal with the aim to attain a venous base excess between 0 and +2. Blood gas and body weight should be assessed at regular intervals during the initial phase after catheter removal.

Thereafter, patients without metabolic acidosis (no negative base excess) or those managed appropriately with oral intake of sodium bicarbonate are instructed to gradually increase their micturition intervals from 3 to 4 hours in order to obtain a bladder capacity of up to 500 mL. When adhering to these prolonged micturition intervals, increased pouch pressures may result in incontinence, but the elevated pressures are essential to increase the reservoir's capacity. Therefore, patients are advised to refrain from voiding when they experience incontinence, as otherwise, the bladder substitute will never achieve the desired capacity. Our patients are followed regularly every 6 months for the first 5 years and then at yearly intervals.

With increasing capacity, nighttime continence will improve; however, a reservoir capacity of >500 mL should be avoided. Overdistention of the reservoir will result in a floppy bag that is unable to empty adequately with increased residual urine, and the potential to develop urinary retention. Residual urine should be monitored, recognized early, and managed promptly. The cause of residual urine needs to be addressed (urethroscopy), and in the case of outlet obstruction, the obstructing tissue is incised or resected (4). Bacteriuria should be treated appropriately.

OUTCOMES

Complications

We published our 20-year experience with the ileal neobladder in 2006 (5). In our experience, early diversion-related complications (within 30 days) occurred in 13% of patients. Pyelonephritis was the predominant complication noted (5.8%). In a recent prospective randomized controlled trial, we were able to show that early complications can be significantly reduced by intraoperative fluid management. A restrictive fluid management combined with norepinephrine administration resulted in significantly less blood transfusions, major early complications, and a shorter hospital stay (6).

Diversion-related late complications (>30 days) that required rehospitalization were metabolic acidosis, pyelonephritis, and sepsis in 4.4%, 3.9%, and 2.1%, respectively, and urinary retention due to infection and consequent mucus production in 4.5% (4). Typical late complications requiring surgery were bladder substitute outlet obstruction in 12% and incisional or inguinal hernias in 10%.

A decline in renal function is observed in approximately 21% of patients with a bladder substitute (BS) after 10 years, which is lower than the 36% in patients with ileal conduits (IC) (7). In this retrospective study, obstruction was the leading and an independent risk factor for renal function deterioration in both IC and BS patients in a logistic regression analysis. In patients with diabetes or hypertension and an IC, the risk of experiencing a deterioration in renal function was significatly higher than in patients with a BS.

Functional Results

The technique described here has been performed at our institution for 30 years in more than 700 patients. Nerve sparing and a standardized technique has allowed for a gradual improvement of results. The majority of patients (>90%) void spontaneously and do not require intermittent self-catheterization. Ninety percent are continent during the day and 78% during the night when adhering to 3 to 4 hourly voiding intervals both during the day and night. Less than 10% require intermittent self-catheterization or have indwelling catheter for nursing home reasons. In addition to the performing the earlier detailed surgical technique correctly, meticulous postoperative care and follow-up is a prerequisite for successful outcome with this method of bladder substitution.

CHAPTER 79 ILEAL NEOBLADDER

RICHARD E. HAUTMANN

SURGICAL TECHNIQUE

Cystectomy (Radical Cystectomy)

This radical cystectomy (RC) section is restricted only to those parts that are essential for good function of the neobladder.

Modifications of pelvic lymphadenectomy and the approach to the pelvic ureter are made to allow for optimum ileal neobladder construction (1–4). Pelvic lymphadenectomy and RC are performed according to standard technique with modifications. Ideally, the ileal neobladder anatomically replaces the native bladder (i.e., it is located extraperitoneally in the pelvic cavity) and ileourethral anastomoses are located also extraperitoneally. Depending on tumor stage and location, this goal can be easily achieved by the creation of two large peritoneal flaps obtained from the visceral pelvic peritoneum (Fig. 79.1).

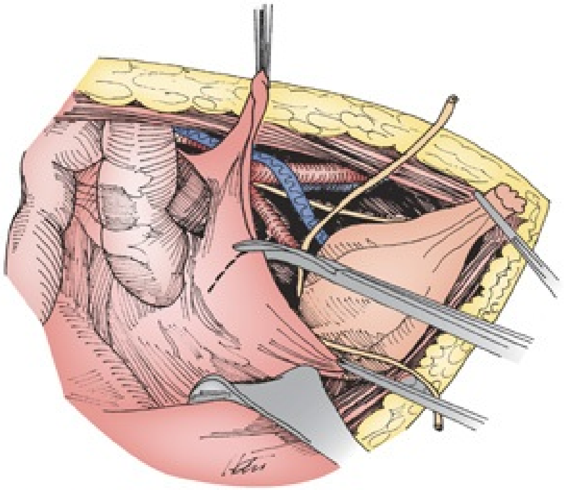

FIGURE 79.1 Modified pelvic lymph node dissection has been completed. Ureters are exposed extraperitoneally. The peritoneum over the bladder is bisected to create two large peritoneal flaps for later total extraperitonealization of the ileal neobladder.

Ureteral Mobilization

The standard vertical incision lateral to the sigmoid mesocolon should not be used. The peritoneal sac should be mobilized medially on both sides. The surgeon should continue to locate the ureter extraperitoneally, realizing that it is displaced during exposure because it adheres to the peritoneum (see Fig. 79.1). The ureters are mobilized with sufficient periureteral adventitia in a cephalad direction on both sides. A plane is established between the ureter and the lateral pedicles of the bladder. As the ureter and bladder are retracted medially, the lateral pedicle is exposed. Finally, the ureter is clamped distally. Fine-traction sutures are inserted in the proximal surface of the ureter, and it is divided against the clamps with scissors. Then, the ureter is dissected proximally so that not more than 3 to 6 cm are free.

Depending on tumor stage and location, the bladder is completely extraperitonealized, and the peritoneum is bisected over the bladder (see Fig. 79.1). If this cannot be done safely, an incision in the peritoneum is made high on the base of the bladder, leaving a peritoneal patch on the posterior bladder wall.

Approach to the Membranous Urethra in the Male Patient

Special details other than those described in Chapter 19 (RC in men) and Chapter 20 (RC in women) that are critical for a perfect outcome including preservation of the erectile function are presented here.

We describe a new technique for nerve-sparing RC and orthotopic diversion with preservation of the vasa deferentia, seminal vesicles, and neurovascular bundles (NVBs). No prostatic tissue is left behind, thus eliminating the risk of local recurrence from bladder cancer as well as de novo prostate cancer (5).

RC is begun with an intrafascial prostatectomy, which is done in a retrograde fashion. For optimal protection of the NVB and to avoid damage to the autonomic nerves running into the membranous urethra, a “high-release” approach with incision of the endopelvic and periprostatic fascia and bunching of Santorini plexus at the level of the prostate and not distal to it is of utmost importance (Figs. 79.2 and 79.3). The dorsolateral NVB can be separated from the prostatic capsule, or the prostatic capsule can be left in place. The prostatic apex is approached laterally directly along the prostatic capsule, and the membranous urethra is delivered sharply out of the donut-shaped prostatic apex to avoid nerve damage on the dorsolateral side of the urethra and to maintain maximum urethral length.

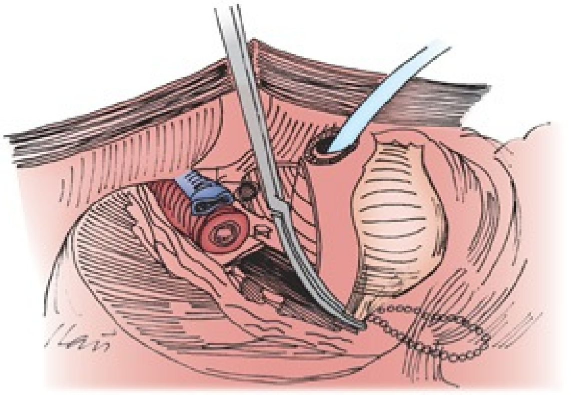

FIGURE 79.2 Standard dissection laterally to the prostatic fascia to free the NVBs from the prostate and the lateral surface of the seminal vesicles carries a high risk to ruin the erectile function by injuring these nerves.

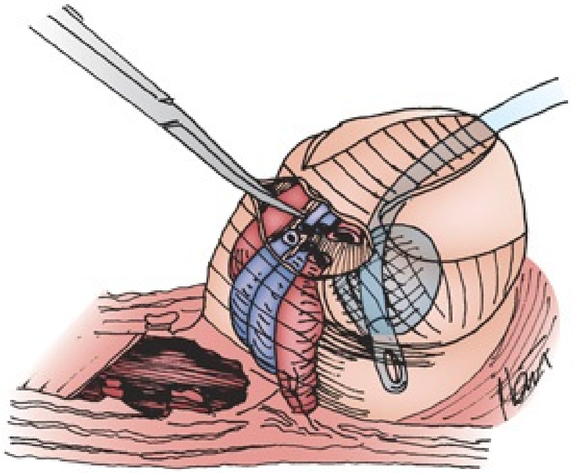

FIGURE 79.3 The radical cystectomy is begun as a standard nerve-sparing radical prostatectomy, with high release of the NVBs. Gentle traction is exerted on the balloon catheter to extrude the vesical neck. Denonvilliers fascia is opened with a short transverse incision over the ampullae of the vases and the base of the vesicles. After transection of vesicles and ampullae, an easy cleavage plane is developed between the trigone and catheter balloon anteriorly and the vesicles posteriorly until the cul-de-sac has been reached.

Despite the intrafascial approach, Denonvilliers fascia very often remains on the posterior surface of the prostate specimen where it is fused with the prostatic capsule in the midline. At the base of the prostate, a 2- to 3-cm transverse incision of Denonvilliers fascia is carried out, and both the vases and the seminal vesicles are transected (Fig. 79.4). A cleavage plane is easily developed anterior to the ampullae/seminal vesicles and dorsal to the trigone. The balloon of the transurethral catheter serves a control because it is easily palpated. In this fashion, most of the NVB are spared. The ascending cleavage plane easily reaches the cul-de-sac, with the inferior bladder pedicles still intact.

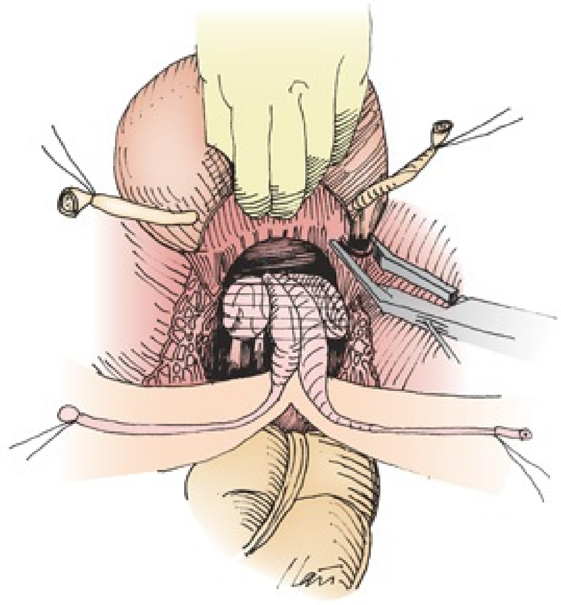

FIGURE 79.4 Posterior view. The plane anterior to seminal vesicles/ampullae of the vases and dorsal to the prostate has been developed. The posterior pedicle of the bladder is transected 3 cm ventral to the NVBs.

The remainder of the RC can be done in an ascending or descending fashion. The latter seems to offer better control of the bundles. The vases are identified and left on the pelvic peritoneum. The peritoneum is incised transversely 5 cm anterior to the cul-de-sac. Care is taken to enter the plane between posterior bladder wall ventrally and the vases and seminal vesicles dorsally (Fig. 79.5).

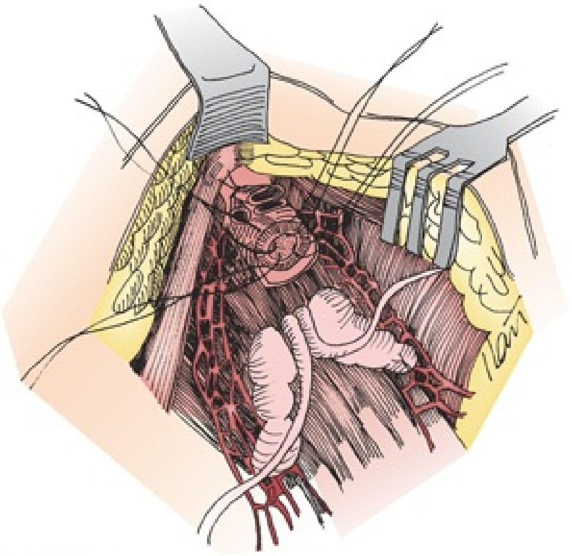

FIGURE 79.5 Final situation. NVBs covered and protected by seminal vesicles.

Approach to the Female Urethra

This is absolutely critical if an orthotopic neobladder is considered. Helpful tricks are as follows: Preparation of the urethra requires special attention to surgical detail to avoid damage to the proximal urethra, anterior vaginal wall, urethral support, and NVB, which could jeopardize the continence mechanism and micturition. This is particularly true when a nerve-sparing approach is planned (2).

This step is greatly facilitated when a povidone-iodine pack is placed into the vagina and the urethra rides on top of the anterior vaginal wall (Fig. 79.6). It is not sufficient just to put sponge stick into the vagina. Packing the vagina snugly has four distinct advantages:

1. The firm urethra is palpable at all times.
2. The urethra is lifted out of the depth of the pelvic cavity into the center of the operative field.
3. The NVBs slip downward and are no longer at risk.
4. The urethra (catheter) rides on top of the vagina and is visible and palpable at all times.

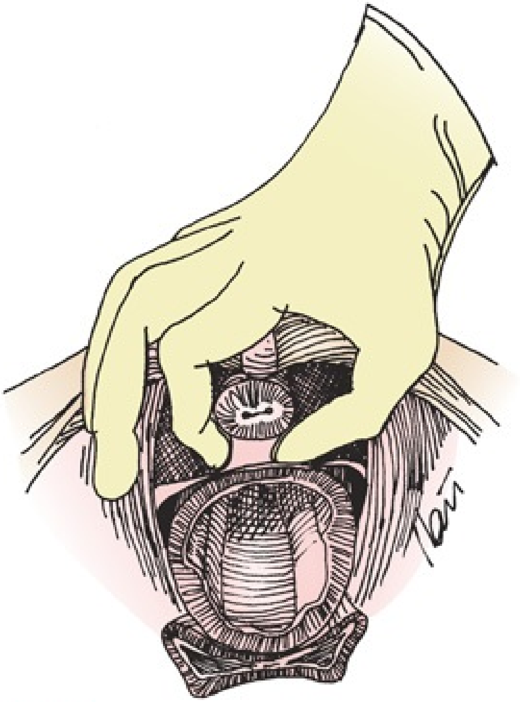

FIGURE 79.6 Packed vagina gives ideal exposure to urethra and pelvic support structures.

The endopelvic fascia is incised immediately lateral to the posterior urethra at the urethrovesical junction (Fig. 79.7). As much of the urethra at the urethropelvic ligament and paraurethral vascular and nerve plexus as possible must be saved.

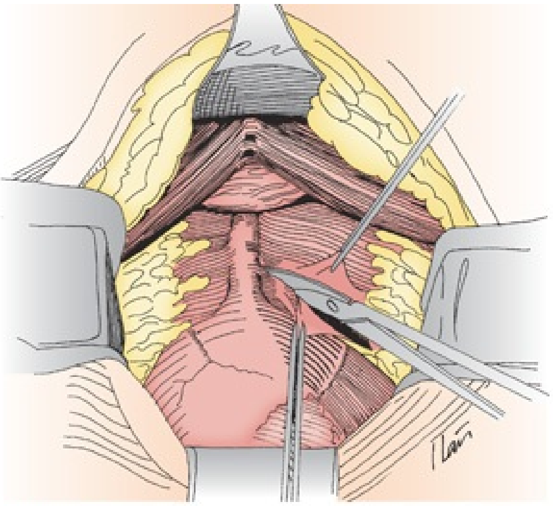

FIGURE 79.7 Urethral support-sparing cystectomy in women. Incision of endopelvic fascia is parallel to posterior urethra and urethrovesical junction.

The proximal urethra is carefully (little sponge stick) prepared. Most surgeons do not transect the urethra, but the bladder neck, assuming that the external sphincter mechanism is located in the proximal urethra. However, this is not the case. An extraordinary helpful trick to find the correct site for urethral transection is to inflate the balloon of the transurethral catheter to 50 mL, pull it into the bladder outlet, and to ligate proximal urethra and catheter before transection (Fig. 79.8).

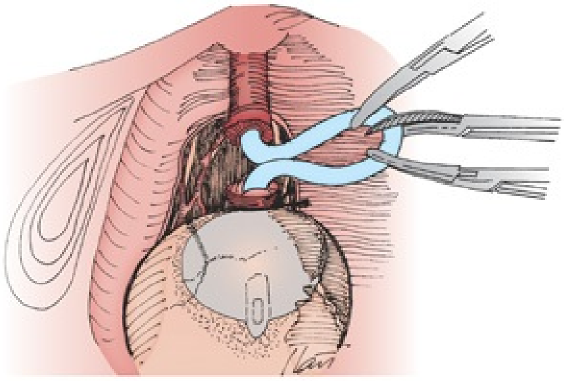

FIGURE 79.8 Balloon with 50 mL inflated. Proximal urethra including catheter ligated just distal to bladder neck. No bladder neck left behind.

As the proximal urethra is transected, six interrupted 2-0 polyglycolic acid sutures are placed circumferentially in the urethra (Fig. 79.9). Frozen sections for pathologic examination are taken from the urethra/bladder neck to identify carcinoma in situ or overt carcinoma, which would result in subsequent urethrectomy.

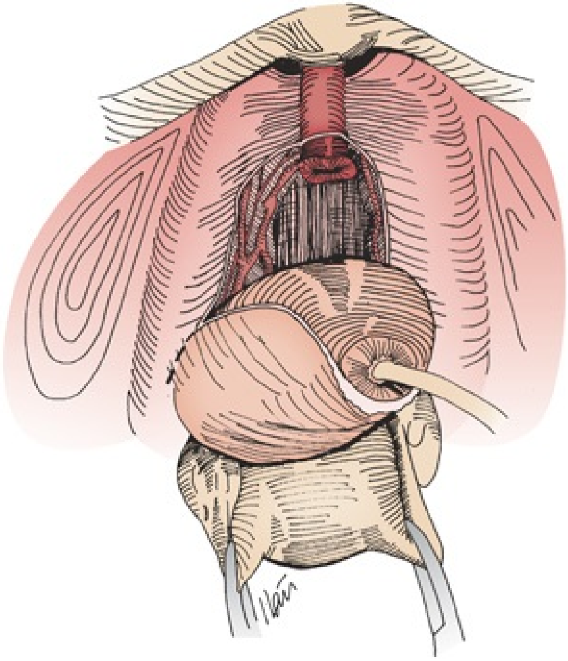

FIGURE 79.9 Urethra transected. Plane between specimen and anterior vaginal wall developed. NVBs/suspensory ligaments well prepared.

Next, the bladder neck is carefully dissected of the anterior vaginal wall. Upward traction of the specimen facilitates dissection between lateral bladder wall and supporting structures that must not be jeopardized. The urethrovesical junction is dissected off of the anterior vaginal wall down to the posterior bladder wall (see Fig. 79.9).

The remainder of the RC is done in a descending fashion. The cardinal ligaments are divided anteriorly to avoid the pelvic plexus. The superior vesical artery and the uterine vessels are cross-clamped, tied, and cut. Once the uterine artery is transected, the distal ureter comes into view and can be isolated to avoid damage to the nerve fibers. The vaginal cavity is entered by a transverse incision, and the edges of the vaginal incision are held open with Allis clamps (Fig. 79.10). The distal stump of the ureter following its division is pulled medially to facilitate dissection of the lateral bladder wall.

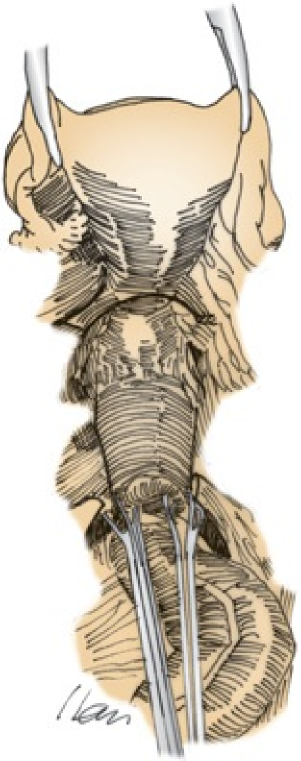

FIGURE 79.10 Posterior view. Uterosacral ligaments on both sides are divided. Edges of transverse incision in posterior fornix of vagina are held under gentle traction with Allis clamps. Posterior bladder wall is dissected off anterior vaginal wall down to bladder neck. Autonomic nerve fibers (inferior hypogastric plexus), which run laterally to vessels, are separated from lateral wall of bladder and vagina.

Figure 79.11 shows the final result with a remarkably small excisional defect and ideally saved anterior vaginal wall. The suspensory ligaments of urethra and vagina are fully intact (Fig. 79.12). Figure 79.12 shows neobladder on top of vagina anastomosed to the urethra.

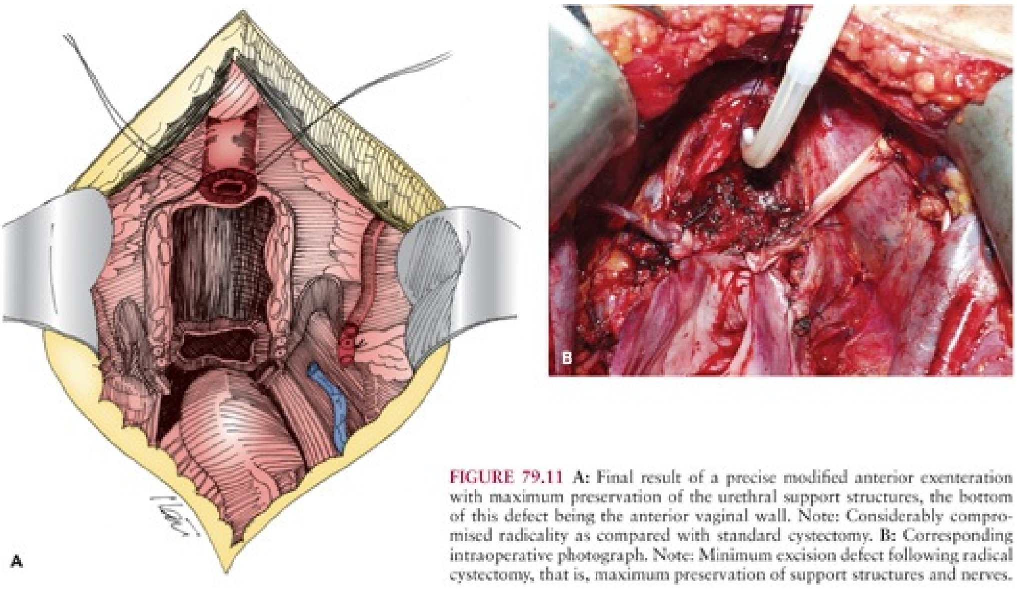

FIGURE 79.11 A: Final result of a precise modified anterior exenteration with maximum preservation of the urethral support structures, the bottom of this defect being the anterior vaginal wall. Note: Considerably compromised radicality as compared with standard cystectomy. B: Corresponding intraoperative photograph. Note: Minimum excision defect following radical cystectomy, that is, maximum preservation of support structures and nerves.

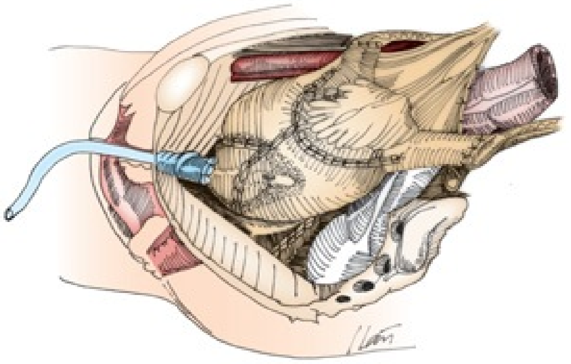

FIGURE 79.12 Final situation: neobladder on top anterior vaginal wall. Ileoureteral anastomoses above common iliac vessels. Left ureter courses lateral to sigmoid in its physiologic bed. Extraperitonealization of neobladder to follow (see Fig. 79.1).

Construction of the Reservoir

The light behind the mesentery should be adjusted, and a 60- to 70-cm long ileal segment should be selected 10 to 20 cm proximally from the ileocecal valve (2,6,7). Spasticity of the bowel or a thick, short mesentery may lead to more bowel than necessary, thus increasing the reservoir capacity. It is helpful to place two temporary stay sutures at the intended resection lines. They can be moved several times if necessary. The most dependable part of the segment should be long enough to reach the top of the symphysis pubica in the skin level. That point should be marked with a suture. This maneuver guarantees that the reservoir will reach the urethral remnant without difficulty. The distal division of the mesentery along the avascular region between the ileocolic artery and the terminal branches of the superior mesenteric artery should extend to the base of the mesentery to provide maximum mobility and sufficient length to reach the membranous urethra. The proximal incision of the mesentery is made as short as possible to provide maximum vascular supply to the ileal segment. The ileum is then divided between bowel clamps. A standard bowel anastomosis is performed, and the mesenteric trap is closed. The isolated bowel segment is thoroughly cleaned or rinsed with saline or an iodine solution (Fig. 79.13).

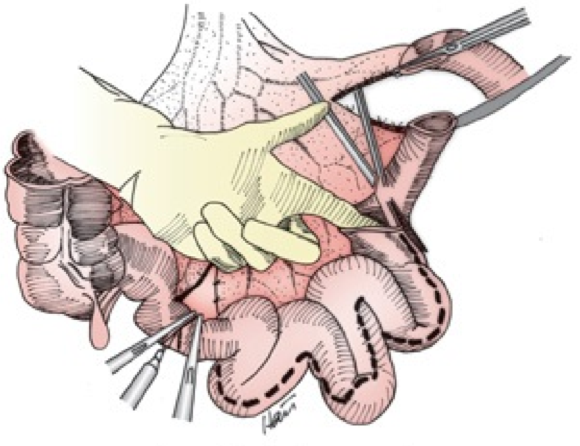

FIGURE 79.13 Selection of the ileal segment with an appropriate vascular supply and antimesenteric incision of ileum, except for the small chimneys on both sides of the W and the intended site of the ileourethral anastomosis (*broken line*).

Four lengths of ileum are arranged in the shape of a W with 3- to 5-cm long chimneys on each side of the W using five to six Babcock clamps or traction sutures. Other than the two chimneys, the bowel is opened on the antimesenteric border except for a 5- to 7-cm section centered around the marking suture, which is opened close to the antimesenteric border to create a U-shaped flap. Two to

3 cm from the tip of that flap, a buttonhole of all layers is excised from the ileal plate. An ileal plate is formed by sewing together the cut edges of the antimesenteric borders of the W using 2-0 synthetic absorbable sutures (SASs) on a straight needle (Fig. 79.14).

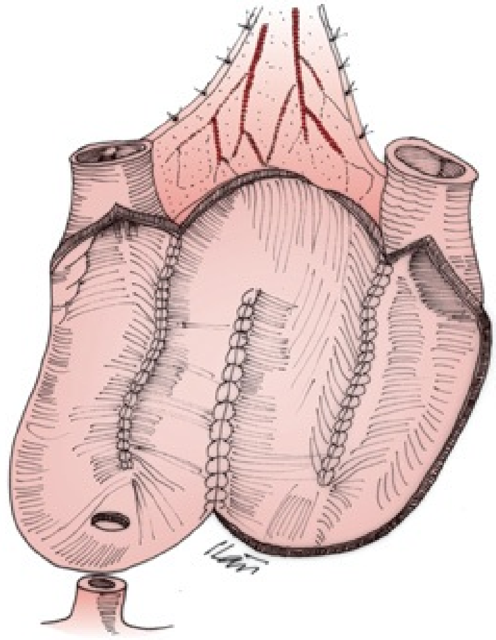

FIGURE 79.14 W-shaped reconfiguration of the intestinal segment after detubularization and asymmetrical incision of the ileal wall at the site of the anastomosis to the urethra, forming a U-shaped flap.

A 22Fr catheter is placed through the buttonhole. For the actual anastomosis, six previously placed double-armed sutures using 3-0 SAS in the urethra are used. The inner sutures are passed through the neobladder outlet in the ileal plate without grasping the ileum, and the corresponding outer sutures grasp the entire ileal wall 5 to 8 mm lateral to the neobladder outlet (Fig. 79.15). This guarantees a wide, ideal, funnel-shaped anastomosis so that mucosa is in direct contact with urethral epithelium. Next, under gentle traction on the transurethral catheter, the ileal plate is manipulated down to the urethral remnant, and the knots are tied inside the bowel (Fig. 79.16). The cut edges of the 5- to 7-cm U-shaped flap are sewn together over the catheter. The lower third of the anterior wall of the neobladder is closed, beginning inferiorly with interrupted 3-0 SAS (Fig. 79.17).

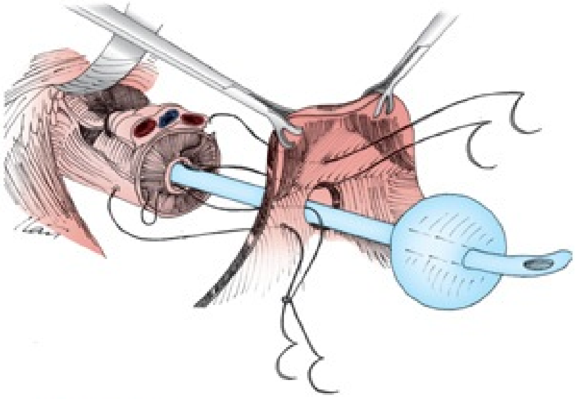

FIGURE 79.15 Ileourethral anastomosis, anterior view.

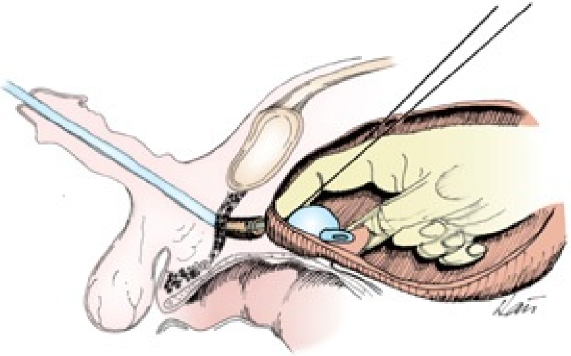

FIGURE 79.16 Lateral aspect of the ileourethral anastomosis. The sutures are tied from inside the ileal neobladder.

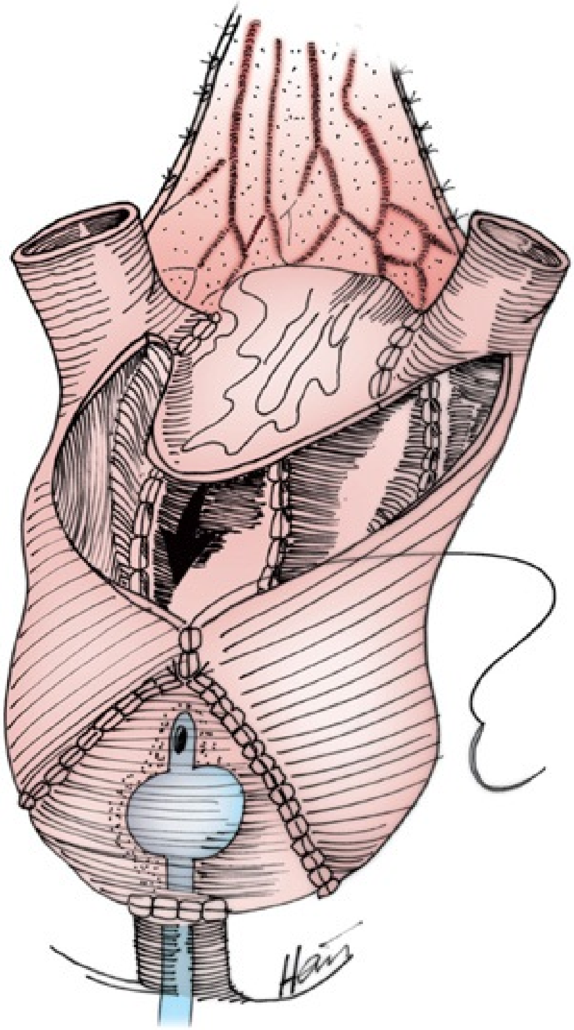

FIGURE 79.17 Closure of reservoir.

In 10% of patients, the ileourethral anastomosis may cause some difficulties. All gauzes, laps, and towels are removed, and gentle traction on the mesoileum is exerted with both hands (one behind and the other ventral to the ileal plate) to guide the neobladder down to the pelvic floor. Some or all of the following tricks are helpful (Fig. 79.18): loosening the retractor, straightening the operating table, removing the sacral cushion, neutralizing the extended position of the patient, bringing up the perineum with a sponge stick, freeing the cecum and descending colon as in retroperitoneal lymph node dissection (RPLND), moving up the neobladder outlet to the tip of the U-shaped flap, or performing an end-to-end anastomosis after tubularization of the U-shaped flap (Fig. 79.19). However, this should be done only as a “last resort” to reach the pelvic floor, if everything else fails. Any incisions into the mesentery of the neobladder should be avoided. The neobladder mesentery should not be pulled roughly to the pelvic floor.

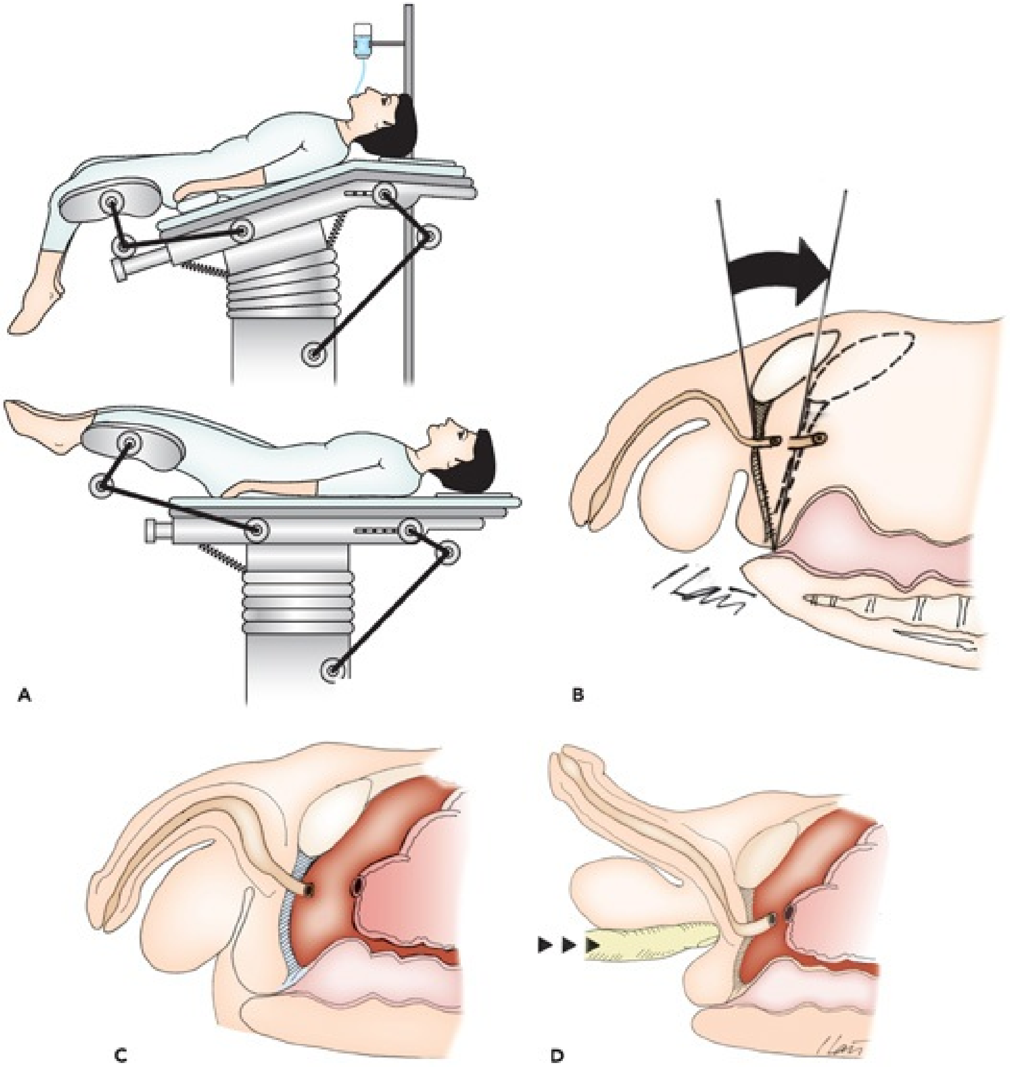

FIGURE 79.18 Methods to get the neobladder to the pelvic floor. A and B: Changing the extended position of the patient to slightly supine and removing the sacral cushion rotate the pelvic floor upward. C and D: Pushing up the perineum with a sponge stick or finger approximates the urethral remnant and neobladder.

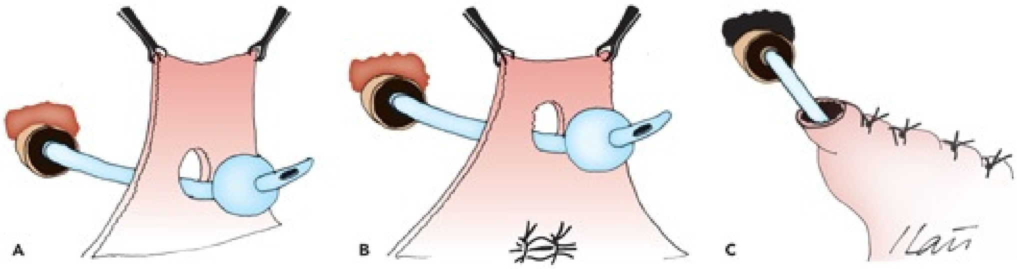

FIGURE 79.19 A–C: Moving the neobladder outlet closer to the tip of the U-shaped flap of ileal plate. If this still does not allow tension-free anastomosis, one should tubularize the U-shaped flap and perform direct (end-to-end) anastomosis.

Ileoureteral Anastomosis

Since 1996, we have been using a freely refluxing, open, end-to-side ureteroileal anastomosis, which is the simplest small-bowel surgery and which has reduced our nontumor related stenosis rate from 16.3% to 5.4%. Further advantages of this chimney modification are the extra length to reach the ureteral stump, the ease of surgery far outside the pelvic cavity, a tension-free anastomosis, no risk of ureteral angulation with neobladder filling, and a simplified flank access for revisional surgery (8–11).

On each side, the ureters are trimmed as appropriate for their chimney (Fig. 79.20). The ureterointestinal anastomosis can be done extraperitoneally above the common iliac vessels using a Bricker or Wallace (our choice) technique without competing with the bowel mesentery for an anastomotic site (see Fig. 79.20). After appropriate ureteral stents are placed, they are brought through the anterior neobladder suture line. The remaining anterior neobladder wall is closed in a T shape with running 3-0 SASs. No cystostomy tube is placed. Two 20Fr silicone drains are placed into the small pelvis.

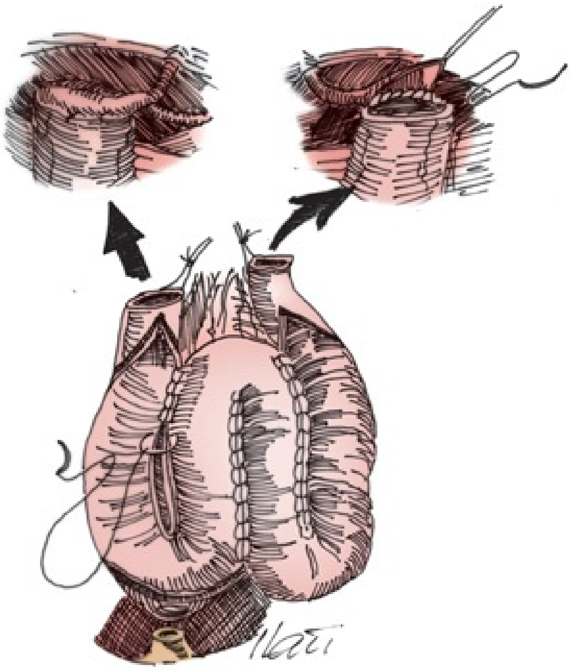

FIGURE 79.20 Refluxing ileoureteral anastomosis using chimneys of a 3- to 5-cm afferent limb on each side.

Using the two large peritoneal flaps from the visceral pelvic peritoneum, this goal can easily be reached (see Fig. 79.1). Both flaps are sewn together, except for the portion where the mesentery of the neobladder runs through them. The peritoneal cavity is closed in a standard fashion (Fig. 79.21). Alternatively, the flaps can be sewn to the posterior wall of the neobladder.

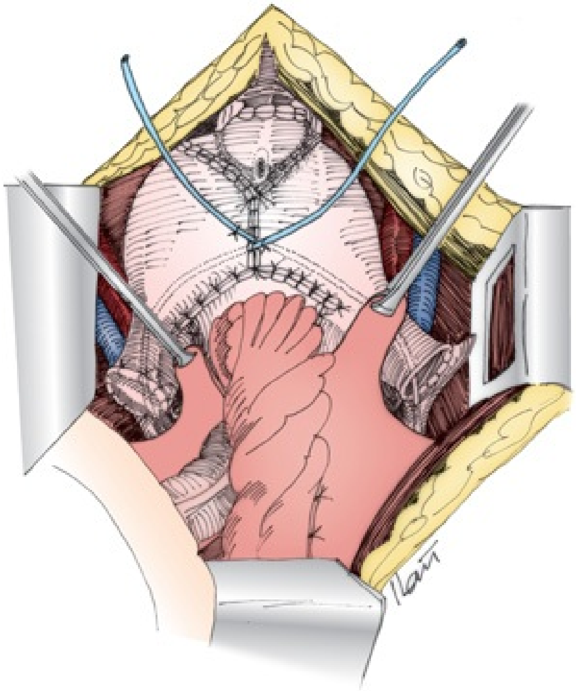

FIGURE 79.21 Completely extraperitoneal localization of the neobladder as well as ileourethral and ileoureteral anastomoses.

Excessive mucus production of the ileal bladder may rarely cause a problem by obstructing the urethral catheter in the postoperative course. Therefore, the ileal bladder is rinsed via the cystostomy with 50 to 100 mL of saline twice a day, starting on postoperative day 5. Routinely, the ureteral stents are removed between postoperative days 7 and 14.

As soon as the urine is in contact with the ileal bladder mucosa, reabsorption of urine electrolytes may occur. Therefore, the base excess is checked at weekly intervals for the first 4 weeks and monthly thereafter. Approximately 50% of all patients need temporary alkalinizing therapy.

The urethral catheter is removed between postoperative days 14 and 21, after a cystogram has demonstrated complete healing of the ileourethral anastomosis. Rarely, there is still leakage from the anastomosis. When this is occurs, it is treated by prolonged catheter drainage until the leak has closed spontaneously.

OUTCOMES

Complications

The complications of orthotopic bladder substitutes in the hands of the most experienced surgeons have been considered in detail (4,8–11). We believe that the morbidity of orthotopic bladder substitutes is actually similar to, or lower than, the true rates of morbidity after conduit formation, contrary to the popular view that conduits are simple and safe.

There are several new complications unknown during the conduit era, including incisional hernias, as a consequence of the Valsalva maneuver: neobladder-intestinal and neobladder-cutaneous fistulas, mucus formation, and neobladder rupture. The secretion of mucus can be dramatically increased.

Spontaneous late rupture of neobladders is a rare but potentially life-threatening complication. In the majority of cases, it is secondary to acute or chronic overdistention and bacterial infection. Other factors are minor blunt abdominal trauma or urethral occlusion. Chronic ischemic changes of the neobladder’s wall, possibly facilitated by detubularization and the variability of the mesenteric circulation, are additional factors that lead to perforation. The rupture site is typically the upper part of the right side of the reservoir. This is the most mobile part of the reservoir and undergoes the most marked distention during overfilling, which may constitute an additional factor for perforation in this location. There is no reliable procedure to establish the diagnosis. Cystography is misleading in three of four patients with neobladder rupture. A high index of suspicion and early aggressive operative treatment in patients suspected of having a neobladder rupture are instrumental in providing a successful outcome. Prevention of neobladder rupture comprises careful monitoring of neobladder emptying. Physicians must be aware of the risk of rupture. Patients must be encouraged to void regularly, especially at bedtime, and perform clean intermittent self-catheterization to avoid chronic reservoir overdistention. In the event of anesthesia, proper bladder drainage should be performed.

Results

In some studies, perioperative death occurred in 3% of patients. Neobladder-related early and late complications occurred in 15% and 23% of patients, respectively. Neobladder-related early and late abdominal reoperation rates were 0.3% and 4%, respectively. Perioperative neobladder-unrelated early complications were observed in 33%, and 12% of patients required operative treatment. Late postoperative complications unrelated to the neobladder occurred in 12% of patients, and 5%

required open surgical revision. Ninety-six percent of male patients voided spontaneously, 4% performed clean intermittent catheterization in some form, and 1.7% performed regular intermittent catheterization. Thirty percent to 40% of women required some form of intermittent catheterization to completely empty their neobladder (7,9). Daytime and nighttime continence was reported as good by 96% and satisfactory by 95% of patients. Unacceptable daytime continence requiring more than one pad per day occurred in only 4% of patients, and only 5% were wetting more than one pad per night.

CHAPTER 80 COLONIC ORTHOTOPIC BLADDER SUBSTITUTION

JOACHIM W. THÜROFF AND LUDGER FRANZARING

Orthotopic bladder substitution can be realized from ileum only or from colonic segments either alone (1,2) or in combination with small bowel segments as a composite reservoir (3–8). The rationale of using large bowel for urinary diversion is based on anatomic and functional considerations. Surgical creation of a urinary reservoir from bowel segments generally means transformation of a cylinder into a sphere (9). The length of bowel to be excluded from the intestinal tract for formation of a reservoir of a given capacity depends on the diameter of bowel used to create the reservoir. In the volume formula of a cylinder ($V = \pi r^2 \cdot l$), the radius determines the volume by its second power; hence, the larger the bowel diameter, the less proportional bowel length is required. Thus, large bowel with its greater diameter can contribute significant capacity to a continent reservoir despite only a shorter segment having to be excluded from bowel continuity.

Physiologically, fat-soluble vitamins (A, D, E, K) and water-soluble vitamins B_{12} and folic acid as well as biliary acids are all absorbed from the entire ileum but not from colon. Consequently, possible malabsorption syndromes are related only to resection of ileum but not to colon resection. The critical length of ileum resection is about 60 cm above, which the risk of secondary malabsorption syndromes starts to increase. These facts should influence choice of bowel segments for reservoir formation in favor of reducing the length of ileum segments for a composite reservoir or of avoiding ileum entirely in an all-colon reservoir (10–12).

However, the large bowel is less distensible than small bowel (13). Although at first, this may be regarded as a disadvantage, it may be advantageous, specifically for spontaneous voiding from an orthotopic bladder substitute in the long run. Intestinal urinary reservoirs start their life at a surgically determined volume that increases over time by gradual distention. During this process, large bowel segments have the advantage that the longitudinal arrangement of taeniae prevents the development of a decompensated substitute megacystis as has been described for ileum reservoirs requiring in up to 60% of females emptying of the orthotopic bladder substitute by intermittent self-catheterization. In addition, large bowel segments, especially cecum and ascending colon, offer several alternatives for safe and effective antirefluxive ureteral implantation.

The downsides of using large bowel for creation of an orthotopic reservoir have to be weighed against the advantages of large capacity, less malabsorption, less overdistention, and reliable antireflux techniques.

First, many urologic surgeons are not familiar with large bowel surgery and feel uncomfortable with it, specifically when performing the bowel anastomosis after resection of the segments for the urinary reservoir. Second, generous mobilization and rotation of segments is required to allow a tension-free transposition as an orthotopic reservoir into the true pelvis. Surgical techniques using large bowel may also be more time-consuming because adhesions with the greater omentum have to be freed.

The different techniques of constructing an orthotopic reservoir, either from large bowel only or in combination with small bowel segments as a composite reservoir, refer to the very same principles of continent urinary diversion: detubularization and spherical reconfiguration (14). Thus, the success of orthotopic bladder substitution is not confined to selection of small bowel segments; good results have been reported with the ileocecal segment, the right colon, and the sigmoid colon. However, the physiology of large bowel segments changes from proximally to distally with decreasing capacity and compliance and increasing wall tension and intraluminal pressures. This translates into higher capacity and lower pressure of the cecum and ascending colon as compared to the descending and sigmoid colon. The surgical technique of the Mainz ileocecal pouch as described in the following in detail (8) may in this context serve as a general example of construction of an ileocolonic composite pouch.

However, one single technique of continent urinary diversion does not fit all patients and all pathologies. Thus, modern concepts of intestinal urinary diversion require surgical versatility for individualization of the surgical technique according to the requirements of the underlying pathology and the wishes of the patient.

DIAGNOSIS

The scope of diagnostic studies is determined by the underlying disease because of which the native bladder has to be substituted. For continent urinary diversion as compared to incontinent diversion, the most important assessment is upper urinary tract morphology and renal function. Grossly dilated upper urinary tracts may not drain as well into a continent urinary reservoir as into an incontinent zero-pressure conduit diversion. Every intestinal urinary reservoir reabsorbs hydrogen and chloride ions. The resulting metabolic acidosis is generally balanced by respiratory compensation and by an increased renal acid secretion. As a consequence, renal reserve must be sufficient as judged by a glomerular filtration rate better than a minimum of 50% of the age-related normal global renal function.

The intestinal tract must be evaluated in order to avoid surgical or postoperative problems. Concerning patient history, special attention must be paid to inflammatory bowel disease, prior abdominal surgery or radiotherapy, and related abnormalities of stool and defecation. When large bowel segments are used for continent diversion, radiographic imaging or colonoscopy is mandatory to exclude asymptomatic tumors of the large bowel.

INDICATIONS FOR SURGERY

The indications for a colonic orthotopic bladder substitute or a composite reservoir of ileum and colon are not different from those for ileal orthotopic bladder substitution (15). However, in patients with neurogenic anal sphincter incompetence, any change in stool consistency secondary to bowel resection bears the risk of worsening a preexisting anal incontinence. Another aspect of all forms of orthotopic bladder substitution, specifically in women, is the risk of urinary retention requiring emptying of the reservoir by intermittent catheterization (16–18). Thus, the willingness and ability to perform intermittent self-catheterization have to be determined and possibly practiced preoperatively. This is of special importance in women, patients with neurogenic bladder, and children (11,12). Generally, children may be able to perform intermittent self-catheterization of the urethra from about 6 years of age.

ALTERNATIVE THERAPY

Alternatives to orthotopic bladder substitution with colonic segments are orthotopic ileal neobladders (15). Alternatives to continent orthotopic bladder substitution are continent cutaneous urinary diversion (e.g., Mainz Pouch I, Indiana Pouch) or continent anal urinary diversion (Mainz Pouch II). Alternatives to continent urinary diversion are incontinent conduit diversions (ileal conduit, sigmoid conduit, transverse colonic conduit).

SURGICAL TECHNIQUE

The day before surgery, the bowel is cleansed by oral administration of 3 L of polyethylene glycol. Perioperative parenteral antibiotic therapy with broad-spectrum antibiotics should include antianaerobic activity (e.g., ampicillin/clavulanic acid and metronidazole). The antibiotics are administered 1 hour before surgery and continued until the fifth to seventh postoperative day.

The patient is positioned supine on the operating table. Radical cystoprostatectomy should adhere to the same principles as radical prostatectomy: that is, to preserve maximum urethral length and, if possible and indicated, to preserve the neurovascular bundles (19,20).

For ileocecal orthotopic bladder substitution (8), the cecum and ascending colon are mobilized beyond the right colonic flexure. Extended mobilization is helpful for easy transposition of the pouch into the small pelvis.

The terminal 30 cm of ileum and 10 cm of cecum and ascending colon are isolated from bowel continuity. The 10 cm of prevalvular ileum and the ileocecal valve will not be opened antimesenterically because the prevalvular ileum will be used for ureter implantation with the ileocecal valve as antireflux mechanism. If the ureters have to be resected short, for example, because of tumor extension/dysplasia or because of radiation damage, a longer segment of prevalvular ileum may be used as ileal substitute for both ureters (see Fig. 80.1 N and O). However, this requires accordingly longer segments of ileum, specifically prevalvular ileum, to be excluded from bowel continuity at this stage.

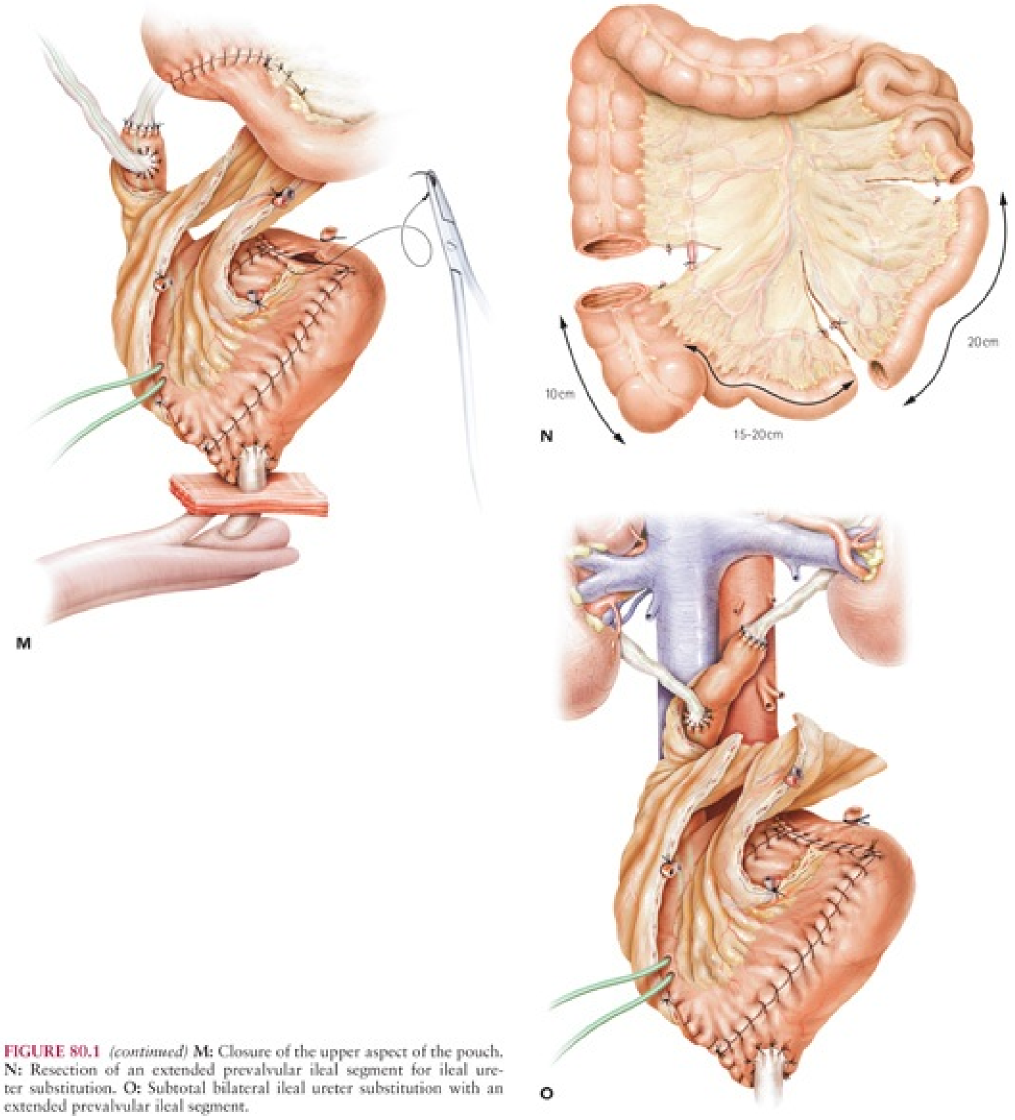

FIGURE 80.1 *(continued)* M: Closure of the upper aspect of the pouch. N: Resection of an extended prevalvular ileal segment for ileal ureter substitution. O: Subtotal bilateral ileal ureter substitution with an extended prevalvular ileal segment.

A Foley balloon catheter is proximally inserted into the ileum of the excluded bowel segments, which are irrigated with generous amounts of saline until the irrigation fluid appears clear. Thereafter, the proximal 20 cm of ileum is separated from the terminal 10 cm (or longer for ileal ureter substitution) of prevalvular ileum, with transection of the superficial arcade of the mesentery only. The appendix is resected.

The intestinal continuity is restored by a spatulated end-to-end ileoascendostomy. The single-row seromuscular anastomosis is established with running 4-0 glyconate sutures.

The separated proximal loop of 20 cm ileum as well as cecum and ascending colon are split open at their antimesenteric borders. The posterior wall of the pouch is completed by side-to-side anastomoses of the separated 20 cm of ileum in a U-shaped configuration to each other and with the ascending colon. The anastomoses are performed by single-row, all-layer running sutures of 4-0 polydioxanone on a straight needle. For closure of the anterior wall of the pouch, the bowel segments are opposed to each other in a door-wing fashion. The anterior wall of the pouch is established as side-to-side anastomosis between ileum and colon with single-row, all-layer running 4-0 polydioxanone sutures on a straight needle. The upper aspect of the pouch is closed with single-row, all-layer 4-0 running glyconate sutures; however, the lower aspect remains open at this stage.

The blood supply of ileocecal reservoirs is based on the ileocolic artery, which always allows tension-free anastomosis to the urethra when a 180-degree counterclockwise rotation of the pouch is performed with the insertion of the ileocolic vessels as axis of rotation. This brings the upper aspect of the pouch (ascending colon) to the urethra and the ileocecal region behind the mesentery into a cranial position on the right side. In pure right colonic pouches, with additional blood supply from the right colonic artery, reaching down to the urethral stump may sometimes be more difficult (Fig. 80.2). The blood supply of the sigmoid colon is from the inferior mesenteric and superior rectal arteries (Fig. 80.3). Sigmoid reservoirs thus always easily reach down to the urethral stump (Fig. 80.4).

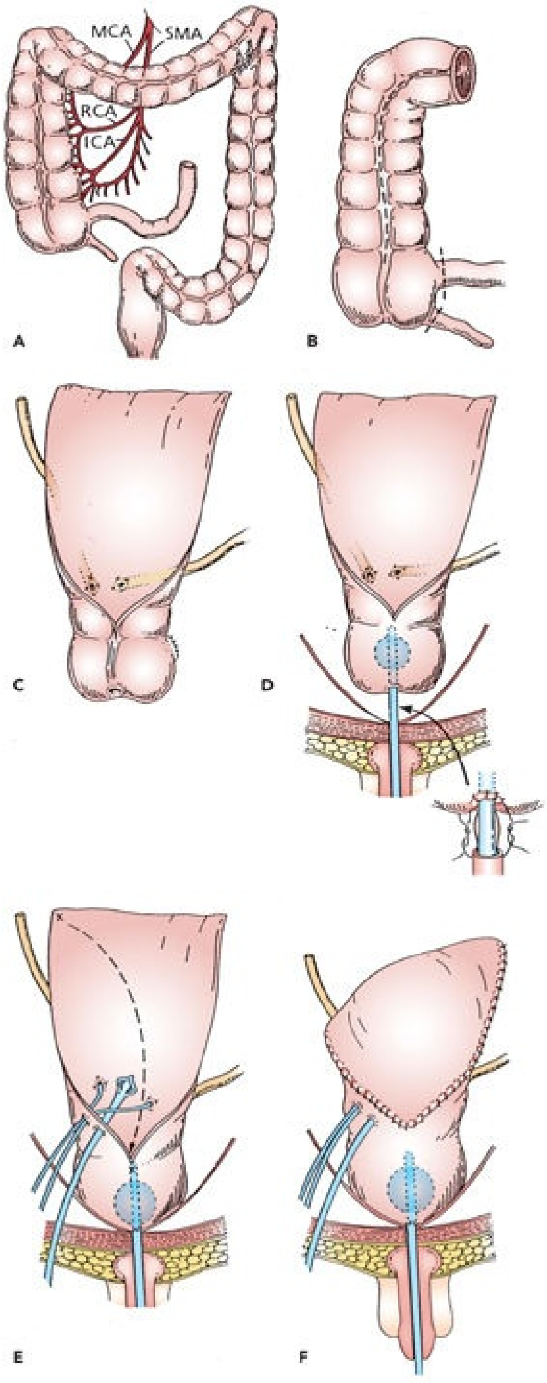

FIGURE 80.2 Construction of a right colonic reservoir (1). **A and B:** Isolation of a colonic segment consisting of cecum, ascending colon, and the right colic flexure. **C and D:** Opening of the segment through the taenia libera, leaving the cecum intact and anastomosing it to the urethra. **E and F:** The ureters are anastomosed into the colonic segment using the "buttonhole" submucosal implantation technique. This technique describes the ureters entering the submucosal tunnel via a buttonhole incision into the posterior wall of the pouch. Reconfiguration is completed by folding the open cranial segment over the caudal segment and anastomosing both lateral margins. *ICA*, ileocecal artery; *MCA*, middle colonic artery; *RCA*, right colonic artery; *SMA*, superior mesenteric artery.

Ureteral Implantation

A variety of techniques reflects the surgical challenge to create an antireflux mechanism without obstruction of the ureter. This challenge may be increased by a number of pathologic conditions in the individual patient. Ureters may be dilated, fibrotic, or ischemic secondary to obstruction, previous surgery, or radiotherapy. Bowel segments may be altered from inflammation, dilatation, or ischemia secondary to inflammatory bowel disease, previous surgery, or radiotherapy. Mechanical factors (e.g., position changes of the reservoir) or biochemical factors (e.g., effects of urine on the ureteral adventitia or on the intestinal mucosa) may have long-term effects on the whole system.

The rationale of implanting the ureters by an antirefluxive technique into an orthotopic bladder substitute is to protect the upper urinary tracts from retrogradely transmitted pressure peaks and from ascending bacteriuria. However, the standard technique of antirefluxive ureteral implantation into large bowel was conceived from ureterosigmoidostomy, which means diverting urine into a high-pressure reservoir containing feces and urine. The necessity of antirefluxive ureteral implantation into orthotopic low-pressure reservoirs is questioned because they provide a pop-off mechanism when overfilled—unlike most forms of continent cutaneous diversion—by transurethral urinary leakage. Another argument is a supposedly lower bacterial contamination rate as compared to continent cutaneous reservoirs that require intermittent catheterization. Nevertheless, protection from poucho-renal reflux remains an advantage, if it can be achieved without an additional risk of introducing ureteral anastomotic obstruction by the surgical technique. A variety of different antireflux mechanisms have been described, which may be classified into two general types. In one type, the ureter itself is part of the antireflux mechanism, whereas in the other type a bowel-derived antireflux mechanism is interposed between ureters and reservoir.

In any case, for implantation of the ureters into cecum or ascending colon, the left ureter has to be rerouted into the right retroperitoneum preferably above the inferior mesenteric artery as for ileal conduit diversion.

Antirefluxive ureteral implantation techniques, in which the ureter becomes part of the antireflux mechanism, mostly follow the “flap-valve” principle: An oblique entry of the ureter into the reservoir is created with a submucosal “tunnel” course that allows transmission of the reservoir pressure onto the ureter and against the seromuscular layer of the reservoir. This pressure transmission passively compresses the ureter with rising reservoir pressures. The most frequently used principles to transmit the reservoir pressure to the ureter are the submucosal tunnel technique and the seromuscular extramural tunnel technique.

In the submucosal tunnel technique (1,2,7,11,12), both ureters are implanted into the colon with a 2- to 3-cm submucosal tunnel. Ureters are anchored with 6-0 glyconate sutures to the muscularis of the bowel wall, and the neo-orifices are established by 6-0 glyconate or 7-0 polyglycolic acid ureteromucosal sutures.

In the orthotopic Mainz pouch, protection from reflux between the urinary reservoir and the kidneys is provided by the antireflux function of the ileocecal valve (3,8). The cecum with the ileocecal valve is incorporated into the pouch, and the right ureter is anastomosed in an end-to-side technique (Nesbit) and the left ureter in a spatulated end-to-end technique (Wallace) into the terminal prevalvular ileum. Thus, the flow of urine is directed from the ureters into the pouch through the ileocecal valve. Separate implantation of the ureters into the prevalvular ileum has the advantage over common Wallace-plate implantation, that surgical revision of a single ureter, for example, because of obstruction or ureteral tumor recurrence is possible without dealing with the other ureter.

The ureters are stented with 6Fr or 8Fr stents, which are routed through the ileocecal valve and brought out through the reservoir wall. For pouch drainage, a 10Fr pouchostomy pigtail catheter is placed into the reservoir. The anastomosis of the pouch with the urethra is performed at the lowest aspect of the pouch as determined with an into the pouch inserted finger. Generally, this is a colonic segment (ascending colon), into which on the inserted finger a 3-mm transverse incision is performed. The mucosa is everted with several 4-0 polyglytone rapidly absorbable monofilament sutures. A 20Fr Foley balloon catheter is inserted transurethrally into the reservoir. The urethral anastomosis is completed using the eight 4-0 glyconate monofilament double armed sutures with two 5/8 needles (FR26), which had been previously at the stage of cystectomy placed through the urethral stump. Closure of the upper aspect of the pouch is completed in the same way as described previously. A 20Fr gravity drain is placed each into the small pelvis and at the ureteral implantation site.

Ureteral stents are removed at day 10 and 11. The transurethral catheter is removed at day 12 when a pouchogram has ruled out extravasation. Residual urine is checked via the pouchostomy catheter when the patient voids spontaneously. The pouchostomy catheter is removed at residual urine volumes <50 mL. In neurogenic cases, patients are instructed in intermittent catheterization.

OUTCOMES

Complications

In the early postoperative months, nonperistaltic contractions of the bowel segments of a Mainz pouch do occur but subside spontaneously with increasing capacity of the pouch. In case of persistent inadequate compliance or persistent contractions of the pouch, antimuscarinics may be used for pharmacotherapy.

About 60% of patients postoperatively have an asymptomatic metabolic acidosis, which can be diagnosed by venous blood gas analysis and should be prophylactically balanced at a base excess below −2.5 by oral alkali substitution (sodium/potassium citrate/bicarbonate) (10).

The risk of secondary malignancies is low, albeit higher than in ileal neobladders (21,22). Follow-up examinations must include renal ultrasound and/or intravenous pyelogram, blood gases, and, starting from the fifth postoperative year, pouchoscopy and evaluation of serum cobalamin (10,12).

Results

In general, the outcome criteria for orthotopic bladder substitution with intestine are (a) function and morphology of the upper urinary tracts, (b) urinary frequency during day and night, (c) continence during day and night, and (d) ability to void spontaneously. However, one has to keep in mind, that especially continence and the ability for spontaneous micturition may significantly be influenced by the type and quality of surgery preceding the orthotopic substitution itself. Related factors are, for example, preparation of the bladder neck and urethra, sparing of the autonomous nerves (19,20,23), and measures to prevent posterior pouch displacement or pouch-urethral kinking, specifically in females (16). Therefore, functional results attributed to specific kinds of reservoirs actually rely on more factors than the segment(s) of intestine chosen. For ileocecal reservoirs with submucosal tunnel implantation of ureters, a ureterointestinal obstruction rate of up to 7% is reported (24). Continence rates for ileocecal reservoirs vary between 75% and 88% during the day and 67% during the night (4,25). Continence rates for sigmoid colon reservoirs are significantly lower (25).

CHAPTER 81 CONTINENT CATHETERIZABLE RESERVOIR MADE FROM ILEUM

HASSAN ABOL-ENEIN AND MOHAMED A. GHONEIM

A substantial number of techniques have been described for the creation of continent cutaneous urinary reservoirs. For construction of such systems, three elements are required: a low-pressure compliant reservoir, an antirefluxive ureterointestinal anastomosis, and a continent stoma that allows easy catheterization.

To create a reservoir with high capacity at low pressure, various segments of bowel have been utilized: the ileum, the ileocolonic region, the ascending colon, and the transverse colon. Regardless of the selected bowel segment, detubularization and double folding are basic prerequisites to achieve this goal.

A reliable antirefluxive ureterointestinal anastomosis is necessary, since bacteriuria is a constant feature in these systems and results from intermittent catheterization. The technique employed should provide a unidirectional but nonobstructed flow. The antirefluxing mechanism should not be at the expense of a higher incidence of obstructive complications.

Hinman (1) classified continent outlets into four categories according to the mechanism of their action. These included an antiperistaltic ileal segment (2); imbricated or tapered ileal segments resulting in passive tubular resistance (3); outlets using the pressure equilibration principle, including an ileal spout valve (4), flutter valve (5), inkwell hydraulic valve, intussusception nipple (6), or ileal servomechanism sphincter (7); and flap valves, which are created by the incorporation of tubular structures within the wall of the reservoir, such as the appendix (8), fallopian tubes (9), parts of ileum (10), or tubularized cecal segments (11). Multiplicity of techniques implies that none is optimal. Many of the previously mentioned techniques rely on an inert or even unphysiologic mechanism, and problems and malfunctions soon appear.

In our proposed technique, we have utilized the ileum for construction of the low-pressure reservoir and a serous-lined tunnel to provide an antirefluxive mechanism (12) as well as to create a reliable continent outlet (13).

INDICATIONS FOR SURGERY

Any patient who requires bladder replacement is a potential candidate for this operation. The indications of continent cutaneous urinary diversion include the following:

1. Pelvic malignancies: in patients for whom cystectomy is indicated for bladder cancer or those requiring an anterior pelvic exenteration for other pelvic malignancies
2. Benign indications: These include neuropathic bladders when conservative measures fail, extensive urethral strictures with damaged urethral sphincter, contracted bladders with compromised urinary continence, complex urinary fistulas affecting the sphincteric mechanism, and some cases of bladder exstrophy with failed attempts of primary repair.
3. Urinary conversion: conversion from other types of urinary diversion, such as ileal conduits in young healthy patients, for patients who develop isolated urethral recurrence following radical cystectomy and orthotopic bladder substitution, and in some cases of ureterosigmoidostomy suffering from intractable metabolic acidosis

PATIENT SELECTION AND EVALUATION

Suitable candidates should have reasonable manual dexterity. Motivation to carry out clean intermittent catheterization at regular intervals is necessary. Furthermore, a good prognosis might be expected if the indication to diversion was a pelvic malignancy. Patients who are unfit for prolonged surgery and those with a history of previous bowel resection, short bowel syndrome, or heavily irradiated bowel are among the contraindications for this procedure. Patients with impaired renal function (serum creatinine equal to or >1.8 mg per dL and/or creatinine clearance equal to or <40 mL per minute) are unsuitable candidates since metabolic acidosis would be inevitable.

ALTERNATIVE THERAPY

Alternative techniques of urinary diversion should be discussed with the patient when orthotopic bladder substitution or continent cutaneous reservoirs are contraindicated or unfeasible. These include conduit diversion and anal sphincter–controlled bladder substitutes. The potential postoperative complications, changes in future lifestyle, and long-term sequelae should be clearly explained to the patients.

SURGICAL TECHNIQUE

Preoperative Preparation

Since the small bowel is utilized, no specific preparation is necessary. The only requirement is fasting overnight with administration of intravenous fluids to ensure good hydration. Patients with histories of thromboembolic disease or varicose veins should receive a prophylactic dose of heparin (5,000 U subcutaneously) the night before the operation and every 12 hours thereafter until ambulation. Compression leg stockings are also advised. Although the intention is to use a concealed umbilical stoma, a stoma therapist should examine the patient and determine a suitable site for an abdominal stoma. A parenteral broad-spectrum antibiotic is given just before induction of anesthesia and continued postoperatively for 3 days.

Operative Technique

The patient is put in the supine position with a Trendelenburg tilt. Slight flexion of the knees will further help in the relaxation of the abdominal muscles, facilitate retraction, and provide wider exposure. If total urethrectomy is planned, the patient is put in a slight lithotomy position for access to the perineum. The surgical area to be sterilized and draped extends from the lower chest down to the upper thighs.

A midline incision from the pubis inferiorly to a point halfway between the umbilicus and xiphoid process of the sternum superiorly is generally employed. The incision is encircling the umbilicus by 2 to 3 cm to the left.

The bowel is examined, and a 60-cm long segment of the terminal ileum is isolated. Backlight transillumination of the mesenteric attachment greatly helps the identification of the arterial arcades supplying the selected segments. The bowel is divided 15 to 20 cm proximal to the cecum in the avascular window of Treves between the ileocolic artery and the terminal branch of the superior mesenteric artery. The ileum is divided proximally in a suitable avascular plane between the superior mesenteric arcades. Continuity of the bowel is reestablished by end-to-end anastomosis. The use of an automatic stapler or a hand-sewn technique is a matter of surgeon's preference. The isolated bowel segment is subsequently subdivided into three parts. The middle 40-cm segment is used for construction of the reservoir, the 10-cm oral segment is used for creation of the antireflux mechanism, and the distal 10-cm caudal segment is used for creation of the outlet valve (Fig. 81.1). Great attention is paid to preserving an adequate blood supply for the oral and caudal small bowel segments.

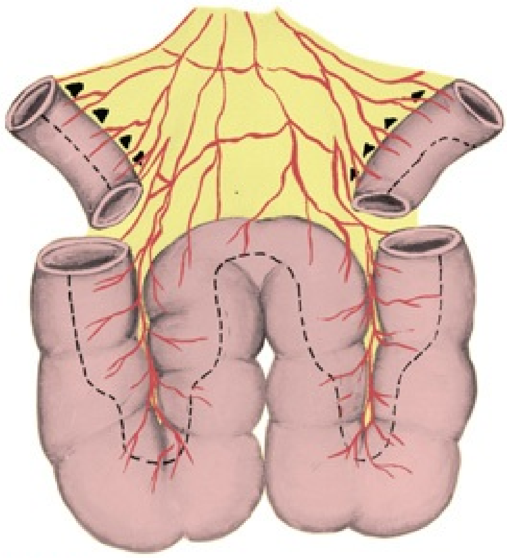

FIGURE 81.1 A 60-cm long ileal segment is isolated; the 40-cm middle segment is arranged in a W configuration and used for construction of the body of the reservoir, the 10-cm oral segment is used for the antireflux mechanism, and the caudal segment is used for the outlet valve.

The middle segment is arranged in a W configuration, and its antimesenteric border is incised by a diathermy knife. The edges of the two medial flaps are joined by a single layer of continuous 3-0 polyglactin sutures. The two lateral limbs are left to serve as serous-lined troughs. The oral and caudal short segments are tapered around a 22Fr catheter. Bowel tapering could be performed either by simple excision and hand-sewn technique or by using a one-step technique with an automatic gastrointestinal stapler. The proximal one-third of the inlet segment is kept untapered for ureteral anastomosis. Three to four small mesenteric windows close to the mesenteric border are created in between the arterial arcades supplying these segments. Each mesenteric window is marked by a small strip of rubber vessel loop. This step will facilitate easy passage of sutures through the mesenteric window (Fig. 81.2).

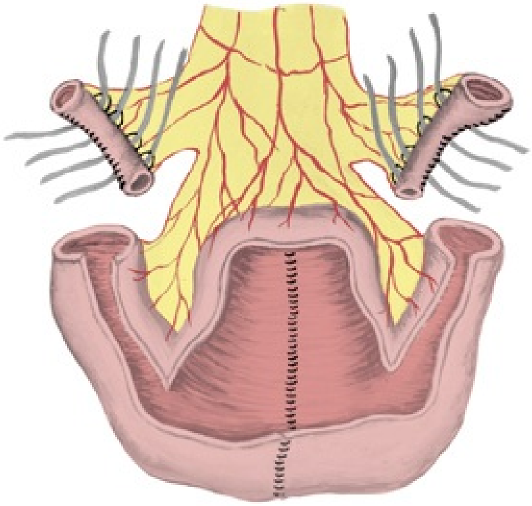

FIGURE 81.2 The bowel segment is incised at the antimesenteric border. The medial flaps are approximated with continuous 3-0 polyglactin sutures. The oral and caudal segments are tapered around a 20Fr catheter. The proximal one-third of the inlet segment is kept untapered. The created mesenteric windows are marked by a strip of vessel loops.

Each tapered segment is inlaid in its corresponding serous-lined trough. The two adjacent limbs of each trough are approximated using 3-0 silk seromuscular suture passing through the mesenteric windows and guided by the inserted strips of vessel loops. The tapered ileal segments are fixed and embedded within the serous-lined extramural troughs. Thus, the bulky mesentery of the embedded segments is excluded behind the pouch (Fig. 81.3). The spatulated distal ends of the tapered segments are anastomosed to the tunnel flaps, and the ileal trough is closed in front of the embedded segment using interrupted 4-0 polyglactin sutures (Fig. 81.4).

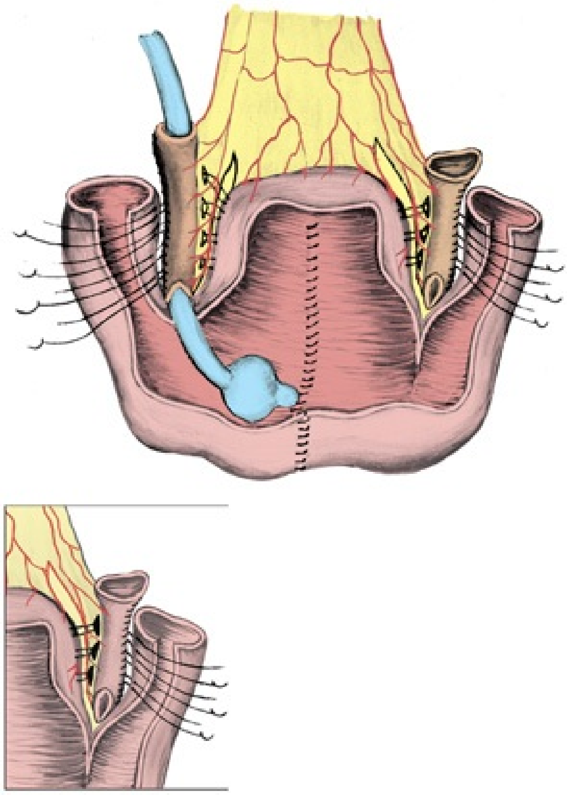

FIGURE 81.3 The tapered ileal segments are fixed and embedded within the serous-lined extramural troughs. The bulky mesentery of the embedded segments is excluded behind the pouch.

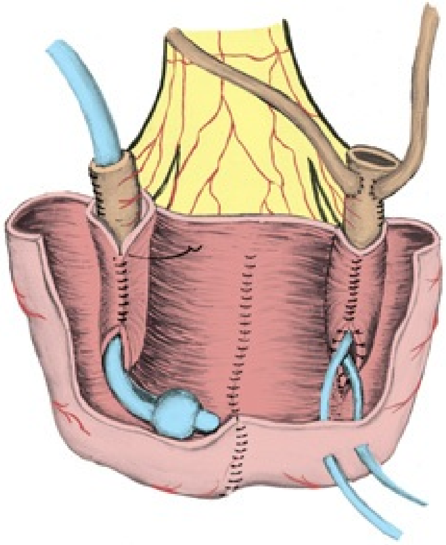

FIGURE 81.4 The spatulated distal ends of the tapered segments are anastomosed to the tunnel flaps, and the ileal trough is closed in front of the embedded segment using interrupted 4-0 polyglactin sutures. Two siliconized stents are threaded through the inlet segment.

Two soft siliconized 8Fr to 10Fr stents are threaded through the inlet segment and secured in place by 4-0 chromic gut sutures. The pouch plate is then closed by approximation of the most lateral ileal flaps anteriorly and to the shoulder flap between the inlet and outlet segments (Fig. 81.5).

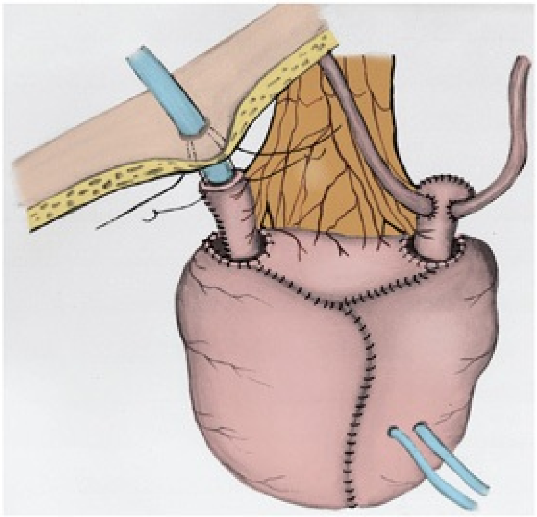

FIGURE 81.5 The pouch plate is closed by approximation of the most lateral ileal flaps anteriorly and to the shoulder flap between the inlet and outlet segments.

The skin of the umbilical funnel is raised and separated from the underlying rectus fascia in the midline. A fascial cruciate incision is made that can admit a 20Fr to 24Fr catheter. The invaginated umbilical skin funnel is identified and a suitable buttonhole is excised. The distal end of the outlet segment is pulled through the rectus fascia aperture. The edge of the intestinal outlet is fixed to the edge of the umbilical skin funnel using interrupted monofilament 4-0 or 3-0 Monocryl sutures including the rectus fascia (Fig. 81.6).

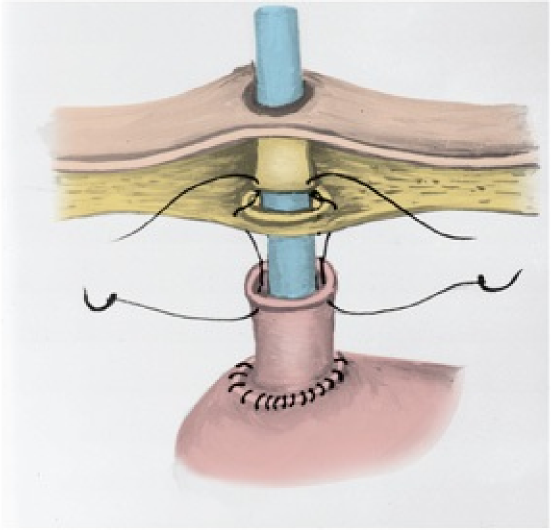

FIGURE 81.6 The edge of the outlet is fixed to the edge of the umbilical skin funnel using interrupted sutures including the rectus fascia.

The body of the reservoir wall around the outlet segment is then fixed to the inner aspect of the abdominal wall. Attention is paid to avoid twisting and/or angulation of the outlet segment. This would avoid difficulties in catheterization later.

The reservoir is drained by an 18Fr to 20Fr Foley balloon siliconized catheter fixed through the stoma.

Both ureters are prepared and oriented toward the inlet segment according to the final position of the pouch. The left ureter is passed from left to right through a high, wide enough mesenteric hole created in the left mesocolon. The right ureter comes from right to left in front of the common iliac artery behind the mesentery of the pouch. Tension-free, widely spatulated, stented implantation of the ureters into the inlet segment is then performed. A Wallace, Nesbit, or end-to-end anastomosis could be utilized according to surgical needs, using 4-0 or 5-0 polyglactin sutures.

The ureteral stents are exteriorized through the anterior wall of the reservoir to which they are secured. This will provide almost a dry reservoir during the healing stage.

The pelvic cavity is drained by two 18Fr fenestrated tubes. Only straight gravity drainage is used. Gastric drainage is established using either a nasogastric tube or open gastrostomy.

An Alternative: Utilization of the Appendix

If the appendix is suitable to serve as an outlet, the ileocecal junction is mobilized sufficiently to ensure a tension-free implantation of the appendix. The appendix is mobilized and detached at its base. The isolated appendix is cut and spatulated at its tip. The lumen is then dilated up to 16Fr to 18Fr using straight dilators. Four windows are created in the mesoappendix. The windows are labeled by rubber vessel loops. The appendix is embedded in the serous-lined trough as described previously (Fig. 81.7).

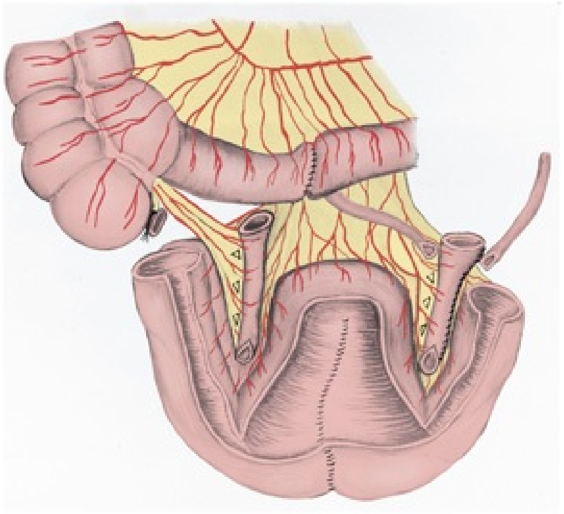

FIGURE 81.7 The appendix is isolated and spatulated at its tip. Four windows are created at the mesoappendix. The appendix is fixed and embedded in the serous-lined trough as previously described.

POSTOPERATIVE CARE

Parenteral fluids are maintained until bowel habit resumes. Prophylactic antibiotics are given routinely for 5 days. Low-molecular-weight heparin is given for 10 days. The draining tubes are removed when the drainage ceases. The reservoir is irrigated with 30 to 60 mL of normal saline every 8 hours to prevent mucus retention. The ureteric stents are removed after 10 to 12 days postoperatively. The pouch is drained for 21 days before training by intermittent catheter clamping. All patients start self-catheterization 2 days before discharge from the hospital. A 2-hour interval is allowed in week 1, which is increased gradually until the pouch matures. By the end of week 6, most of the patients evacuate the pouch every 4 to 5 hours.

OUTCOMES

Complications

In our experience with 101 patients, early complications were observed in 15%. These included urinary leakage (2%), pelvic collections (8%), ureteroileal obstruction (1%), ileus (3%), and wound complications (3%). Small nonsymptomatic pelvic collections need no treatment. Sizable and/or infected symptomatic ones are usually treated by ultrasound-guided needle aspiration with or without an indwelling tube drain. None of these pelvic collections required open drainage. Urinary leakage was an infrequent complication in our series (2%). This complication was due to pouch perforation during catheterization training. Prolonged pouch drainage was required for an additional 2 weeks until healing of the injury occurred. Early evidence of ureteroileal obstruction was observed in one patient. Antegrade fixation of a double-J stent was done for 6 weeks. The stent was removed by pouchoscopy carried out through the umbilical stoma. Gastrointestinal and wound complications were similar to those for other urinary diversion procedures.

Late complications included stomal stenosis at the skin level with catheterization difficulties in 6% of the patients. Two-thirds of them had an appendix stoma. Half of these patients required revisional surgery to widen the mucocutaneous stenotic area using a wedge skin flap technique. In one child, it was impossible to pass a catheter into the pouch due to overdistention resulting in angulations of the outlet tract. Under ultrasound guidance, percutaneous insertion of a pigtail catheter was carried out. Once the pouch became empty, outlet catheterization again was easy. Rupture of the pouch was observed in one patient following blunt abdominal trauma. Laparotomy was necessary, and the pouch tear was adequately repaired. Pouch stones were observed in 5% of the patients. All of them were amenable for endoscopic manipulations, but one patient required open pouch lithotomy. The incidence of upper tract dilatation due to anastomotic stricture was minimal (1%); the stricture was treated by antegrade balloon dilatation. One patient required left nephroureterectomy 3 years following cystectomy due to a renal pelvis tumor. Gravity pouchography demonstrated reflux in three patients (3%). Reflux was asymptomatic in all, and the patients were kept on prophylactic antimicrobial suppressive therapy. None of the operated patients developed metabolic acidosis. All patients were advised to use oral alkali therapy.

Results

Patients regained their normal lifestyle once healing was completed. Ninety-five percent of our patients were completely dry day and night. The catheterization interval was every 4 to 5 hours during daytime and every 1 to 2 hours at night. The average capacity at 6 months postoperatively was 550 ± 130 mL.

Five patients (5%) had a frequently wet stoma due to failure of the continence mechanism. Two patients were revised. One underwent revision of the continent outlet, and augmentation ileopouchoplasty was required to increase pouch capacity in the other. Two patients preferred frequent catheterization to avoid leakage. The remaining patient fixed a collection device during nighttime and refused further intervention.

Patients have to understand that they have a neobladder constructed from the bowel and that this bladder is different from the native one. The usual desire to micturate and the familiar micturition mechanism no longer exist. However, all patients with a dry, continent outlet stoma enjoy an excellent lifestyle, normal social activities, an accepted body image, and personal satisfaction.

CHAPTER 82 ■ CONTINENT CATHETERIZABLE RESERVOIR MADE FROM COLON

HUBERTUS RIEDMILLER, ELMAR W. GERHARZ, AND ARKADIUS KOCOT

INDICATIONS

The most common indication for continent cutaneous diversion is bladder replacement after anterior pelvic exenteration for malignant disease, followed by functional or morphologic bladder loss for other reasons. Diagnostic modalities therefore should be directed at the underlying pathology and definitive treatment. Despite the recent trend toward orthotopic substitution, continent catheterizable diversions are still a good form of diversion. Whereas previous or synchronous urethral transitional cell carcinoma (TCC) is an absolute contraindication to urethral preservation, the role of multifocality, associated carcinoma in situ, bladder neck, and prostatic involvement on urethral recurrence are less well defined. In these cases, continent cutaneous diversion still is a safe alternative in the appropriate patient. Advanced age (older than 70 years) with its physiologic deterioration of sphincter competence is another contraindication for orthotopic reconstruction; older patients who are otherwise physically fit may well benefit from a continent cutaneous reservoir. Whenever the native sphincter mechanism is lacking, destroyed, or dysfunctional or urethral catheterization is painful or technically impossible, cutaneous diversion is the only alternative to modified ureterosigmoidostomy and ileal loop. As salvage procedure in failed exstrophy reconstruction, other complicated congenital abnormalities of the urinary tract, neurogenic bladder dysfunction (wheelchair-bound myelomeningocele patients), otherwise intractable urinary incontinence, severe pelvic trauma, and complicated fistulas, continent cutaneous reservoirs provide excellent results even in extremely complex cases.

Until recently, renal transplant patients were excluded from the benefits of continent urinary diversion. Recently, several authors reported encouraging experiences with kidney transplantation into continent urinary intestinal reservoirs as a planned two-stage procedure in patients with functional or morphologic bladder loss (see the following text) (1,2). But long-term results in larger series of patients are still missing.

Other factors to consider when deciding on the type of urinary diversion include patient age, prognosis of underlying disease, comorbidity, urinary and anal sphincter competence, manual dexterity, renal function and upper urinary tract configuration, and subjective criteria (motivation, compliance, expectation of social support, emotional capability of dealing with clean intermittent catheterization). Patient priorities are considered whenever medically justifiable and technically feasible.

Contraindications of continent urinary diversion include impaired renal function with serum creatinine greater than 2 mg per L (other authors choose a cutoff level of 1.5 mg per L), inflammatory bowel disease, large bowel malignancy, or previous history of multiple bowel ablative procedures, and history of diarrhea.

ALTERNATIVE THERAPY

Alternatives to catheterizable colonic reservoirs include pouches made from ileum (Kock), ileal or colonic conduits, classic and modified ureterosigmoidostomy (e.g., sigma rectum pouch/Mainz pouch II), and orthotopic neobladder (Hautmann, Studer).

SURGICAL TECHNIQUE

While there is a broad consensus among reconstructive urologists regarding detubularization and spheric reconfiguration of bowel as basic principle in the creation of a low-pressure, high-capacity reservoir, the issues of reflux prevention (afferent limb), and continence (efferent limb) are more controversial. The still growing number of techniques described for achieving continence in urinary reconstruction indicates that a universally applicable procedure with a low complication rate has not yet evolved. The principal methods for construction of a continence mechanism depend either on the formation of a nipple valve, utilization of the ileocecal valve, or construction of a flap valve. Among the different techniques, the versatile Mitrofanoff principle (3) has reached significant popularity, predictably providing continence and allowing easy catheterization in more than 90% of cases. In 1990, Riedmiller et al. introduced the Mitrofanoff theme to the ileocecal reservoir, significantly facilitating the Mainz pouch procedure (4).

When performing a Mitrofanoff, the method of attachment of the appendix to the reservoir (reversed, in situ; imbricated, embedded, unaltered), the location of the stoma (umbilicus, lower abdomen), and appropriate alternatives remain controversial. It is known that the success of the Mitrofanoff principle is not dependent upon the underlying pathologic condition, the type of tube and its possible peristalsis, the type and configuration of the reservoir, or the patient’s age but the maintenance of a pressure gradient between channel lumen and the reservoir. It is therefore the availability of the required material and the simplicity of a technique that determine its popularity. Recent variations of the Mitrofanoff theme have aimed at its simplification and reduction of long-term complications.

Ileocecal Pouch (Mainz Pouch I)

Intussuscepted Ileal Nipple

After mobilization of cecum, ascending colon, and the right colonic flexure, the mesentery is divided between the right colic and the ileocolic artery. A 13-cm segment of cecum and ascending colon is isolated along with two equal-sized limbs of distal ileum. If the vermiform appendix is absent as in cloacal exstrophy, completely obliterated, immobile, insufficient in diameter and length, or had been removed beforehand, we usually isolate an additional portion of ileum measuring 10 to 12 cm (Fig. 82.1A). While the latter is left tubularized, the remaining bowel segment is split antimesenterically. These three opened bowel loops are folded in the form of an incomplete W, and their posterior aspects are sutured to one another to form a broad posterior plate (Fig. 82.1B). Both ureters are implanted into the large bowel segment of the pouch plate, forming submucosal tunnels for reflux prevention (Fig. 82.1C).

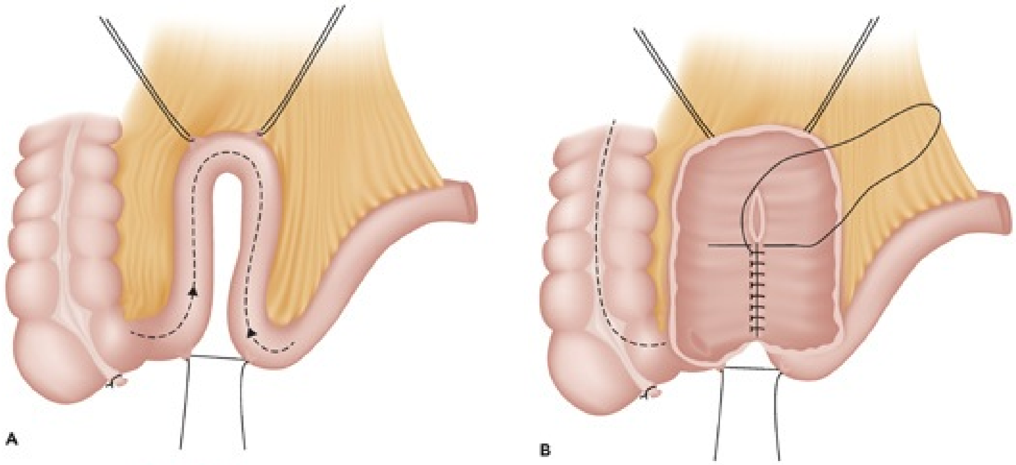

FIGURE 82.1 Ileocecal pouch (Mainz pouch I) with IIN valve. **A:** Isolation of the cecum/ascending colon (13 to 15 cm) and two equal-sized ileal loops (13 cm each) for reservoir formation and an additional ileal segment (10 to 12 cm) for nipple formation. Antimesenteric splitting of the bowel. **B:** Side-to-side anastomosis of the terminal and next proximal ileal loop with subsequent detubularization of the ascending colon. *(continued)*

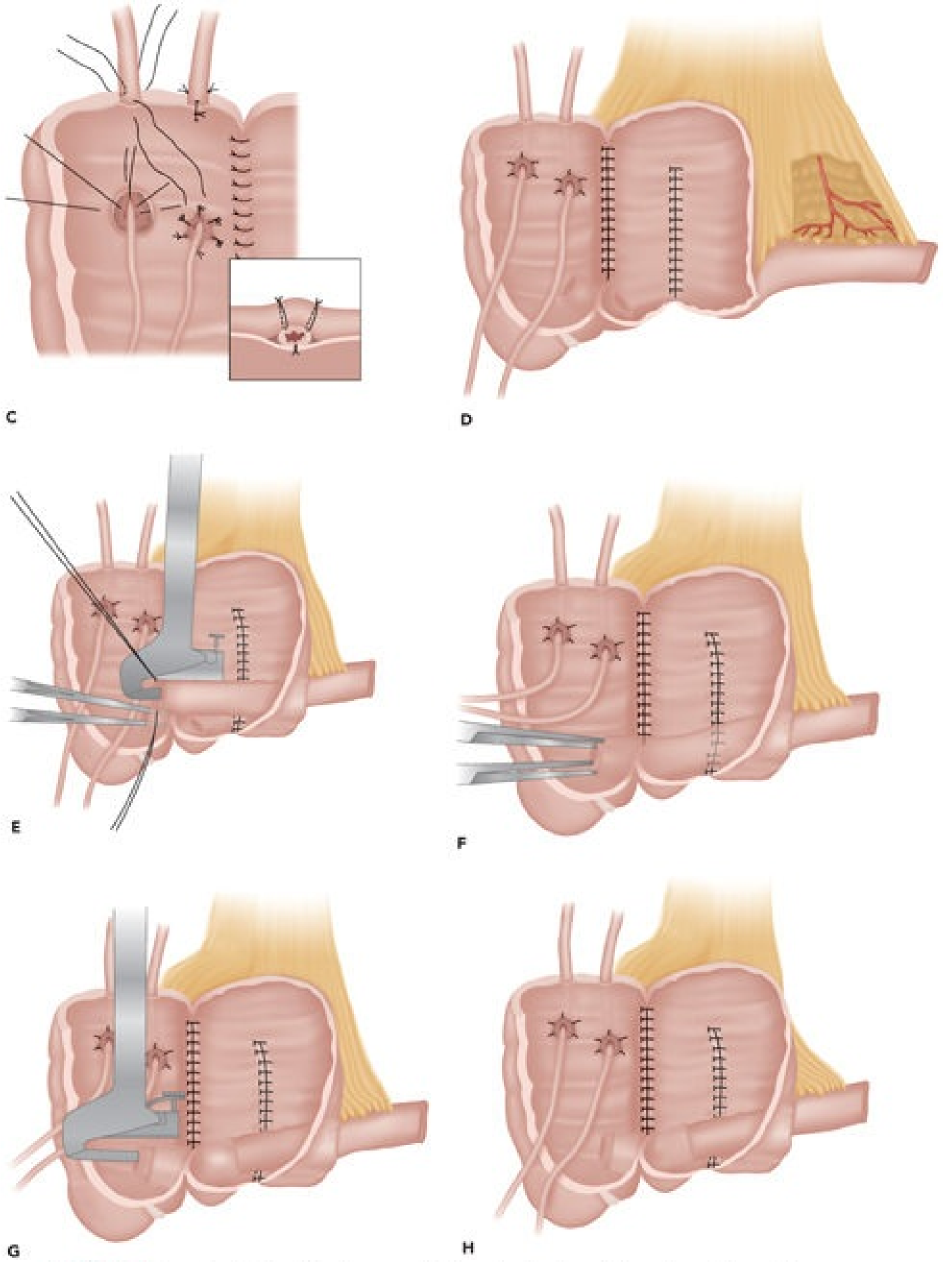

FIGURE 82.1 *(continued)* **C:** Antirefluxing ureteral implantation into the colonic portion of the pouch plate using submucosal tunnels (3 cm length) with insertion of 6Fr or 8Fr ureteral stents. **D:** Removal of mesentery (4 to 5 cm) in the midportion of the most proximal intact ileal segment in preparation for intussusception. **E:** Intussusception of the ileal segment and stabilization by applying one row of staples. **F:** The IIN pulled through the ileocecal valve. **G:** Two additional rows of staples are used to attach the nipple to the valve. **H:** Completed attachment of the nipple to the valve.

The midportion of the intact ileal segment is freed of its mesentery for a distance of 4 to 5 cm to allow its intussusception (Fig. 82.1D and E). We apply only one row of staples to stabilize the intussusception itself (Fig. 82.1F). Thereafter, the intussuscepted nipple is pulled through the intact ileocecal valve and two additional rows of staples are applied to attach the nipple to the ileocecal valve. After the mucosa has been removed from the rim of the intussuscepted nipple and the colonic aspect of the ileocecal valve, their circumferences are sewn together with a resorbable running suture.

The bowel is then folded on itself in a side-to-side fashion, thus creating a low-pressure and high-capacity reservoir. Ureteral stents (6Fr or 8Fr) and a 10Fr pouchostomy are led through the abdominal wall at separate sites. The entire pouch is rotated so as to bring the efferent limb to the region of the umbilicus. A small button of skin is removed from the depth of the umbilical funnel. The pouch is carefully attached to the posterior fascia with interrupted nonabsorbable sutures to prevent the pouch from rotating and kinking. The efferent limb is then connected to the umbilical funnel with interrupted absorbable sutures. If no umbilicus is present (as in the case of exstrophy), it is created by tubularizing a V-shaped cutaneous flap and connecting it to the appendicular stump.

A vigorous washout regimen is started early in the postoperative course. Ureter stents are removed after 10 to 14 days. Clean intermittent catheterization is usually started at the end of postoperative week 3 after leakage and reflux has been ruled out by pouchogram.

Appendix Stoma

If the appendix is present and can be dilated to accommodate a 16Fr to 18Fr catheter, it is our first choice as ideal efferent segment for construction of a continence mechanism. In this case, a 15-cm segment of cecum and ascending colon is isolated along with two equal-sized limbs of distal ileum (12 to 13 cm each). The lower 5 cm of the cecum (cecal pole) is left tubularized and intact. The seromuscular layer of the intact cecal pole is divided along the tenia down to the mucosa analogous to the Lich-Gregoir procedure for vesicoureteral reflux (Fig. 82.2A). By careful dissection of the seromuscular tissue, a broad submucosal bed (5 cm in length) is created for the appendix.

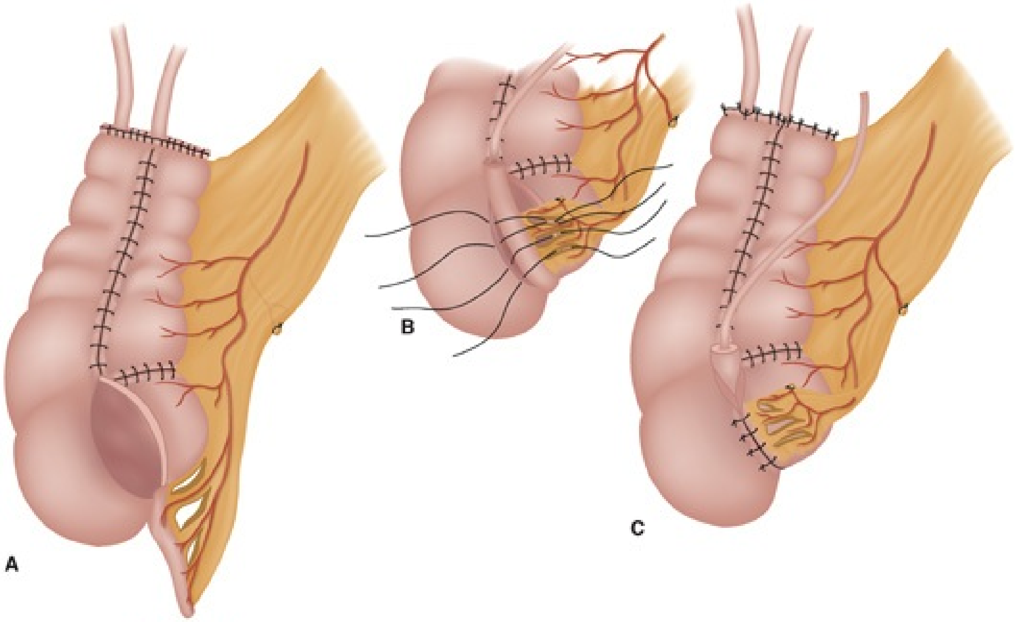

FIGURE 82.2 Ileocecal pouch (Mainz pouch I) with appendix stoma. **A:** The seromuscular layer of the intact cecal pole is split along the tenia down to the mucosa; a broad submucosal bed (5 cm in length) for the appendix is created. **B:** Windows in the mesoappendix are excised between the branches of the appendicular artery without compromising the blood supply. **C:** After the appendix is correctly positioned, the seromuscular layer is closed over the embedded in situ appendix.

The appendicular mesentery is freed of its excessive fatty tissue. Windows in the mesoappendix are excised between the branches of the appendicular artery without compromising the blood supply (Fig. 82.2B). Anatomic variations of the appendicular artery have to be respected, and an additional branch of the anterior or posterior cecal artery supplying the base of the appendix should be preserved. After the appendix is correctly positioned, the seromuscular layer is closed over the embedded in situ appendix with interrupted 4-0 polydioxanone sutures. A short mobile portion of the distal appendix remains for creation of the appendicoumbilical stoma (Fig. 82.2C). Formation of the pouch plate, ureterointestinal anastomosis, and attachment to the umbilicus are identical to the pouch with intussuscepted nipple.

Alternative Techniques for Construction of Continence Mechanism

More recent alternative techniques use a small-caliber conduit fashioned from the cecal wall. One technique uses a full-thickness tube lined by mucosa (Fig. 82.3A and B) and the other, a seromuscular tube lined by serosa (Fig. 82.4A–C) (5). Other authors have described transversely retubularized ileum (Fig. 82.5A–C) to create a tunneled access into the right colon (6).

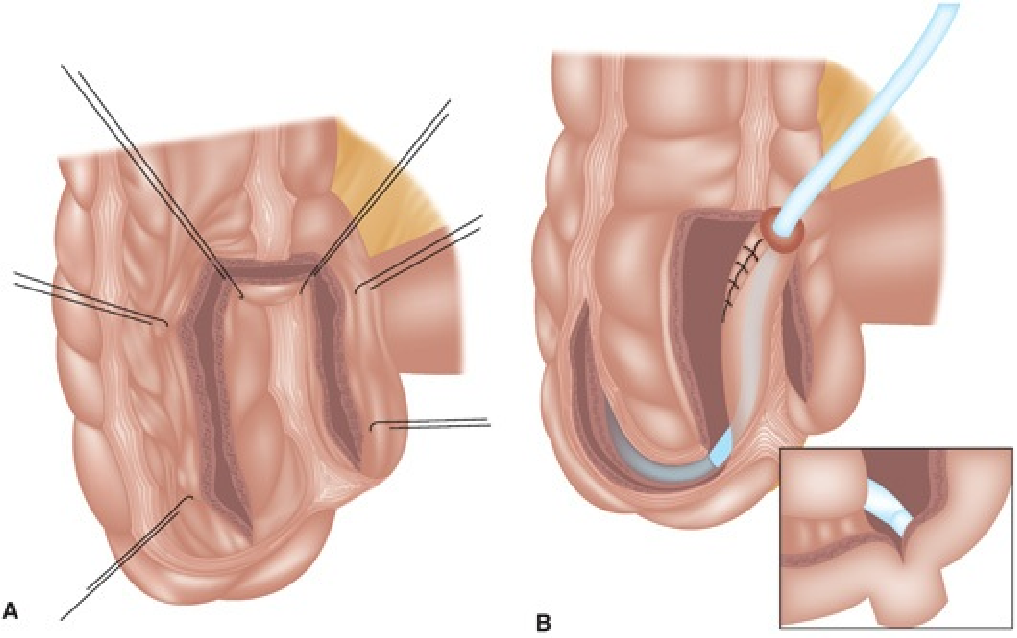

FIGURE 82.3 Full-thickness bowel flap tube. **A:** U-shaped incision (3 cm × 6 cm) of all layers of bowel wall resulting in pedicled bowel flap at the lower pole of the cecum. **B:** Tubularization of pedicled flap over an 18Fr Foley catheter and incision of the seromuscularis of the tenia omentalis (5 cm) for submucosal embedding starting at the pedicle of the bowel flap tube.

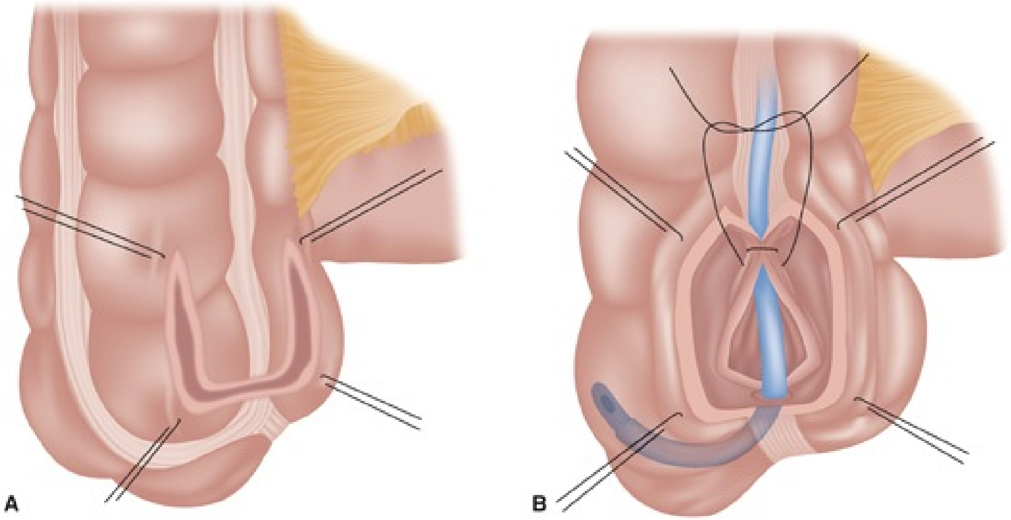

FIGURE 82.4 Seromuscular bowel flap tube. **A:** U-shaped incision (3 cm × 5 cm) of seromuscular layer at the lower pole of cecum and transverse incision of mucosa (0.5 cm) at the oral end of flap for insertion of an 18Fr Foley catheter into the lumen of the *reservoir*. **B:** Tubularization of the seromuscular bowel flap *over* an 18Fr Foley catheter. *(continued)*

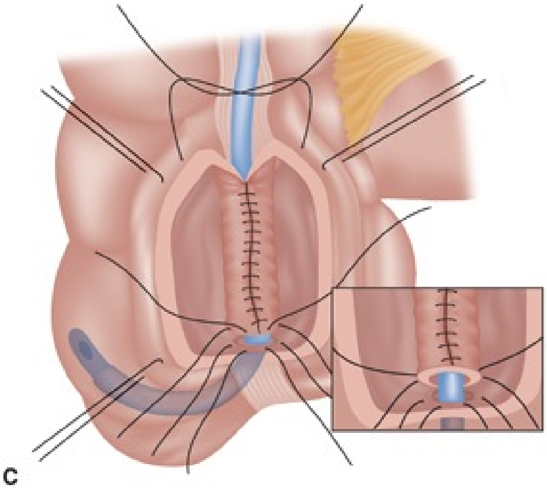

FIGURE 82.4 *(continued)* C: Suturing of anterior circumference of the seromuscular tube to the margin of mucosa (*inset*).

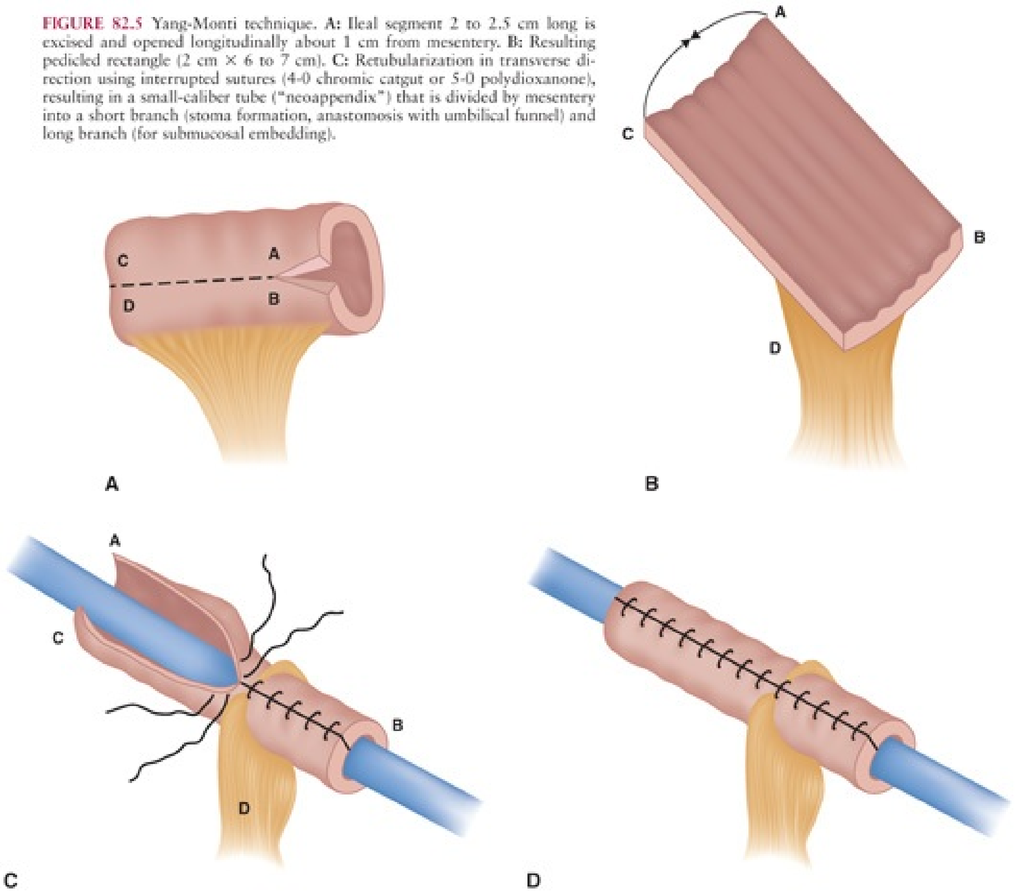

FIGURE 82.5 Yang-Monti technique. A: Ileal segment 2 to 2.5 cm long is excised and opened longitudinally about 1 cm from mesentery. B: Resulting pedicled rectangle (2 cm × 6 to 7 cm). C: Retubularization in transverse direction using interrupted sutures (4-0 chromic catgut or 5-0 polydioxanone), resulting in a small-caliber tube ("neoappendix") that is divided by mesentery into a short branch (stoma formation, anastomosis with umbilical funnel) and long branch (for submucosal embedding).

Alternative Techniques for Ureteral Implantation

In dilated, irradiated, or otherwise compromised ureters, ureterointestinal anastomosis may be performed according to a technique that has been described by Abol-Enein and Ghoneim (serous-lined extramural tunnel) (Fig. 82.6A and B) (7).

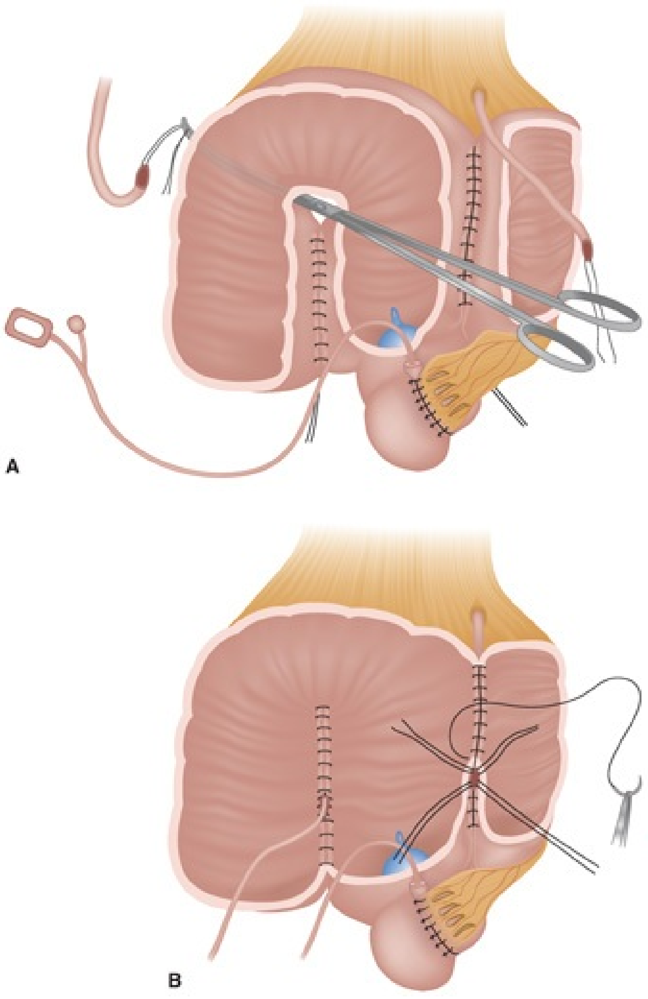

FIGURE 82.6 Ileocecal pouch (Mainz pouch I) with serous-lined implantation of ureters. **A:** In contrast to the original technique, the pouch plate is not created by anastomosing the edges of detubularized bowel segments but by creating two serous-lined extramural troughs. **B:** The ureters are placed into the serous-lined tunnels and covered by approximating the margins of the detubularization.

Right Colon Pouches with Intussuscepted or Embedded Tapered Terminal Ileum

Several other authors use the ileocecal region in continent cutaneous urinary diversion. In contrast to the Mainz technique, they employ the ileum for construction of the continence mechanism but not for creation of the reservoir itself. Other colon pouches using nipple valve technology for the continence mechanism include modifications from many other centers and differ from one another by only a few features, predominantly related to the technique employed for stabilizing the nipple valve. In the “Tiflis” technique, the continence mechanism is created by tapering and submucosal embedding of terminal ileum (Fig. 82.7A and B) (8).

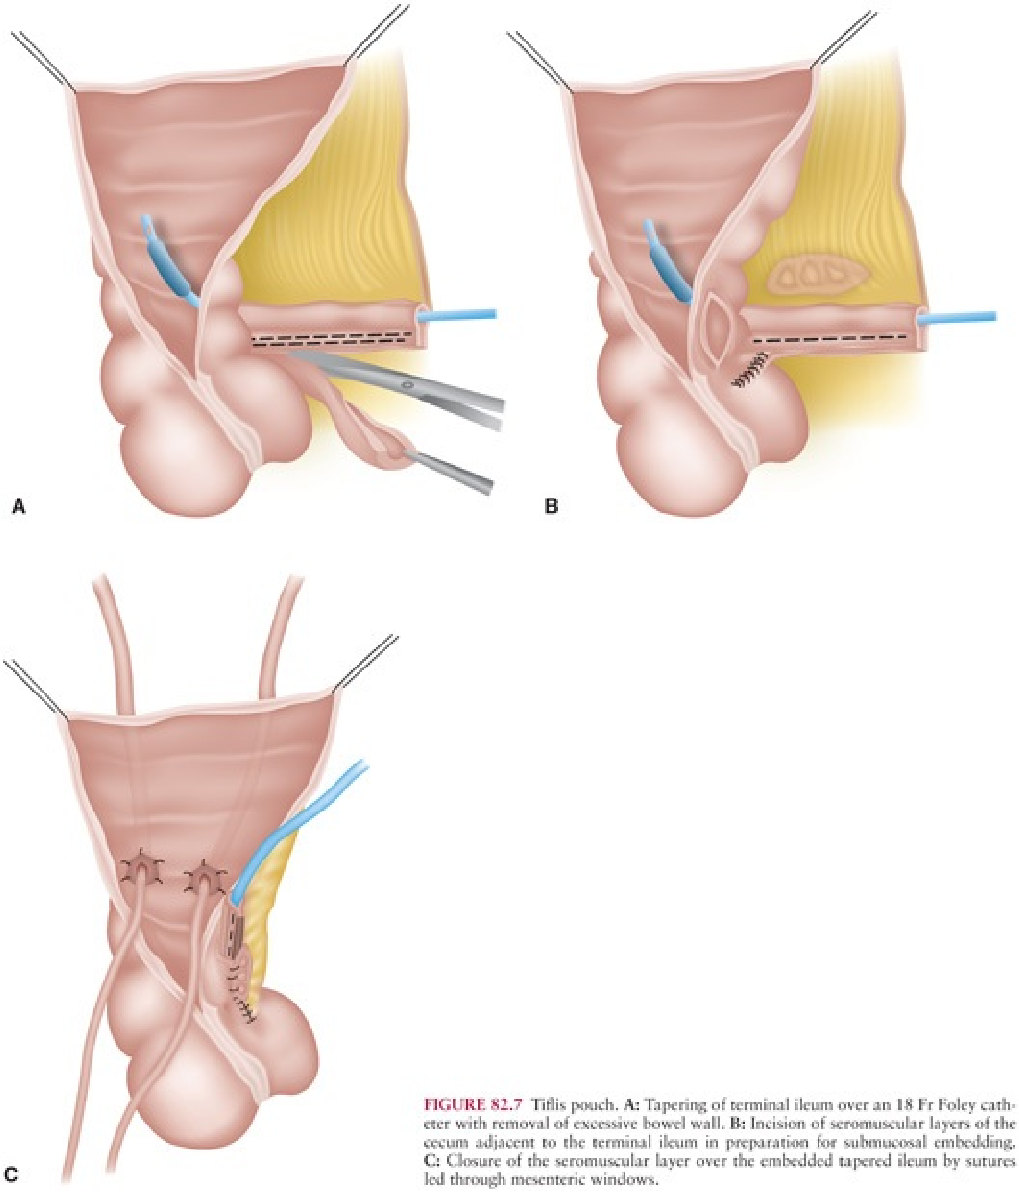

FIGURE 82.7 Tiflis pouch. **A:** Tapering of terminal ileum over an 18 Fr Foley catheter with removal of excessive bowel wall. **B:** Incision of seromuscular layers of the cecum adjacent to the terminal ileum in preparation for submucosal embedding. **C:** Closure of the seromuscular layer over the embedded tapered ileum by sutures led through mesenteric windows.

Indiana Pouch

Between 25 and 30 cm of cecum and ascending colon and 8 to 10 cm of terminal ileum are isolated (9). The entire colonic segment will be detubularized by incising it along its antimesenteric surface. If an appendix is present, it is removed at this time. Reconfiguration of the opened bowel segment by folding the cephalad end down to the apex of the antimesenteric incision allows creation of a spheric reservoir (Fig. 82.8A). For construction of the efferent limb and continence mechanism, metal staples are applied sequentially to narrow the efferent limb over a 12Fr straight catheter (Fig. 82.8B). Excess antimesenteric ileum is removed. The last row of staples is placed at an angle to prevent stapling into the wall of the cecum. After narrowing the efferent limb, the ileocecal valve area is plicated with five to seven Lembert stitches of 3-0 silk suture (Fig. 82.8C). Care is taken to avoid having the sutures enter the lumen of the bowel. Each Lembert suture is progressively wider than the last. This has the effect of narrowing the ileocecal valve by wrapping cecal wall over the angled staple line. The tightness of the plication sutures is tested by passing an 18Fr catheter through the efferent limb. Once the efferent limb and continence mechanism have been completed and a Malecot catheter has been placed as cecostomy tube in the dependent portion of the cecum, the reservoir is closed. Both ureters are led in such a manner as to allow alignment with a tenia. A tenial incision is made for each ureter. The ureter is cut obliquely or spatulated, and the site for the ureteral orifice is created by incising the bowel mucosa. The ureteromucosal anastomosis is performed with interrupted sutures of 5-0 synthetic absorbable monofile material. The tenia is reapproximated over the ureter with a nonabsorbable 5-0 suture.

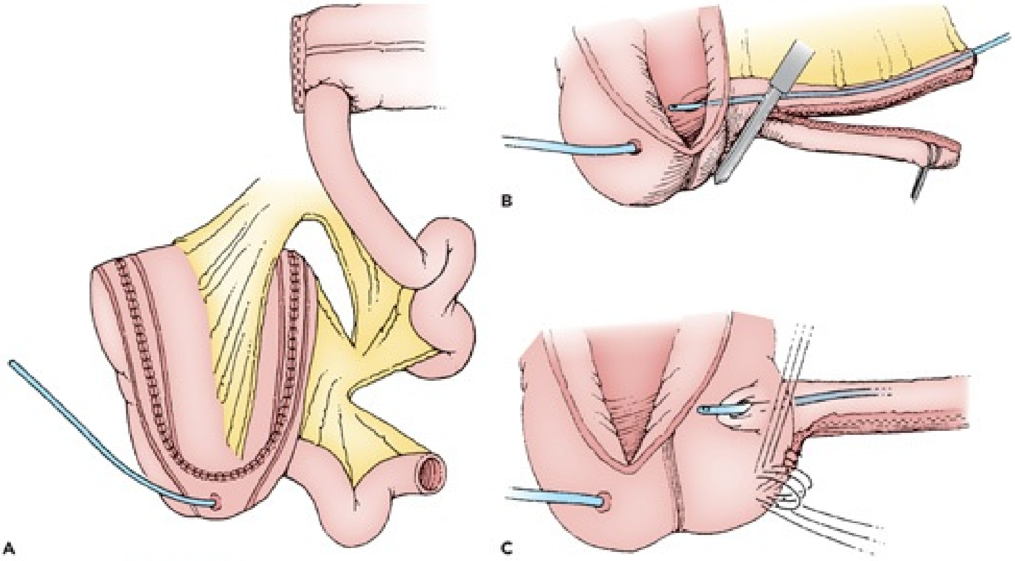

FIGURE 82.8 Indiana pouch. **A:** The cephalad end of the detubularized right colon segment is folded caudally to the apex of antimesenteric incision. A Malecot catheter is placed in the dependent portion of the cecum prior to closing the reservoir. **B:** A stapler is used to trim away the excess bowel wall of the ileal segment (tapering). **C:** A total of five to seven Lembert sutures are placed to plicate the ileocecal valve.

Colon Pouch (Mainz Pouch III)

Between 15 and 17 cm of transverse colon and either ascending (transverse-ascending pouch [TAP]) or descending colon (transverse-descending pouch [TDP]) (Fig. 82.9A) is required to create a pouch of adequate capacity (350 to 400 mL) (10). Complete mobilization of the right or left colonic flexure should be performed to gain adequate colon length for the pouch. The greater omentum is dissected from the transverse colon from right to left in the TAP and vice versa in the TDP. The bowel segment is detubularized antimesenterically, leaving 5 to 6 cm of the oral or aboral end intact for construction of the efferent limb. The terminal segment is tapered over an 18Fr silicone catheter, thus creating a neoappendix (Fig. 82.9B). Mucosa is sewn with polyglycol suture and the seromuscular layer with a nonabsorbable running suture, serous-lined implantation of ureters. Easy insertion of the catheter is important as a shrinkage of approximately 30% has to be reckoned with. After the pouch plate is created, antirefluxing ureterointestinal implantation is performed on both sides of the suture line (Fig. 82.9C). For refluxing ureteral implantation, about 1 cm^2 of the bowel mucosa is excised and the seromuscular layer is incised in the shape of a cross. After anchor sutures at the 5 and 7 o’clock positions are placed, a watertight anastomosis with 5-0 Monocryl sutures is performed. Ureteral stents and a 10Fr pouchostomy are led through the abdominal wall at separate sites.

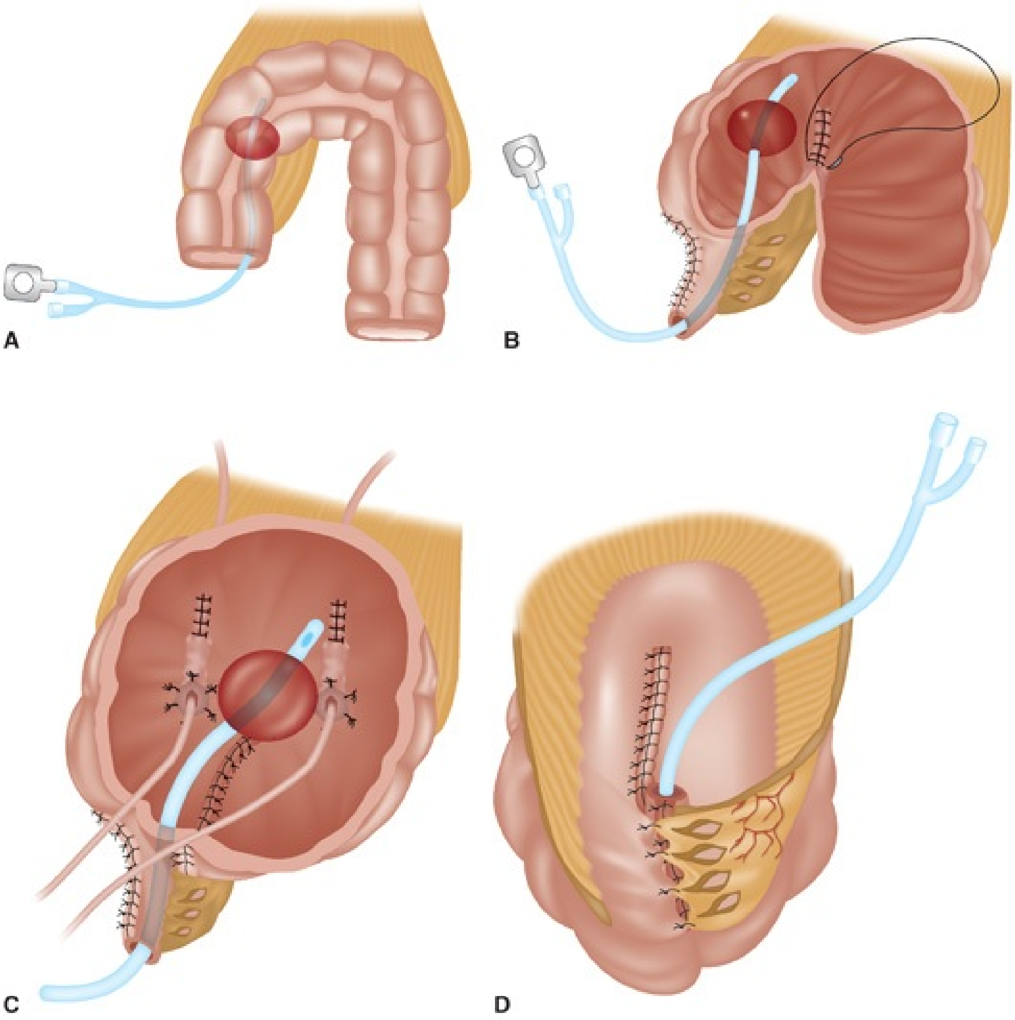

FIGURE 82.9 Colon pouch (Mainz pouch III) with tapered colon as efferent limb. **A:** About 15 to 17 cm of nonirradiated large bowel are isolated for reservoir creation. The oral end with a Foley catheter is used for construction of efferent limb. **B:** The colonic segment is detubularized and the pouch plate is formed. The oral end is tapered over an 18Fr Foley catheter and windows are made in the mesentery. **C:** The ureters are attached to the posterior pouch wall through a submucosal tunnel. **D:** Pouch formation is completed by closing the anterior wall. The efferent segment is embedded serosa-to-serosa by sutures led through mesenteric windows.

The pouch is closed and the efferent segment is established. Windows are dissected in the mesentery of the tapered colon between the vessels. The efferent limb is then placed in the suture line, and the seromuscular layer of the anterior wall is approximated through the windows in the mesentery (Fig. 82.9D). Our favorite technique comprises isolation of a short segment of jejunum or ileum, which is tapered over an 18Fr Foley catheter and embedded submucosally after incising the tenia of a tubularized portion of the colonic segment. Sutures are led through windows in the ileal mesentery (Fig. 82.10A–D).

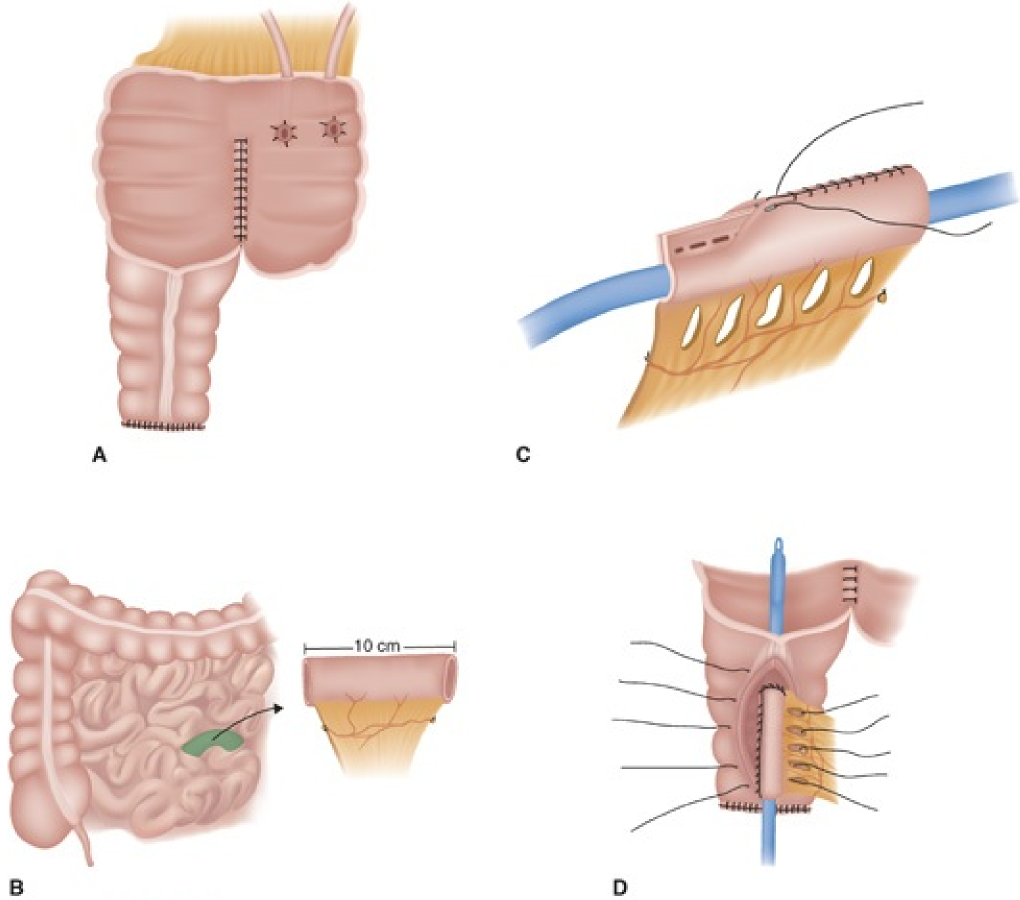

FIGURE 82.10 Colon pouch (Mainz pouch III) with tapered small bowel as efferent limb. **A:** The oral end of the large bowel segment is closed and left intact. **B:** A 10-cm jejunal or ileal segment is isolated with careful preservation of its mesenteric pedicle. **C:** The ileal segment is tapered over an 18Fr Foley catheter, trimming away the excess bowel wall. The tube is formed using a running suture. Windows are created between the vasculature of the mesentery. **D:** Submucosal embedding of tapered ileum after incision of the seromuscular layer of the tenia of the intact colonic segment. Sutures are led through mesenteric windows.

The umbilicointestinal anastomosis is performed in the same fashion as in the ileocecal pouch. Finally, the reservoir is attached to the abdominal wall. The greater omentum is used to cover the pouch and bowel. Ureter stents are removed after 10 to 14 days. Clean intermittent catheterization is started 3 weeks postoperatively.

OUTCOMES

Complications and Prevention

While continence using the appendix, once established, is durable with late-onset failure of 1% to 2% at about 4 years, stomal stenosis is seen in 8% to 23% of patients, depending on the length of follow-up. Although stenosis represents a minor technical problem, the subsequent inability to insert the catheter is a distressing complication with potentially serious consequences in patients in whom the Mitrofanoff channel is the only route of evacuation. In these cases, the reservoir must be immediately emptied percutaneously, which is facilitated by fixation of the pouch to the abdominal wall.

Skin stenosis may be dilated, incised, or repaired by open surgery, carefully removing fibrotic tissue. According to our experience, dilatation alone seldom produces a lasting improvement. We therefore tend to early intervention. Although revisions are usually successful, prevention of stenosis is desirable. Stomal stenosis can be avoided by incorporation of a V-shaped flap of umbilical funnel into the spatulated appendix. To prevent recurrence, we have developed a cone-shaped metal dilator. Its effective length was designed to cover only the known critical segment of the channel. Directly before inserting the catheter for evacuation of the reservoir, the stoma is gently dilated for a few minutes once or twice daily. A similar effect might be produced by occasionally leaving the catheter in the pouch at night.

Complications of intussuscepted ileal nipples resulting in impaired clean intermittent self-catheterization and/or urinary incontinence may be caused by nipple gliding, prolapse, or, in the worst case, by nipple necrosis. Initial complication rates for sutured or stapled ileal intussusception nipples were significantly reduced, when the intussuscepted ileal segment was additionally fixed to the ileocecal valve and the wall of the reservoir by metal staples (11). Obesity has been identified as a significant risk factor for nipple gliding.

Ureterointestinal stenosis is the most frequent complication of the upper urinary tract and ranges between 2% and 15% for submucosally implanted ureters into colonic segments and between 2.9% and 5.1% for ureters, with a serosa-lined extramural tunnel within a mean follow-up of 91.1 months (range 4.3 to 220.2 months) (12). Most discussed factors for ureterointestinal stenosis are fibrosis and inflammatory changes, previous surgery or radiation, preexisting ureteral dilatation, and urinary leakage. Differential choice of surgical technique during ureteral implantation is mandatory to reduce the risk of anastomotic strictures.

Metabolic complications are due to either reduction of the absorptive bowel capacity through functional loss of those segments required for reservoir construction or the highly unphysiologic exposure of the reconfigured bowel to urine. Factors that affect solute absorption include the size and segment of bowel used, time of retention of urine, concentration of the solutes in the urine, renal function, and pH and osmolality of the fluid (13,14).

The most common consequence of intestinal urinary diversion is metabolic acidosis. Depending on definition, diagnostic modality, reservoir characteristics, renal function, and length of follow-up, it has been reported in 20% to 100% of patients after ureterosigmoidostomy, bladder substitution, and continent diversion using ileal and/or colonic segments.

Intestinal urinary reservoirs have an increased propensity to form urinary calculi, predominately as well in the upper as in the lower which frequently recur with an increasing incidence over time.

Pouch urolithiasis is a well-known complication of continent cutaneous diversion with an incidence of approximately 5% to 25% (15–17).

Risk factors include the presence of foreign material (e.g., staples), recurrent and chronic infection, composition of the urine, mucus production, urinary stasis, and noncompliance with irrigation and catheterization regimens.

Stone formation in pouches is best managed by prevention. This includes the treatment of symptomatic infections and daily irrigations to reduce mucus retention.

Bile stones in pouch patients are reported with an incidence of 11% comparable to the 10% to 20% incidence in the normal population (17,18).

Spontaneous rupture or perforation during catheterization has been observed after bladder augmentation, orthotopic ileal, and ileocolonic bladder replacement and in continent cutaneous reservoirs 4 weeks to more than 5 years after surgery.

Hypovitaminosis is a well-studied sequela to resection of bowel, and in particular on vitamin B_{12}, as patients may develop irreversible neurologic disease in case of unrecognized deficiency. Substitution of vitamin B_{12} is simple and even less expensive than regular determination. Empirical supplementation may therefore be considered.

Bile acids with consecutive laxative effect might cause chologenic diarrhea with an incidence up to 30% in patients with ileocecal urinary reservoirs but can successfully be managed with loperamide or cholestyramine.

In the risk group of patients with stool frequency already prior to surgery, reconstruction of the ileocecal valve is recommended (17).

Troubleshooting

Ureterointestinal Stenosis

The general causes of ureteroenteric strictures in continent cutaneous diversion are similar to those in conduit diversion with basic etiologic factors including failure to achieve mucosal-to-mucosal apposition, tension at the anastomosis, tissue is chemia, radiation injury, and recurrent malignancy (19).

Due to the very low success rate of dilatation and stenting procedures, early neoimplantation is the treatment of choice in most cases. In our experience, a modified Lich-Gregoir procedure (20) has proven to be a very effective option (Fig. 82.11). In a cohort of 30 patients with ureterointestinal stenosis, ureteral reimplantation was performed successfully in 36 of 37 renal units (mean follow-up: 53 [range: 3 to 166] months).

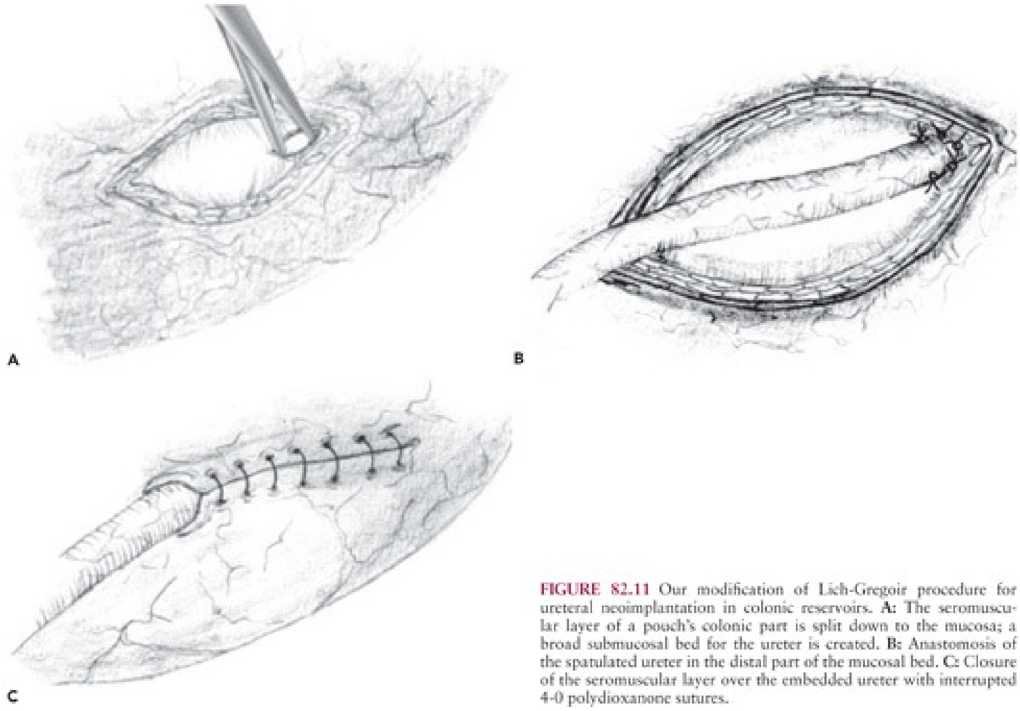

FIGURE 82.11 Our modification of Lich-Gregoir procedure for ureteral neoimplantation in colonic reservoirs. A: The seromuscular layer of a pouch's colonic part is split down to the mucosa; a broad submucosal bed for the ureter is created. B: Anastomosis of the spatulated ureter in the distal part of the mucosal bed. C: Closure of the seromuscular layer over the embedded ureter with interrupted 4-0 polydioxanone sutures.

A flank incision (Fig. 82.12) should be chosen as a surgical (retroperitoneal) approach to avoid incision of the laparotomy scar and transabdominal approach to the ureter.

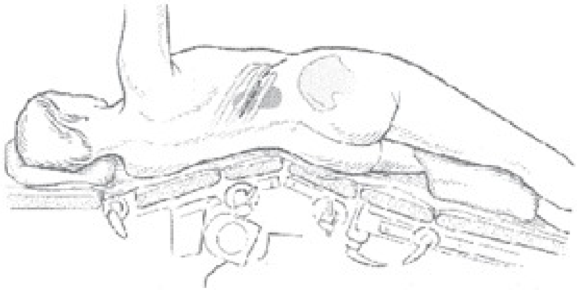

FIGURE 82.12 The patient is placed in a modified flank position.

Partial or total ureteral replacement using ileum might be necessary in severely damaged ureters.

Continence Mechanism

Problems with catheterization can be avoided when paying utmost attention to proper surgical details at the time of continence mechanism creation. Stable and durable fixation of the continence mechanism and a straight course of the continent outlet are mandatory to guarantee ease of catheterization.

High surgical competence, creativity, and variability are required in cases of revisional surgery for stomal insufficiency in continent cutaneous urinary diversion.

Nipple prolapse in ileocecal reservoirs frequently can be treated by refixation of the nipple to the ileocecal valve (Fig. 82.13)

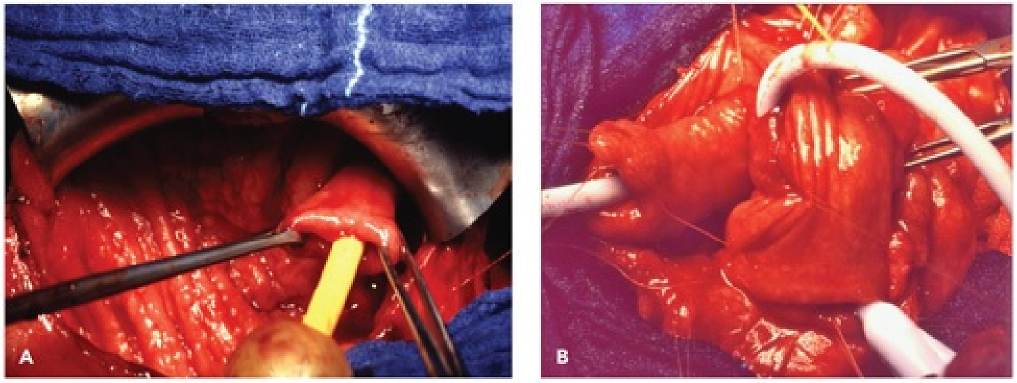

FIGURE 82.13 Nipple gliding. A: Open pouch, IIN dislocated out of the ileocecal valve. B: IIN relocated and pulled through the ileocecal valve. Refixation with two rows of staples.

In complex cases and especially in the presence of a devastated appendix continence mechanism or of a necrotic ileal nipple, creation of a secondary intussuscepted ileal nipple (IIN) might become necessary.

In revisional surgery of continence mechanisms, laparotomy is inevitable. Sufficient adhesiolysis and at least partial mobilization of the ileocecal reservoir from the abdominal wall are preconditions for successful repair or substitution of the continence mechanism.

In our institution, 16 patients underwent revisional surgery with creation of a secondary IIN. Thereafter, all patients were continent day and night with ease of catheterization. The mean follow-up was 53.9 (range 2 to 159) months. In the long-term setting, no stoma stenosis was observed, but two of these patients required refixation of the secondary IIN due to nipple gliding 36 and 54 months after surgery (Fig. 82.14).

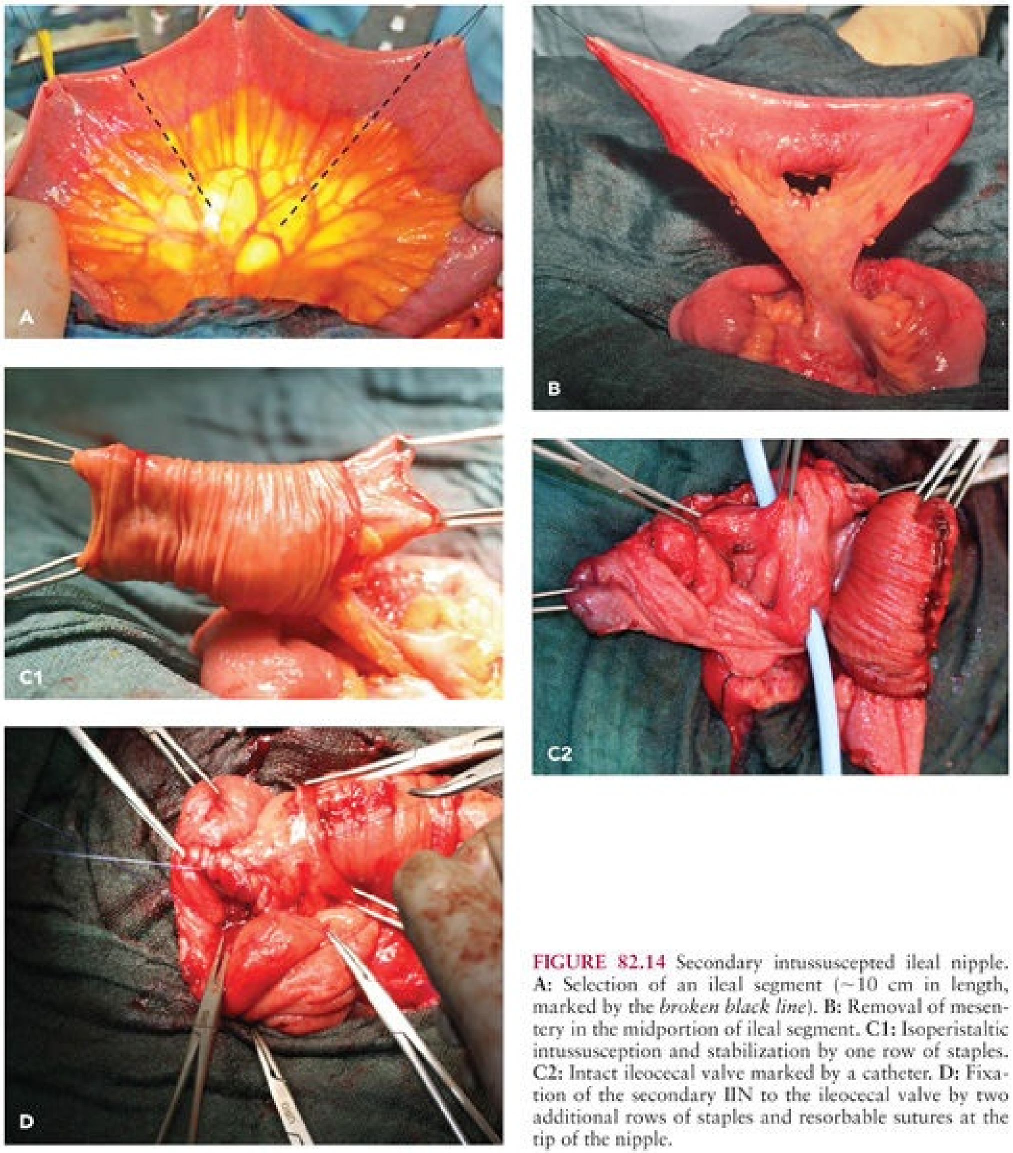

FIGURE 82.14 Secondary intussuscepted ileal nipple. A: Selection of an ileal segment (~10 cm in length, marked by the *broken black line*). B: Removal of mesentery in the midportion of ileal segment. C1: Isoperistaltic intussusception and stabilization by one row of staples. C2: Intact ileocecal valve marked by a catheter. D: Fixation of the secondary IIN to the ileocecal valve by two additional rows of staples and resorbable sutures at the tip of the nipple.

In case of otherwise intractable outlet failure resulting in impaired clean intermittent self-catheterization and/or urinary incontinence, creation of a secondary continence mechanism is also required.

Despite careful planning, in revisional surgery, final decisions about bowel segments to be used for creating the continence mechanism and (if necessary) a reservoir obviously have to be made during surgery, depending on the degree and location of intra-abdominal adhesions and additional factors such as previous radiation damage to exposed bowel segments.

Own Results

Between 1990 and 2013, 1,313 patients underwent urinary diversion at our department with creation of continent reservoirs in 761 patients (58%). The most common indication for urinary diversion was bladder replacement after anterior exenteration for pelvic malignancies (81.2%).

Continent urinary diversion was performed as a primary surgical approach, in conversion procedures, and in salvage maneuvers after failure of previous reconstruction. Two hundred three patients underwent continent urinary diversion with an orthotopic ileocecal substitute, whereas 45 patients received a sigma rectum pouch.

In 511 patients, an ileocecal pouch with continent umbilical stoma (mean follow-up: 83.2 [range: 1 to 244 months]) was performed. As a continence mechanism, the submucosally embedded in situ appendix could be used in 225 cases. In 286 cases, an ileal intussusception nipple was established.

The submucosal tunnel was used for most ureteral implants (87%). Perioperative mortality was 0.8% in patients with continent diversion. Eleven major stoma-related complications were observed in patients with in situ appendix (4.9%), minor problems (outlet stenosis at skin level) occurred in 26 patients (11.6%). Forty-six patients with IIN (16.1%) required surgical revision of the nipple. All patients with umbilical stoma ($n = 511$; mean follow-up: 83.2 months)—including those with need of revisional surgery of the continence mechanism—finally were completely continent day and night with easy catheterization.

Ureterointestinal stenosis was encountered in 42 patients (8.2%). Early ureteral reimplantation was performed in most cases; nephrectomy was inevitable in eight patients due to a significant loss of renal function. Rupture of the continent reservoir occurred in six patients (1.1%) in all cases related to a blunt abdominal trauma. Whereas no pouch calculi were observed in the appendix group, stones in the reservoir had to be removed from eight patients (2.7%) with ileal nipple.

In 44 of the 511 patients (8.6%), the serum concentration of vitamin B_{12} had dropped below normal requiring vitamin B_{12} substitution. Mild hyperchloremic metabolic acidosis occurred in 19.5% of the patients requiring alkalizing medication.

In 18 patients with absent or dysfunctional lower urinary tract, a continent urinary reservoir has been created and renal transplantation was performed in a second stage (2). Within a mean follow-up of 89.2 months (ranging from 2 to 188 months), renal function remained stable in 15 patients, whereas 3 patients lost renal function 42, 62, and 109 months after transplantation. Two of these patients were excluded from the transplant program due to severe compliance problems.

CHAPTER 83 ▪ URETEROSIGMOIDOSTOMY AND MAINZ POUCH II

MICHAEL RINK AND MARGIT FISCH

The first ureterocolonic anastomosis using the anus as continence mechanism was described over 160 years ago by John Simon of St. Thomas' Hospital for a child with ectopia vesicae (1). Since its first description, more than 60 modifications of ureterosigmoidostomy have been published (2). This technique was the method of choice for urinary diversion until the late 1950s, when electrolyte deterioration and secondary malignancies arising at the ureteral implantation site were observed (3,4). However, secondary malignancies, although to a lesser extent, were later also reported in other forms of urinary diversion (5). Critics of ureterosigmoidostomy tend to quote publications dealing with complications in patients treated prior to the 1950s (6). The development of new absorbable suture material, modern ureteric stents, antibiotics, and alkalinizing drugs served in solving many of the traditional shortcomings of ureterosigmoidostomy and have revitalized the interest in this technique.

A distinct drawback of ureterosigmoidostomy was frequency and urgency especially reported at night (3,7,8). Urodynamic investigations found that bowel contractions increased the pressure in the reservoir provoking incontinence (8,9). By interrupting the circular contractions (antimesenteric opening of the bowel and "reconfiguration"), low-pressure reservoirs can be constructed, thus improving continence rates and protecting the upper urinary tract by reducing the rates of reflux-related pyelonephritis (10). The era of low-pressure anal reservoirs began.

Kock et al. (9) were the first who applied these principles to ureterosigmoidostomy. Reports on similar techniques either augmenting the sigma with ileal (11) or ileocecal (12) segments followed. The sigma-rectum pouch (10,13) represents an equally effective but simpler operative procedure for creating a rectal low-pressure reservoir. The idea was initially described by Kocher in 1903 (14). R. Coffey (15) revolutionized the ureterointestinal anastomosis by inventing the physiologic submucosal tunnel, which also became the standard technique for ureteral implantation in classical ureterosigmoidostomy. However, in dilated or ureters with thick walls, this technique is associated with increased complication rates. Thus, for patients with these conditions, the ureteral implantation technique into an ileal neobladder published by Abol-Enein and Ghoneim (16,17) represents an alternative. This technique is also applicable for the sigma-rectum pouch (18). In the past decades, further modification of the original technique were described (19–21) underscoring the perpetual interest in this procedure. Nowadays, the techniques of low-pressure anal reservoirs have completely replaced classical ureterosigmoidostomy (2).

INDICATIONS

Indications for Surgery

The sigma-rectum pouch is suitable for primary urinary diversion, revision of ureterosigmoidostomy, and conversion of incontinent diversion. A major goal in patient counseling about urinary diversion is to determine the method, that is, the safest for the underlying disease (e.g., cancer control), has the fewest complications during short- and the long-term follow-up, and provides the easiest adjustment for patients' lifestyle, thereby supporting the best quality of life (QOL) (22). Hence, it is important to notice that adults, particularly elderly patients, often have problems adopting to a reservoir holding the urine with the anal sphincter, as they habitually used the urinary sphincter.

Nevertheless, the procedure is indicated in patients with actual or functional loss of the urinary bladder. The main indications were urinary diversion in patients with bladder exstrophy or after radical cystectomy for bladder cancer. The technique shows particularly good results in children that adjust well to anal reservoirs. Paramount to the success of anal sphincter–controlled urinary diversion is a competent anal sphincter mechanism. This is essential for the sigma-rectum pouch as well as for ureterosigmoidostomy.

Contraindications for Surgery

An absolute contraindication for rectosigmoid reservoirs is an incompetent anal sphincter. Inability of the patient to retain at least 400 mL in the upright position for 1 hour is a contraindication (22,23). Patients with neurogenic bladder dysfunction also have to be evaluated with caution because of the possible association of anal sphincter dysfunction (22). Another absolute contraindication is a preceding irradiation of the pelvis. In addition, rectosigmoid reservoirs are contraindicated in patients with diverticulosis of the sigmoid colon or polyposis.

Compromised renal function or chronic renal failure with serum creatinine levels above 1.5 to 2 mg/dL also represents a contraindication. In addition, severe hepatic dysfunction is a contraindication to continent diversion in general. Patients with compromised intestinal function, particularly inflammatory bowel disease, may benefit from an incontinent urinary diversion (22).

DIAGNOSIS

Preoperative Examinations

When a patient is considered for ureterosigmoidostomy or the sigma-rectum pouch, the anal sphincter function should be examined by a tap water enema (perianal instillation of 200 to 300 mL saline, which the patients should keep at least for 3 hours) as well as a rectodynamic investigation (exclusion of incontinence during measurement; anal sphincter profile: resting closure pressure >60 cm H_2O, closure pressure under stress >100 cm H_20). Bowel diseases such as polyposis or diverticulosis have to be excluded. To that end, bowel imaging with water-soluble contrast media should be performed preoperatively. In case of conspicuous findings, coloscopy is recommended for further diagnostics.

Patient Preparation

Nowadays, bowel preparation before urinary diversion is debatable particularly in ileal diversions. For elective colorectal surgery, mechanical bowel preparation has been practiced as a clinical routine for many decades. However, contemporary randomized clinical trials and meta-analyses found no strong evidence supporting the use of mechanical bowel preparation for elective colorectal surgery (24). Yet, the authors of this chapter recommend some type of bowel preparation prior to elective colonic surgery to reduce the stool burden. This may facilitate surgery and potentially avoid postoperative complications.

Broad-spectrum antibiotics such as cephalosporins combined with metronidazole are administered perioperatively. Alternatively, piperacillin sodium combined with an aminoglycoside can be given at the beginning of surgery. A gastric tube (occasional alternative: gastrostomy) and a rectal tube are placed. For parenteral nutrition, a central venous catheter is placed.

ALTERNATIVE THERAPY

Alternatives to the sigmoid-rectal pouch are any other forms of urinary diversion, including bladder substitution, continent cutaneous urinary diversion, and conduit diversion.

SURGICAL TECHNIQUE

Classical Ureterosigmoidostomy

After a median laparotomy, the peritoneum is incised lateral to the descending colon and the left ureter is identified. A peritoneal incision is made on the contralateral side lateral to the ascending colon and the right ureter identified. Both ureters are dissected, respecting the longitudinal vessels running inside the Waldeyer sheet. The dissection is extended caudally to the ureterovesical junction. The ureters are cut as distal as possible, and stay sutures are placed at the 6 o’clock position. The ureteral stumps are ligated.

The colon is slightly elevated at the rectosigmoid junction by four stay sutures. After opening of the sigmoid colon over a length of 4 cm by an incision of the anterior teniae, four mucosal stay sutures are placed in the mucosa of the posterior aspect of the sigmoid (Fig. 83.1). The bowel mucosa is incised between the proximal stay sutures, and a buttonhole type of excision of posterior bowel wall is performed. A straight or slightly curved clamp is advanced through the opening, and a tunnel is created by blunt dissection below the visceral peritoneum of the mesosigmoid (Fig. 83.2). The ureter is pulled into the lumen of the intestine. After creation of a submucosal tunnel of about 3 cm in length, the ureter is threaded through this tunnel, avoiding torsion of the ureter (Fig. 83.3). The anterior wall of the ureter is spatulated for a length of 1 cm (Fig. 83.4A). For the ureterointestinal anastomosis, an anchor suture is placed at the 6 o’clock position grasping intestinal mucosa and musculature (5-0 polyglactin), and the anastomosis is completed by several ureteromucosal single stitches (6-0 polyglactin). A 6Fr silastic stent is inserted into the ureter and fixed to the mucosa by a polyglactin rapide 4-0 suture (Fig. 83.4B). The contralateral ureter is implanted about 3 cm lateral and either proximal or distal to the first anastomosis using the same technique (Fig. 83.5). The ureteral stents are inserted into the rectal tube and pulled out through the anus. Thereafter, the rectal tube is reinserted.

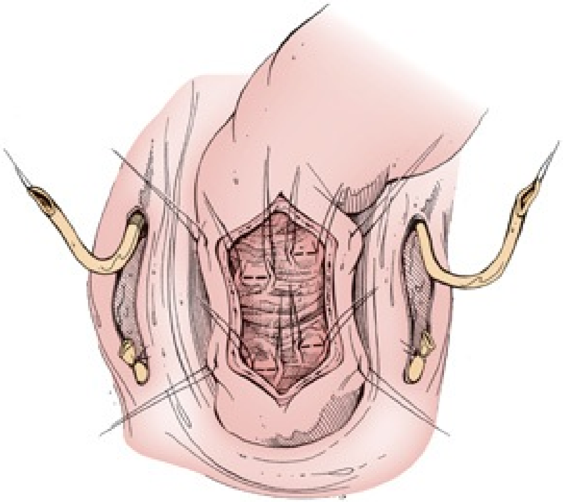

FIGURE 83.1 Open transcolonic ureterosigmoidostomy: Both ureters have been cut at its entrance into the bladder and mobilized. The site of the planned ureteral implantations in the posterior sigmoid wall are outlined by stay sutures.

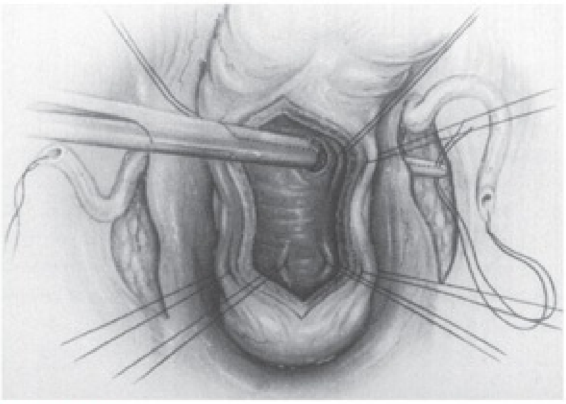

FIGURE 83.2 After incision of the mucosa and excision of a buttonhole type of excision of the posterior bowel wall site, the ureter is brought through the intestinal wall; a subperitoneal tunnel is modelled bluntly from this point to the left incision in the peritoneum. The curved clamp is advanced precisely below the peritoneum.

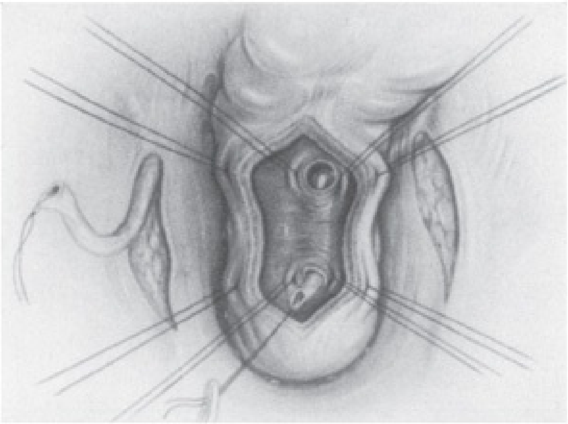

FIGURE 83.3 The ureter has been pulled into the bowel and through a submucous tunnel reaching from the proximal to the distal stay suture.

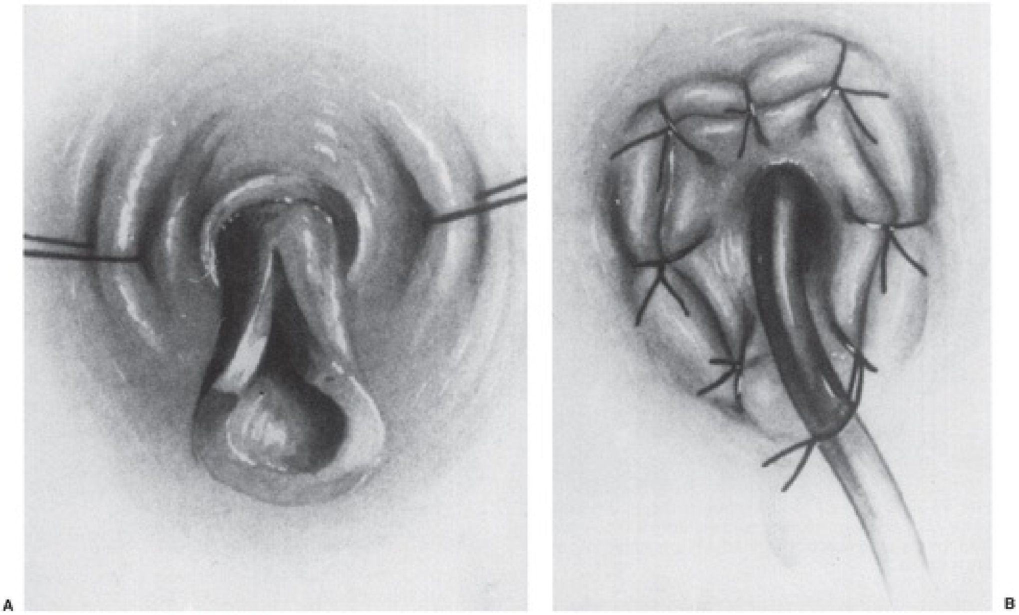

FIGURE 83.4 Spatulation of the anterior wall of the ureter (A) and ureteromucosal anastomosis between ureter and intestinal wall. The ureter is stented (B).

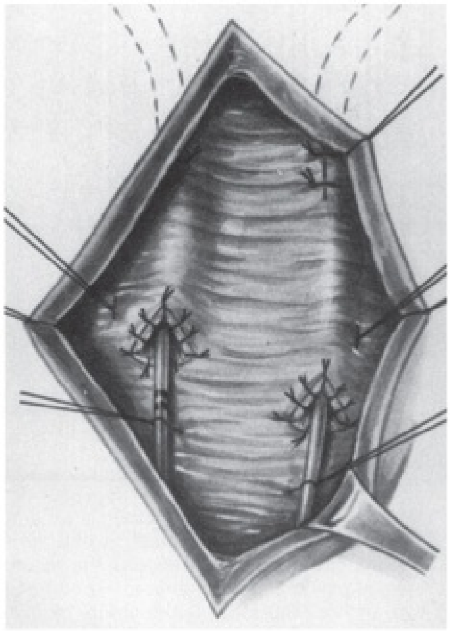

FIGURE 83.5 Identical implantation of the right ureter 3 cm lateral and proximal or distal of the first anastomosis.

The anterior sigmoid colon is closed in one layer using interrupted sutures of 4-0 polyglactin or in two layers using running sutures (5-0 polyglactin for the mucosa and 4-0 polyglactin for the seromuscularis). The peritoneal incisions are closed. At the end of the operation, separate fixations of the rectal tube and ureteral stents to the skin of the anus are performed (nonabsorbable material).

Sigmoid-Rectal Pouch (Mainz Pouch II)

Access is gained by a median laparotomy as for ureterosigmoidostomy. The rectosigmoid junction is identified and two stay sutures are placed. The peritoneum is incised lateral to the descending colon and the left ureter is identified. Another perineal incision is made lateral to the ascending colon and the right ureter is identified. Both ureters are dissected down to the ureterovesical junction, respecting the longitudinal vessels running inside the Waldeyer sheet. The ureters are cut as distal as possible, stay sutures are placed at the 6 o’clock position, and the ureteral stumps are ligated.

For creation of the pouch, the intestine is opened at the anterior tenia starting from the rectosigmoid junction over a total length of 20 to 24 cm distal and proximal of this point (Fig. 83.6). By placing two stay sutures in the middle of the incision at the right side of the opened rectosigmoid, the intestine is positioned in a shape of an inverted U. The posterior wall of the pouch is closed by side-to-side anastomosis of the medial margins of the U using two-layer running sutures of 4-0 polyglactin for the seromuscular layer and 5-0 polyglactin for the mucosa (Fig. 83.7).

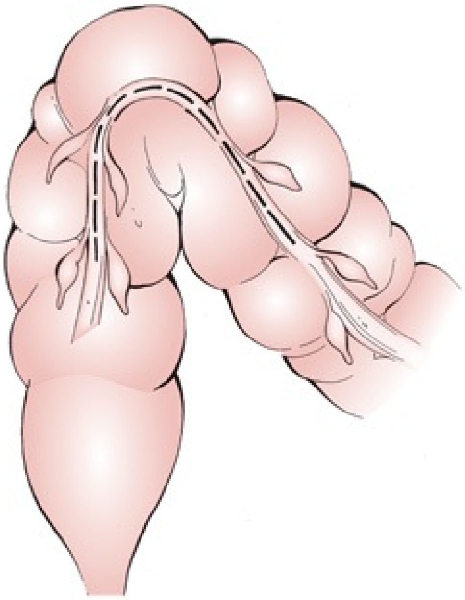

FIGURE 83.6 Sigmoid-rectal pouch (Mainz pouch II). Identification of the rectosigmoid junction.

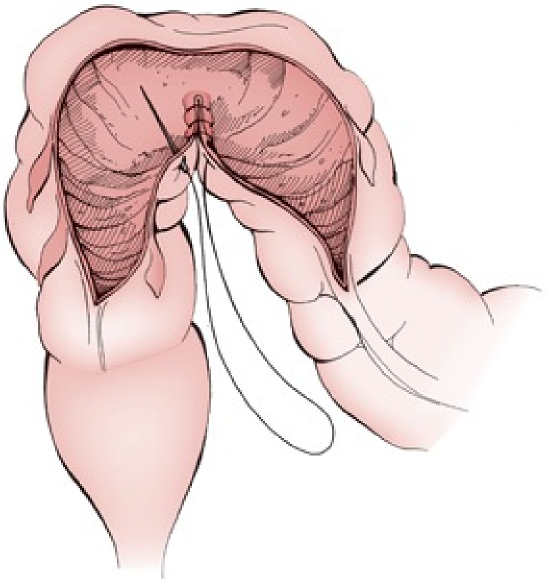

FIGURE 83.7 Opening of the rectosigmoid at the anterior tenia starting from the rectosigmoid junction over a total length of 20 to 24 cm distal and proximal of this point. Side-to-side anastomosis of the medial margins of the cut bowel edges by two-layer closure using running sutures of absorbable synthetic suture material (4-0 for the seromuscular layer and 5-0 for the mucosa).

The left ureter is pulled through retromesenterically above the inferior mesenteric artery from the left to the right side (Fig. 83.8). For ureteral implantation, four mucosal stay sutures are placed parallel right and left to the medial running suture. The mucosa is incised, and the seromuscular layer is excised between the two cranial stay sutures to create a wide buttonhole type of opening as an entrance of the ureter into the pouch. The dissection of the submucous tunnel starts from this incision downward over a length of 2.0 to 2.5 cm. The mucosa is incised at the distal end of the tunnel and the ureter is pulled into the tunnel. After having resected the ureter to an adequate length, implantation is completed by placing an anchor suture at the 6 o’clock position (5-0 polyglactin) and several interrupted ureteromucosal sutures (6-0 polyglactin). The cranial mucosal incision is closed by a running suture with polyglactin 4-0, which has a short reabsorption time. The contralateral ureter is implanted in the same manner (Fig. 83.9).

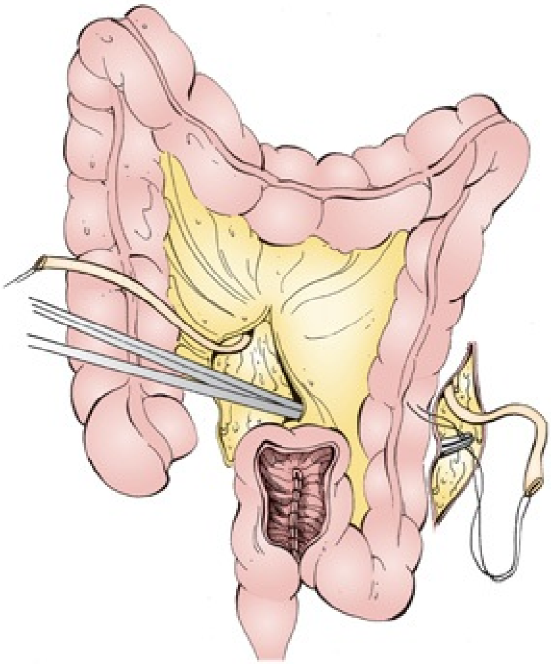

FIGURE 83.8 The left ureter is pulled through retromesenterically to the right side.

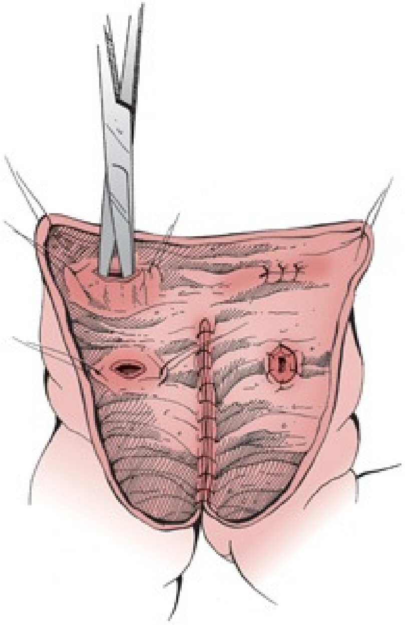

FIGURE 83.9 Creation of a wide buttonhole as an entrance of the ureter into the pouch and preparation of a submucous tunnel (2 to 2.5 cm in length). Incision of the mucosa at its distant end and pull-through of the ureter. Ureteral implantation by two anchor sutures at the 5 and 7 o'clock position and single-stitch mucomucous sutures. Closure of the cranial mucosal incision by a running suture with 6-0 absorbable synthetic suture material.

Next, 6Fr ureteral stents are inserted into the ureters and are pulled out through the anus with the rectal tube, which is afterward reinserted. The pouch is fixed to the anterior longitudinal band at the sacral promontory in the region of the proximal end of the posterior medial running sutures by two Bassini sutures of 3-0 nonabsorbable suture material (Fig. 83.10). Closure of the anterior pouch wall is performed in two-layer sutures (5-0 polyglactin for the seromuscular and 4-0 polyglactin for the mucosal layer). Alternatively, single-layer closure using locked running suture (Fig. 83.11) or interrupted stitches can be used. The peritoneal incisions are closed and the anastomotic site of the pouch is covered by omentum. The rectal tube and the ureteral stents are separately fixed to the skin of the anus (nonabsorbable material).

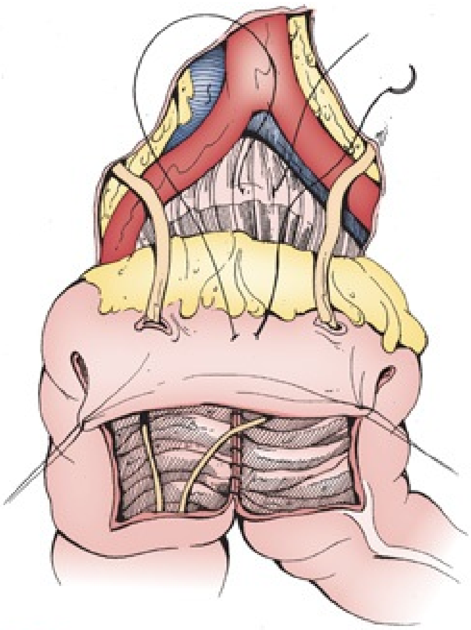

FIGURE 83.10 After a 6Fr stent is placed in each ureter, which are pulled out through the anus with the rectal tube, the pouch is fixed to the anterior longitudinal band of the spine (promontory) in the region of the proximal end of the posterior medial running sutures by two Bassini sutures.

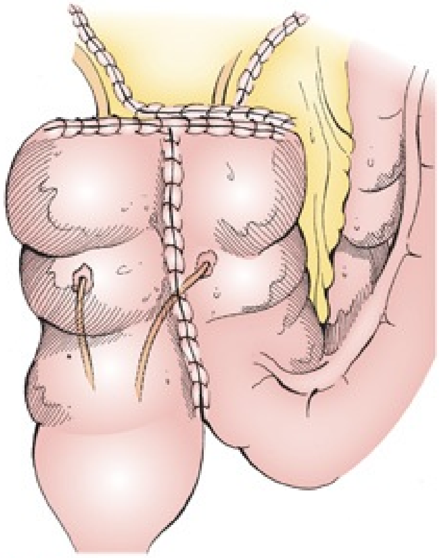

FIGURE 83.11 Closure of the anterior pouch wall by seromuscular single stitches with 4-0 absorbable synthetic suture material. Closure of the peritoneal incisions.

Serosa-Lined Extramural Tunnel Ureteral Implantation

Mobilization of the bowel includes the left colonic flexure (in cases of a short sigmoid segment). Dissection of the ureters is identical to the standard technique (Fig. 83.12). An S-shaped sigmoid segment is outlined by stay sutures, with each limb of 10- to 12-cm length, resulting in a total length of 30 to 36 cm (Fig. 83.13). After antimesenteric opening of the S-shaped sigmoid colon (Fig. 83.14) in the area of the anterior tenia, a side-to-side adaptation of the seromuscularis of both limbs is obtained by single-stitch sutures close to the mesentery (nonabsorbable suture), thereby creating two serosa-lined channels.

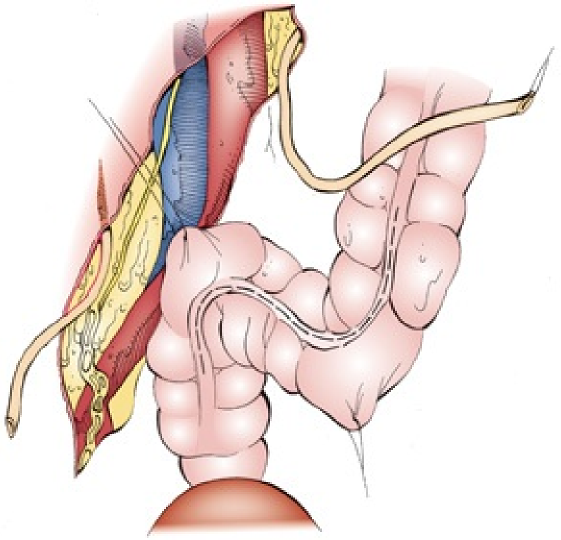

FIGURE 83.12 Ureteral implantation into a sigma-rectum pouch via a serous-lined extramural tunnel. Right and left paracolonic incision; identification and dissection of the ureters.

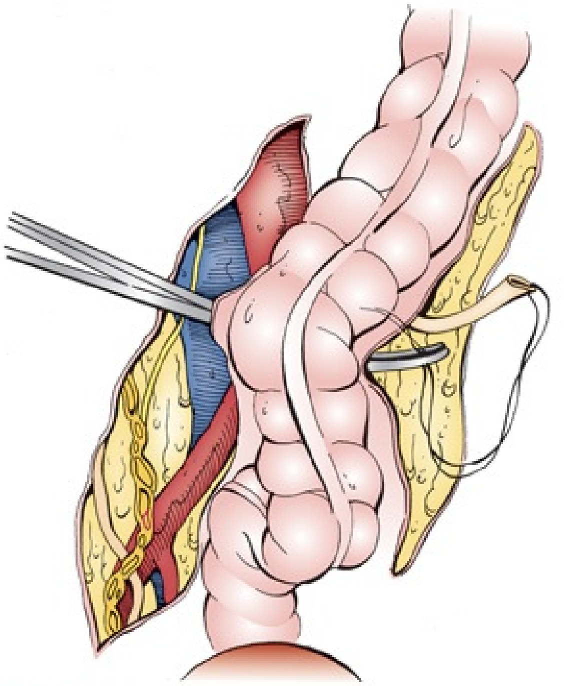

FIGURE 83.13 An S-shaped sigmoid segment is outlined by stay sutures. The length of each segment is 10 to 12 cm, starting at the rectosigmoid junction (= standard technique), adding another segment of 10 to 12 cm of the ascending colon.

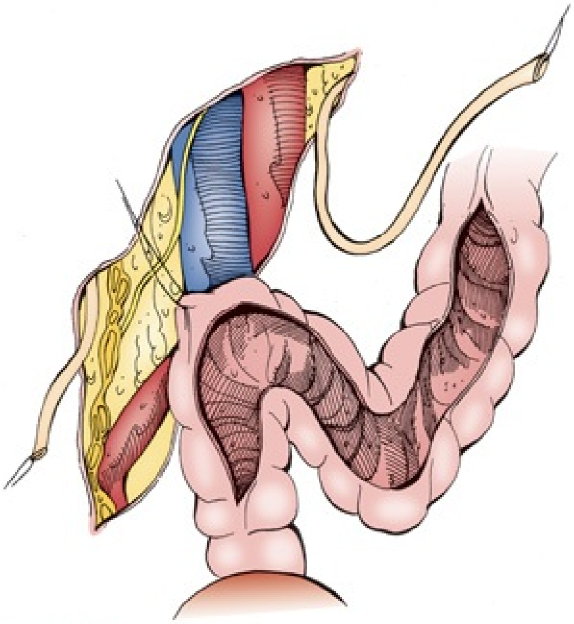

FIGURE 83.14 The marked segment is opened in the area of the anterior taenia. Excision of a mesenteric window for pull-through of the left ureter.

On the right side, an entrance for the right ureter is created at the cranial aspect of the running suture. The mesentery cranial to the left running suture is incised and the left ureter pulled through. The ureters are placed in their respective channels (Fig. 83.15), and the cut edges of the bowel are sutured above the ureter with a running suture incorporating all layers, thus converting the channel into a tunnel. The length of the tunnel should be four times the diameter of the ureter. For implantation, the ureter is cut at its required length and spatulated. Four anchor sutures are placed at the 11 and 1 o'clock and the 5 and 7 o'clock positions through all layers of the ureter as well as all layers of the bowel wall (4-0 polyglactin). Ureteromucosal sutures are placed in between the anchor sutures to complete the anastomosis (5-0 polyglactin) (Fig. 83.16). Two ureteral stents are inserted and pulled out through the anus with the rectal tube after having been fixed to the bowel mucosa (4-0 polyglactin rapide). The anterior pouch wall is closed by interrupted seromuscular sutures (4-0 polyglactin) (Fig. 83.17).

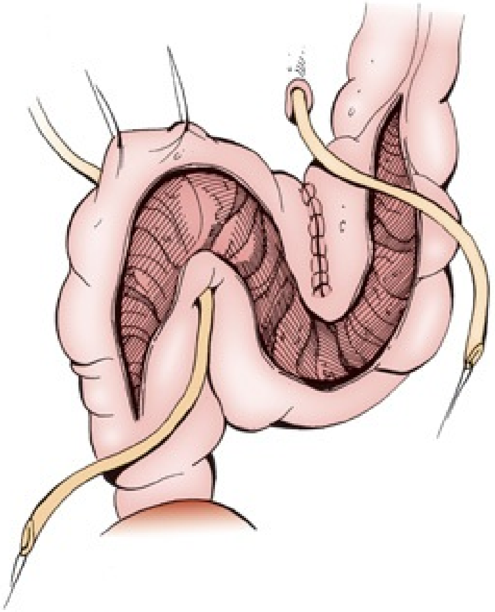

FIGURE 83.15 Side-to-side adaptation of the seromuscularis of the limbs of the S by two interrupted sutures close to the mesentery (4-0 nonabsorbable suture), thereby creating two serous-lined channels. On the right side, an entrance for the right ureter is left at the cranial aspect of the running suture and the ureter is pulled through. One ureter is placed in each channel created between the segments of the S.

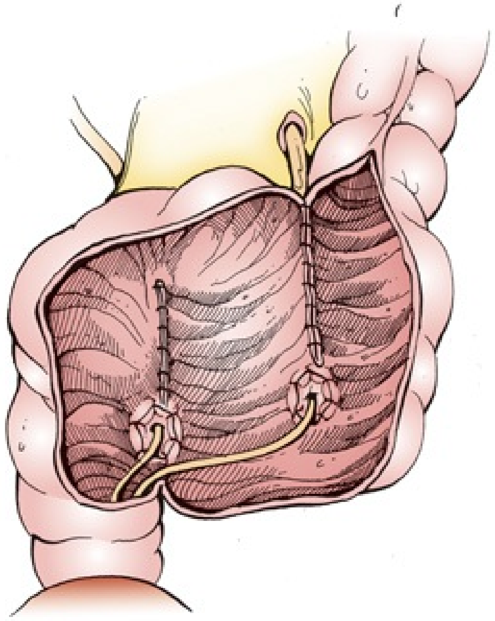

FIGURE 83.16 Ureteral implantation in the area of the continuous suture line. Insertion of ureteral stents.

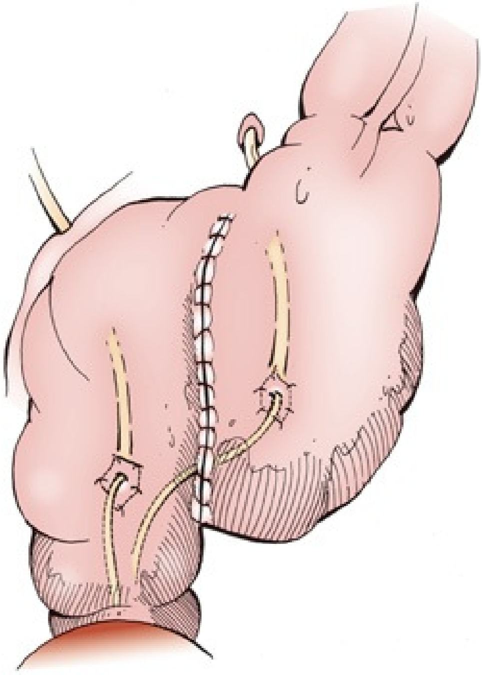

FIGURE 83.17 The stents are pulled through the anus and the pouch is closed.

Surgical Tricks (Sigmoid-Rectal Pouch)

When the anastomosis reaches deep down to the rectum, it is easier to suture the pouch starting caudally, as the deepest point of the anastomosis is the most critical part and can be reached more easily at the beginning of the anastomosis. To facilitate fixation of the pouch to the promontory, one sutured end of the dorsal running suture can be pulled through dorsally outside of the pouch and be tightened with the fixation suture placed in the anterior band at the promontory. A Bassini needle facilitates placement of the fixation suture through the anterior band of the spine. During ureteral implantation, sufficient spatulation of the ureters is of utmost importance to avoid a nipple-like protrusion of the ureters.

To drain an incidental hematoma of the submucous tunnel, the mucosa covering the tunnel can be selectively incised at different points. The S-shaped sigmoid-rectal pouch as created for the ureteral implantation via a serosa-lined tunnel has an ideal and stable position within the pelvis; therefore, no fixation to the promontory is needed.

OUTCOMES

Low-pressure rectal reservoirs have replaced classical ureterosigmoidostomy (10). The technique is excellent for continent diversion particularly in women and has gained widespread acceptance in countries in which catheter material or stoma bags are difficult to obtain or do not find patient acceptance (19,21,25,26). Another indication is bladder exstrophy, especially in those patients in whom bladder reconstruction has failed (25,27).

An adequate patient selection is of utmost importance for outcomes. Most important is a competent anal sphincter mechanism. However, other technical details such as ureteral implantation, side-to-side anastomosis by two layers, and the fixation at the promontory (classical technique) are further improvements that are associated with more favorable outcomes.

Meanwhile, several groups have published long-term outcomes and complication rates (28–31). Comparability of the different report regarding outcomes is difficult due to the distinct techniques. Overall, results of ureterosigmoidostomy and the sigmoid-rectal pouch are reasonable. However, some specific issues have to be considered during follow-up and patient counseling regarding these techniques.

Development of Colorectal Carcinoma

Secondary malignancies (i.e., colorectal carcinoma) particularly at the position of ureteral implantation in the sigma or rectum are common finding during long-term follow-up (5). The risk of colorectal carcinoma development was increased 0 to 42 times in different reports (29,31–34). In some reports with small patient series, no colorectal malignancies were observed in patients treated with ureterosigmoidostomy (31,33). Similar findings were reported for 38 children who underwent Mainz pouch II urinary diversion and had a follow-up of more than 10 years receiving annual rectosigmoidoscopy (28). In contrast, a collaborative report from 44 German urologic departments comprising 17,758 urinary diversions found the tumor risk in ureterosigmoidostomies was 22-fold higher than in other continent forms of urinary diversion such as neobladders or pouches (34). A recent Swedish study reported on 24 patients with half century of follow-up in which ureterosigmoidostomy was performed in early childhood (29). Of the 24 patients, 7 developed invasive colorectal adenocarcinoma with 6 of those being low differentiated. One additional patient experienced colorectal adenocarcinoma in situ.

In conclusion, due to the significantly increased risk of a secondary malignancy in these types of urinary diversion, an annual lifelong surveillance with rectoscopy starting from the fifth postoperative year is mandatory.

Continence Rates

Both, ureterosigmoidostomy and the Mainz pouch II, are associated with very good day and nighttime continence rates. In the literature, the overall continence rates for rectal reservoirs are approximately 95% (30,31). The majority of studies found patients continent during the daytime with an emptying frequency of three to five times (25,28). Although complete continence during the night is reported in some studies (25), the majority of studies report nighttime incontinence requiring pads in about 10% to 20% of patients (28). About one-third of the patients have to urinate more than six times during the day and more than three times during the night (35). It has been suggested that the risk of severe nocturnal incontinence may be higher in patients after revision surgery for their rectal reservoir (36).

Upper Urinary Tract Safety

In general, upper urinary tract outcomes after ureterosigmoidostomy and Mainz pouch II urinary diversions are reasonable. Indeed, it is difficult to make a point on the true impact of these diversion types on upper urinary tract outcomes, as all studies analyzing this issue were retrospective. In addition, differences regarding age, follow-up, additional underlying conditions, such as diabetes and hypertension with increased risk for renal deterioration, and pre- and postoperative techniques and routines might affect study outcomes. Another problem relates to the methods of measuring renal function after urinary diversion. Most reports have relied on serum creatinine and intravenous pyelography (IVP), but both are imprecise for this purpose.

In the published literature, a wide range of upper urinary tract function is reported. Some investigators found a normal urinary tract function with creatinine levels within normal limits (28) or reported on improved or stabilized renal function in the majority of renal units (64/66 RUs) (25), respectively. In contrast, other found impaired renal function ranging from 3% to 40% (31,37), although definitions for impaired renal function vary between reports. Frequently observed upper tract complications, which may be associated with subsequent renal impairment, include acute pyelonephritis (~16%), obstructive uropathy (~10%), recurrent urinary tract infections (mainly due to reflux [~4%]), and development of renal stones, respectively (38). In addition, metabolic acidosis is a common finding in these patients, which may be promoted by renal impairment (28,38–41).

In summary, upper urinary tract impairment may occur to a certain degree after rectal reservoir urinary diversion during long-term follow-up. Therefore, we recommend periodic follow-up examinations to check the upper urinary tract and prevent metabolic deterioration (28).

Quality of Life

Concerning quality of life, the Mainz pouch II serves as a satisfying continent urinary diversion for both sexes. No statistically significant differences in functional and symptom scales or global health status were detected between males and females. All scales but diarrhea showed good results, and the outcome was comparable to health-related quality of life in a reference population (35).

COMPLICATIONS

There are some specific complications that frequently occurred during short- and long-term follow-up of rectal reservoir patients. Early and late complications are reported in approximately 10% of patients (31,39) and 40% of patients (31), respectively.

A repeat surgical intervention is a common finding in patients with rectal reservoirs. In contemporary reports, reoperation rates are mentioned in up to 37% (31), although lower rates are reported from tertiary care centers. Different reasons are responsible for these high reintervention rates: Reimplantation of the ureter is a common indication (14.4%) in these patients, with ureterointestinal stenosis being a more common indication (10.1%) than reflux (4.3%) (28). In addition, conversion to different forms of urinary diversions during long-term follow-up has been reported in a significant number of patients (48%) in some studies (37).

As mentioned earlier, the foremost complication is stenosis at the ureterointestinal anastomosis. The incidence ranges from 10% to 22% (28,31). Hadzi-Djokic and Basic (41) reported a stenosis in 11 out of 220 patients. Hammouda et al. (42) used the serosa-lined extramural tunnel as well as the submucosal tunnel for ureteral implantation in 95 patients and found reflux in 1.6% of RUs and stenosis in 5.3%, respectively. Balloon dilatation and endoscopic incision of the stenosis have been described to treat ureterointestinal anastomosis, however, we would recommend open revision with ureter reimplantation, which offers reliable results for successful treatment (40).

Pyelonephritis is described with an incidence of 3% to 16% and should be treated with antibiotics (31,36,39,41). Only those patients with recurrent pyelonephritis and a decrease in split renal function require ureteral reimplantation.

About two-thirds of patients will develop an acidosis with a negative base excess. Early correction (starting from a base excess of –2.5) with alkali supplementation is recommended to avoid further complications, especially in children.

CHAPTER 84 PALLIATIVE URINARY DIVERSION

STEPHAN DEGENER, BURKHARD UBRIG, AND STEPHAN ROTH

The word *palliative* derives from the Latin *palliare*, which means "to cover with a coat." The term *palliative therapy* implies the impossibility of cure. The main goal of palliative urinary diversion is the control or the prevention of symptoms caused by incurable diseases of the urinary tract, usually cancer. In addition to bladder and prostate cancer, advanced cervical, ovarian, breast, or colorectal cancer may interfere with the urinary tract.

INDICATIONS FOR SURGERY

There are no prospective studies that compare bladder-preserving strategies and palliative cystectomy in locally advanced bladder cancer. However, the clinical course of patients with advanced muscle-infiltrating bladder cancer under a bladder-preserving strategy is often dismal. In one study, 24 patients with muscle-infiltrating bladder tumor not eligible for cystectomy (mean age 81 years) were treated with bladder preservation for a mean 22.6 months. All complained of frequency, urgency, and severe nocturia. The mean hospital readmission rate was 8 times per patient. Salvage cystectomy was required in 11 of 24 cases, in 7 solely because of recurrent macrohematuria. Major complications that might have been prevented with early cystectomy were ileus in three cases and an enterovesical fistula in one. All patients in whom the bladder was preserved complained of severe symptoms that reduced the quality of their remaining life (1).

Therefore, in most palliative patients with locally advanced pelvic cancer, cystectomy or complete pelvic exenteration is the standard option, unless it is a nonresectable tumor. There is some evidence that radical cystectomy itself, if performed efficiently and with minimal blood loss, does not decisively increase the morbidity of the palliative urinary diversion. By contrast, the high disease-related complication rate with explicit impairment of the remaining life span has to be considered in conservative strategy (1–3).

In a specific group of patients with high surgical risk, frozen pelvis, or a short residual life expectancy, supravesical diversion without exenteration may be a viable option that results in good symptom control (3). Indications are infrequent, and results of this strategy have rarely been reported. Further alternatives to radical cystectomy with urinary diversion are observation, repeated transfusions, or indwelling catheters depending on the underlying disease process.

Nevertheless, the decision will be made in individual cases by the urologic surgeon and the patient. Despite all surgical and anesthesiologic advances in some borderline cases, the risk of the surgical approach is considered too high. The American Society of Anesthesiologists (ASA) score has been described as one reliable decision criterion: ASA scores ≥3 is significantly associated with increased complication and reoperation rate, especially those related to the type of urinary diversion (4).

SURGICAL TECHNIQUE AND OUTCOMES

Palliative urinary diversion will usually be performed with the lowest risk options that are acceptable to the patient. In general, conduits will often be preferred in palliative situations. Some patients for whom palliation is the goal may be very poor surgical candidates. Therefore, in these cases, less elaborate techniques such as cutaneous ureterostomy can be a safe and simple alternative. Nephrostomy placement should be considered in patients with extreme anesthetic or perioperative risks and in end-of-life situations.

Ileal Conduit

Assuming adequate surgical risk and life expectancy, an ileal conduit is the first choice of many urologists in a palliative situation. Ileal conduit can be performed despite previous abdominal surgery (e.g., enterostomy) in cases of impaired renal function and in patients with limited compliance because ostomy care is relatively easy. Patients may return to normal activity soon after discharge (Fig. 84.1). Postoperative complications such as metabolic acidosis or ureteroenteric anastomotic stenosis are extremely rare, and increasing conduit-related complication rates are only seen in long-term survivors (5).

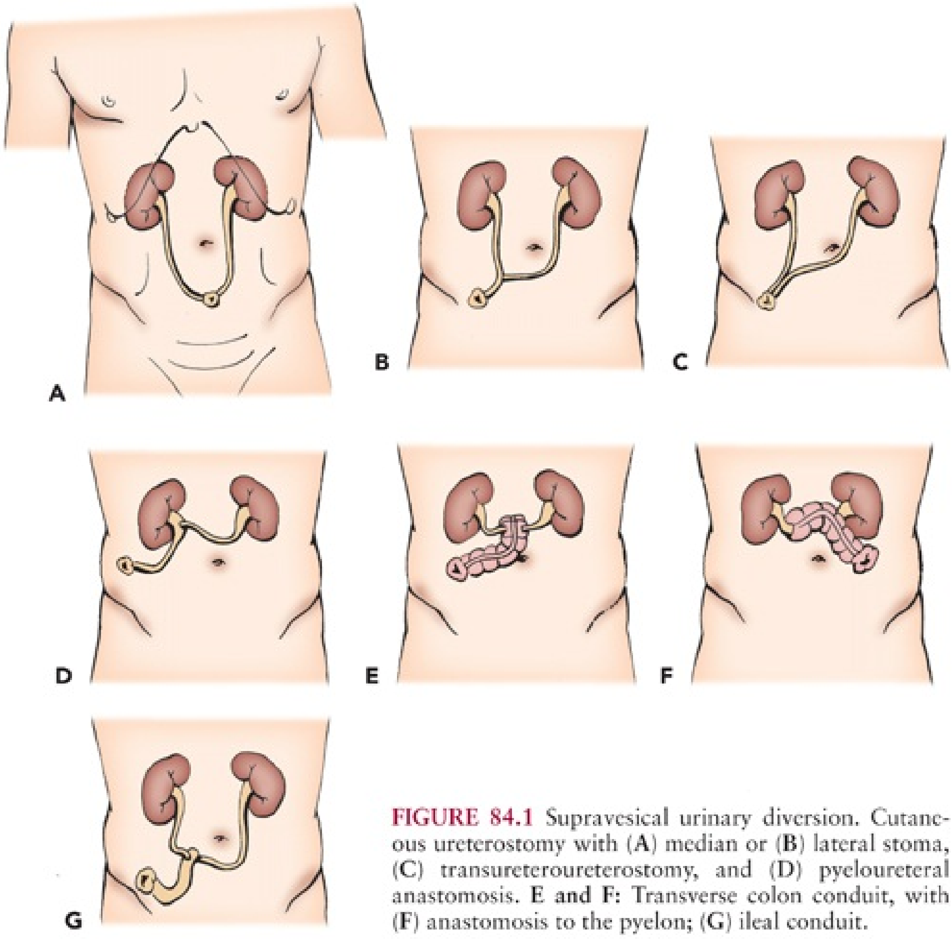

FIGURE 84.1 Supravesical urinary diversion. Cutaneous ureterostomy with (A) median or (B) lateral stoma, (C) transureteroureterostomy, and (D) pyeloureteral anastomosis. E and F: Transverse colon conduit, with (F) anastomosis to the pyelon; (G) ileal conduit.

An ileal conduit should not be used in patients with short bowel syndrome, inflammatory small bowel disease, or in those who have had high-dose radiation to the ileum. The small intestine and ureters are usually within the radiation portals for treatment of pelvic malignancy which may cause long-term sequelae: impaired postirradiation healing of gut anastomosis, and scarring with stricture formation of the ureterointestinal anastomosis may occur. Strategies to prevent strictures are high ureter resection, prolonged anastomotic single-J ureteral stenting, and preservation of paraureteric blood supply with minimal use of electrocautery.

Sigmoid Colon Conduit

The sigmoid colon is a viable alternative to the ileum if the latter cannot be used for conduit construction (see earlier). However, it should not be used if it is diseased, has been exposed to radiation, or if the internal iliac arteries have been embolized (or ligated) with the rectum still in place. This last condition might lead to rectal sloughing because of compromised rectal blood supply (6). The stoma will usually be placed in the lower left abdominal quadrant (see Fig. 84.1).

Transverse Colon Conduit

In patients irradiated for urologic, gynecologic or intestinal malignancies, the use of the ileum and lower colon segments is associated with a higher early and late complication rate. In these cases, a transverse conduit can be indicated because this part of the colon is not within the common radiation portals (avoidance principle). The blood supply via the middle colic artery is usually ample. Indications for the use of transverse colon for conduit construction can be marked radiation fibrosis of the ureters or impaired ureteral mobilization because of frozen pelvis or periureteral lymph nodes. The ureterointestinal anastomosis can be accomplished with very short ureteral stumps. Also, anastomosis with the renal pelvis is feasible (see Fig. 84.1). The perioperative mortality rate has been reported at 3% (6).

Bilateral Cutaneous Ureterostomy with Single Stoma

In patients for whom major gut surgery is not advisable, cutaneous ureterostomy is a safe and simple alternative to transintestinal diversion (see Fig. 84.1); operative time is short, and renal function is not a selection factor, although the most common complication of all intestinal urinary diversion, mechanical or paralytic ileus, rarely occurs. A single stoma construction in the lateral or midline position is generally feasible and ensures easier care with minimal discomfort in patients without excessive obesity, extensive paraureteral lymph node involvement, previous radiation therapy, or frozen pelvis (3).

Ureterocutaneostomic Stomal Construction

Stomal construction is of critical importance. Stoma stenosis is the major problem with all forms of ureterocutaneostomies, although recent data show significantly better tube free rates of up to 80% to 100%. Stomal stenosis mainly results from ischemia of the distal ureteral end with consequent sloughing and fibrosis. Different strategies like an omentum wrapping or the preservation of the fascia between the spermatic cords and the ureters (2,7) have been described to prevent ischemia. Additionally, distal spatulation of the ureteral end and plastic augmentation with a V-shaped skin flap as proposed by Rodeck (8) or the split-cuff nipple should be considered. Therefore, the ureter is spatulated, folded back to form split-cuff nipple, and corners are sewn with small gap to prevent ureteral constriction (9).

To prevent ureteral obstruction Rodríguez et al. (10). reported a postoperative stent placement for at least 3 months with obstruction in only 4.5%. Also, postoperative tension or hyperplastic epithelium at the ureterocutaneous anastomosis may also play a role in luminal constriction. Firm fixation of the anastomosis to the skin and healing by first intention is essential. The following technique has been proposed. Both ureters are guided to the skin and anastomosed with each other and the stomal skin (see Fig. 84.1). This can be done by passing one ureter to the contralateral side through the retroperitoneum and behind the descending colon (2). Alternatively, in slender patients, the ureters may be mobilized completely extraperitoneally, led around the peritoneal sac, and conjoined in the midline. An infraumbilical stoma can then be formed (3).

Transureteral Cutaneous Ureterostomy

One ureter is retroperitoneally led to the other side and anastomosed to the contralateral ureter end to side (e.g., with 5-0 Monocryl). This technique is particularly well suited in patients with one dilated ureter. Thus, the nondilated ureter is implanted into the dilated one which will be guided through the abdominal wall and anastomosed to the skin.

Transureteropyelocutaneous Ureterostomy

Alternatively, the collecting systems of both renal units can be connected via a high ureteral or pyeloureteral anastomosis (see Fig. 84.1). The operative mortality is 1.75%; severe late complications occur in 10.5% of cases. The most frequent problems (14%) arise from the nephrostomy (dislocation, pyelonephritic episodes, and urine leakage) and from stenosis of the ureteropelvic or ureteral anastomosis (10%) (11).

Percutaneous Nephrostomy

Percutaneous nephrostomy is another alternative for supravesical diversion. The advantages are the relative ease with which these can be placed under local anesthesia, but the drawbacks are the need for continuous replacement owing to encrustation as well as the propensity for these to become dislodged. Bilateral nephrostomies are sometimes badly tolerated, and usually only the kidney with better function should be diverted by nephrostomy. To prevent discomfort for the patients, the nephrostomy should be positioned as lateral as possible. For the balloon filling, a concentration equivalent to 5% saline is recommendable. Additionally, displacement can be prevented efficiently by using nephrostomies with a locked tie or other attachment devices. However, recent data show that nephrostomy diversion is associated with no significant difference in the quality of life but can improve the chance of survival in the short term (12).

In rare cases of further ureteral urine flow, additional occlusion of the ureter may sometimes be necessary. Transection and ligation of the ureter with nonabsorbable material may be performed. This may be accomplished by a small flank incision or laparoscopically. If feasible, a unilateral cutaneous ureterostomy may be the better alternative in such cases.

Several percutaneous techniques to obliterate the ureteral lumen have been proposed, with poor long-term results: butyl-2-cyanoacrylate, detachable balloons, liquid polyacrylonitrile, electrocautery, nylon and silicone occlusion devices, coil embolization by interventional radiology, and nephrostomy devices for transient closure of the ureteral lumen did not survive the test of time.

Eliminating Function of the Contralateral Kidney

If only one kidney is diverted, and urine continues to flow downstream from the contralateral kidney, it may be necessary to render the latter nonfunctional. Some palliative patients are poor candidates for nephrectomy. Ligature and transection of the ureter will usually result in long-term success in a previously obstructed hydronephrotic kidney with significant parenchymal reduction. Postinterventional paralytic ileus and some pain may be expected during the first postoperative days.

However, in unobstructed kidneys, ligature of the ureter should not be done because of significant pain and spontaneous ureteral recanalization. Usually, renal arterial embolization will be considered. Since the first description in 1969 by Lalli et al., (13) there have been only a few case series published. Excellent results to stop urine production from the kidney have been reported in cases of transcatheter ablation, with a mixture of ethanol and contrast agent and a combination of sponge and coil plugging of the proximal artery: Of 20 patients, urinary flow ceased after 2 days in 18 patients, 2 required a second session. The authors proposed epidural anesthesia, which may also be used in the first 2 postoperative days for pain control. Transient postinterventional paralytic ileus and fever may be expected. Other reports show good symptom control and low complication rates (14,15).

PALLIATIVE TREATMENT OF URETERAL OBSTRUCTION

Common causes of malignant compression of the ureterovesical junction and the prevesical ureter are bladder, prostate, and cervical cancers. Malignant obstruction of the mid- or upper ureter is usually caused by metastatic lymphatic spread, such as from metastatic breast cancer, lymphatic disease, colon cancer, and cancers of the female internal genitalia. However, even years after radiation therapy, newly arising ureteral obstruction, rather than tumor recurrence, may represent a long-term sequelae of radiation.

Indications for treatment should be considered very carefully. Septic episodes, with accompanying persistent pain, are rare in malignant ureteral obstruction if there has been no retrograde endoscopic manipulation. The insertion of a regular double-J stent or a nephrostomy will result in repeated consultations to change the catheters, sometimes under general anesthesia. Any measure carries the risk of infection or dislocation. Many patients are in critical condition, and the quality of life should be the main treatment goal.

In patients with unilateral ureteral obstruction and sufficient function of the contralateral kidney, one should generally abstain from therapy; however, if nephrotoxic chemotherapy is planned, or life expectancy exceeds 1 to 2 years, intervention may be indicated. In patients with bilateral ureteral obstruction and impending renal failure, it is usually sufficient to stent, divert, or bypass only one renal unit (usually the one with better function). The use of the techniques mentioned in the following text assumes normal bladder function. Otherwise, supravesical diversion may be considered.

Retrograde stenting with replaceable double-J stents is often considered the first-line option for relieving ureteral obstruction (Fig. 84.2). Transurethral resection will sometimes be necessary to find the ureteral orifice or intramural ureter hidden in the tumor. In these situations, prior antegrade placement of a guide wire or antegrade placement of the stent itself may be very useful. Specific drawbacks of double-J stents are irritative bladder symptoms, stent obstruction, and encrustation—necessitating repeated changes (intervals range from 6 weeks to 6 months but can be much shorter)—and stent migration.

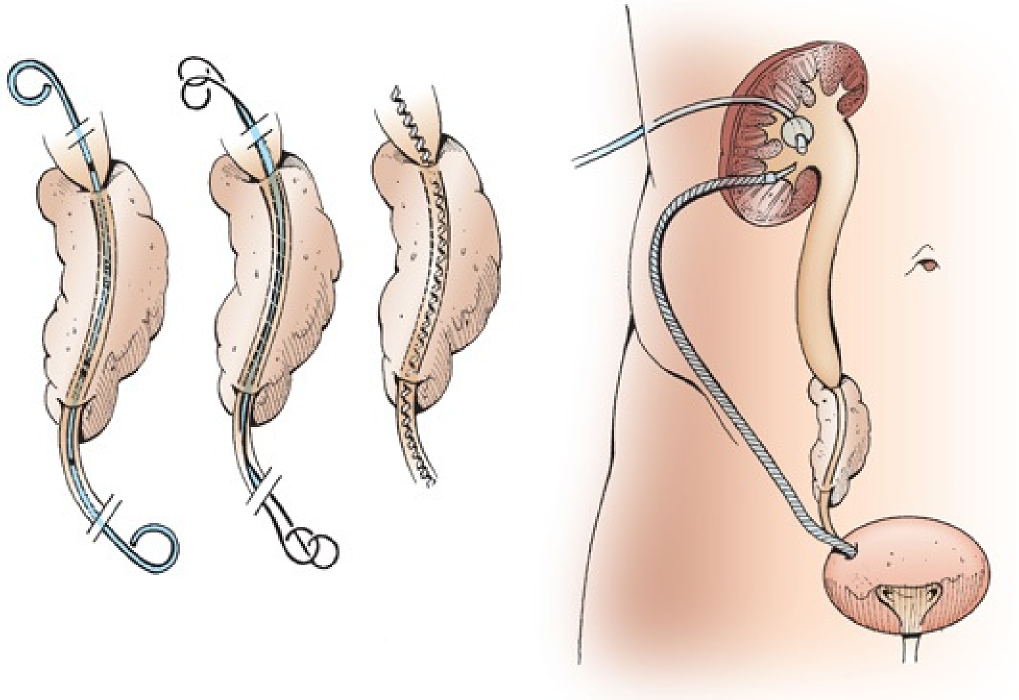

FIGURE 84.2 Endourologic techniques for treatment of malignant ureteric obstruction. **A:** Ureteral stent. **B:** Two parallel ureteral stents. **C:** Metal stent. **D:** Nephrostomy tube. **E:** Extra-anatomic prosthetic bypass.

Under conditions of extrinsic compression, hard polyurethane “tumor stents” are preferred to soft silicone to ensure patency of the stent lumen. Especially for extrinsic compression, newly developed metallic ureteral stents show acceptable results. Additionally, patients in a palliative setting can benefit from a longer dwell time up to 12 months.

In some patients, however, it may be preferable to abstain from any treatment at all. Ishioka et al. (16) developed a risk stratification model for predicting poor survival after palliative urinary diversion (by percutaneous nephrostomy) with three risk groups. They thereby identified three significant risk factors: low preinterventional serum albumin (≤3 g/dL), hydronephrosis grade 1 to 2, and three or more events related to malignant dissemination. The risk groups were defined as favorable (no risk factor), intermediate (one risk factor), and poor (two to three risk factors): Median survival in the favorable risk group was 7 months (1-, 6-, and 12-month survival rates were 97%, 69%, and 39%, respectively) and 3 months in the intermediate risk group (1-, 6-, and 12-month survival rates were, respectively, 76%, 24%, and 5%). In the poor risk group, the median survival was only 2 months (1-, 6-, and 12-month survival rates were 66%, 2%, and 0%, respectively). The differences in the survival profiles were highly significant (16).

Two Double-J Stents

Extensive compression from the tumor may lead to obstruction of conventional double-J stents or may inhibit the urine capillarity along the outside of the double-J stent. When drainage with a single ureteral stent has failed, two 4.7Fr or 7.0Fr double-J stents passed simultaneously over guide wires increase the stiffness and reduce kinking and luminal compression. A decisive factor is the potential space between the stents most likely preserving flow around as well as through them. In all patients, the insertion of two parallel stents was technically possible and in 70% of patients with extrinsic tumor compression, the stents provided sufficient drainage (17,18) (see Fig. 84.2). Alternatively, coiled ureteral stents which do not allow for a complete compression and obstruction because of their outer surfaces can be used.

Metallic Mesh Stents

Metallic mesh stents such as the Wallstent have been used with limited success. Epithelial hyperplasia and tumor ingrowth through the mesh have been reported to result in recurrent ureteral obstruction. These stents are virtually unremovable, and certain problems limit the application of metal mesh stents in the ureter. Therefore, some authors indicate that expandable metallic stents cannot be recommended for malignant ureteral obstruction (19). However, a recent study with a self-expandable, double-layered and coated metallic mesh stent (Uventa) showed a primary success rate of 65% after a follow-up of nearly 1 year. But again, tumor progression was the most common reason for primary stent failure (75.0%) (20).

Extra-anatomic Pyelovesical Prosthetic Bypass

In 1992, Desgrandschamps and colleagues (21) introduced their technique of pyelovesical bypass with a composite prosthesis (internal diameter, 18Fr; external diameter, 28.5Fr), and Jabbour et al. (22) reported long-term results with 35 prosthetic ureters in 27 patients, 22 with malignancies. Minor early and late complications were noted in 5 and 3 patients, respectively. No encrustations of the inner silicone lumen were noted, although asymptomatic bacteriuria sometimes was. The 5 surviving patients (4 with renal transplants, 1 with retroperitoneal fibrosis) were followed from 34 to 84 months (mean, 47 months), and the authors found no encrustation, kinking, or obstruction (22). In cases of persistent vesicovaginal or vesicocutaneous fistula, a pyelocutaneous bypass can also be performed. Data from different work groups suggest that the quality of life may be better for those patients than with conventional nephrostomy tubes.

Transverse Retubularized Colon Segments

In selected patients, transverse reconfigured colon segments may be used successfully to reconstruct extensive ureteral defects (Figs. 84.3 and 84.4). The successful use of a combination of two such segments has been described to divert solitary kidneys in palliative situations (23). In patients with renal insufficiency or a history of irradiation, this technique may be superior to the use of ileum. An advantage of the colon is its immediate proximity to the ureters bilaterally, its position outside the radiation portals for treatment of pelvic malignancy, its optimal cross-sectional diameter for the graft, and low intraperitoneal surgical trauma. Long-time follow-up from our work group shows no impairment of renal function, metabolic disorders, mucus obstruction and stricture, or adhesive ileus for reconfigured colon interponats (24). Nevertheless, unreconfigured colon has not been widely recruited for ureteral replacement because of its wide diameter: Its large volume when replacing long defects could result in metabolic or septic complications. Surgical access is via a flank or pararectal incision, and intraperitoneal surgery is minimal. The colonic segments are taken immediately proximal to the ureteral defect, necessitating little mobilization of the mesenteric pedicle.

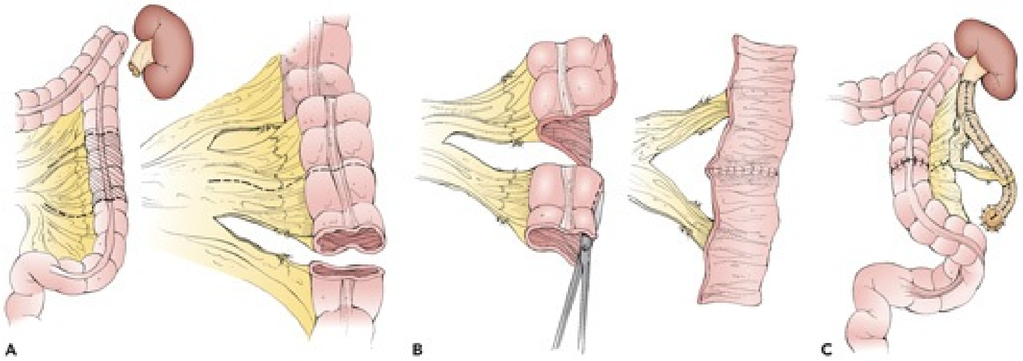

FIGURE 84.3 Combined reconfigured colon segments for incontinent diversion of solitary kidney. **A and B:** A 6-cm segment is excised from the ascending or descending colon. The segment is split in the middle and the rings are opened antimesenterically. When reconfigured, the tube produced will be approximately 18 cm long, suitable for incontinent urinary diversion. **C:** Pyelocolocutaneostomy in a solitary kidney.

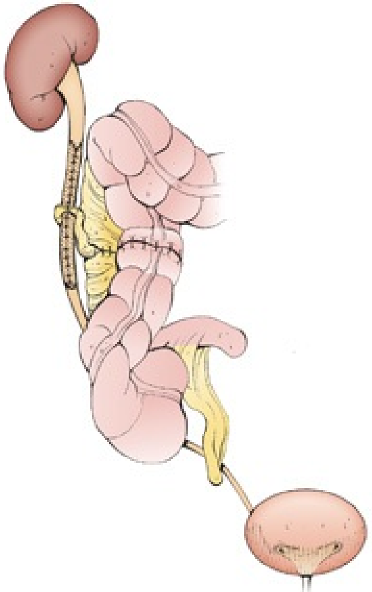

FIGURE 84.4 Interposition of a reconfigured colon segment to repair an extensive ureteral defect.

SECTION VIII ■ PEDIATRICS

Section Editor: H. GIL RUSHTON

CHAPTER 85 ■ WILMS TUMOR

MARK D. TYSON AND MICHAEL L. RITCHEY

Wilms tumor, or nephroblastoma, is the most common renal tumor of childhood, constituting approximately 6.3% of all cancers and 95% of all kidney cancers in children younger than the age of 15 years in the United States (1,2). According to the Surveillance, Epidemiology, and End-Results (SEER) registry, the average annual age-adjusted incidence rate of Wilms tumor is 8.0 per million, which translates into approximately 500 new cases in the United States per year (1). The incidence is highest among children younger than 2 years of age and declines precipitously with increasing age. The incidence rates are also somewhat higher for females and blacks (3,4).

Although most cases of Wilms tumor are sporadic, up to 10% of Wilms tumors are associated with overgrowth and non-overgrowth syndromes (5). Examples of overgrowth syndromes include Beckwith–Wiedemann syndrome, which is characterized by macroglossia, visceromegaly, and an omphalocele at birth, and is caused by microduplication mutations at 11p15.5. Other overgrowth syndromes include Simpson–Golabi–Behmel syndrome (an X-linked fetal overgrowth syndrome), Perlman syndrome (macrocephaly, macrosomia, visceromegaly, and dysmorphic facial features), and Sotos syndrome (cerebral gigantism). Examples of non-overgrowth syndromes include isolated aniridia, trisomy 18, WAGR syndrome (Wilms tumor, aniridia, genitourinary malformations, and mental retardation), Bloom syndrome (autosomal recessive disorder characterized by short stature, micrognathism, and café au lait spots), and Denys–Drash syndrome (male pseudohermaphrodism and mesangial renal sclerosis). Wilms tumor is also associated with isolated genitourinary anomalies such as hypospadias, cryptorchidism, and renal fusion.

The identification of the relationship between Wilms tumor and WAGR syndrome led to the discovery of genes associated with Wilms tumor. The WT1 gene located on chromosome 11p13 encodes a zinc finger transcriptional factor that serves both tumor-suppressive and developmental regulatory functions (5). Wild-type WT1 is critical in the early embryogenesis of the genitourinary system and is expressed in the kidneys, gonads, spleen, and mesothelium. The incidence of WT1 mutations in patients with nonsyndromal Wilms tumor is 2% (6). Another genetic mutation associated with Wilms tumor has been designated the WT2 gene, located at the chromosome 11p15 locus, which contains a cluster of imprinted genes. Loss of heterozygosity (LOH) at this locus is associated with Beckwith–Wiedemann syndrome.

LOH at chromosome 16q and/or 1p occurs in up to 20% of Wilms tumors (7). These have been shown to be associated with an increased risk for tumor relapse and mortality. In National Wilms Tumor Study (NWTS)-5, patients with stage I or II favorable-histology Wilms tumor (FHWT) and LOH of either 1p or 16q had an increased relative risk of relapse and death compared to patients lacking LOH at either locus. The risks of relapse and death for patients with stage III or IV FHWT were increased only with LOH for both regions.

Nephrogenic rests (NRs) are foci of primitive metanephric tissue that persist into infancy and are found in 1% of postmortem infant kidneys. Because NRs are found in up to 44% of kidneys removed for Wilms tumor and nearly 100% of patients with bilateral Wilms tumors, NR were thought to represent precursor lesions in children genetically predisposed to Wilms tumor. NRs are categorized as either perilobar or intralobar based on their anatomic location within the kidney. Perilobar NRs are observed in kidneys harboring Wilms tumors with WT2 locus deletions, whereas intralobar NRs are more often observed in those with WT1-associated tumors (8). The presence of multiple NRs in the nontumoral portion of a Wilms tumor kidney has been shown to be a risk factor for development of metachronous tumor in the contralateral kidney.

DIAGNOSIS

More than 90% of children with Wilms tumor present with an asymptomatic abdominal mass discovered incidentally by a family member or physician. The mass may be extremely large relative to the size of the child and is not necessarily confined to one side. Approximately 20% of children with Wilms tumor have hematuria at diagnosis and 25% will have hypertension at diagnosis. Gross hematuria warrants further evaluation to rule out tumor extension into the collecting system (9). Other symptoms include fever, anorexia, and weight loss in 10% of patients. Rarely, children may present with acute abdominal pain from tumor rupture into the peritoneal cavity or bleeding within the tumor. Physical examination may reveal a firm, nontender mass that classically does not cross the midline. A persistent varicocele in the supine position or hepatomegaly may be reflective of inferior vena caval obstruction from tumor thrombus. Atrial thrombus may present as hypertension or congestive heart failure.

The preoperative laboratory evaluation of a child with an abdominal mass should include a complete blood count, liver enzymes, and serum electrolytes, including blood urea nitrogen, creatinine, and calcium. Because as many as 8% of newly diagnosed patients with Wilms tumor will have acquired von Willebrand disease, coagulation studies should be considered (10). This includes prothrombin time and partial thromboplastin time, which may be normal in the presence of von Willebrand disease. This defect can be corrected preoperatively with the administration of 1-desamino-8-D-arginine-vasopressin (DDAVP).

The first radiographic study usually obtained in children with an abdominal mass is an abdominal ultrasound, which can differentiate between solid and cystic masses. Real-time ultrasonography of the renal vein and inferior vena cava (IVC) can evaluate for the presence of tumor thrombus in children with renal tumors. All patients should undergo either computerized tomography (CT) of the abdomen and pelvis with oral and intravenous contrast or magnetic resonance (MR) of the abdomen and pelvis with gadolinium. These imaging modalities allow for improved preoperative planning by evaluating for extrarenal spread of disease, the relationship of the tumor to adjacent visceral structures, and the presence of synchronous tumors in the contralateral kidney. The Children’s Oncology Group found that CT has moderate specificity but poor sensitivity in the detection of preoperative tumor rupture. Ascites beyond the cul-de-sac was most strongly associated with tumor rupture (11). Preoperative chest CT with or without contrast is performed to rule out pulmonary metastases (12,13).

INDICATIONS FOR SURGERY

The survival metrics of children with Wilms tumor appear to be improving over time. According to the SEER registry, the relative 5-year survival rate for children younger than the age of 15 years has improved from 73.1% in 1975 to 93.6% in 2002 (2). This improvement in the long-term survival of children with Wilms tumor is a testament to the systematic approach from which multimodal therapy has evolved. Despite the advances in chemotherapy protocols and radiation techniques, a high-quality surgical operation remains paramount in the treatment of Wilms tumor. Primary radical nephrectomy is the procedure of choice for the majority of patients with unilateral Wilms tumor diagnosed in North America. Renal-sparing surgery has been traditionally used in patients with bilateral Wilms tumors. However, the Children’s Oncology Group is now studying the role of renal-sparing surgery for select patients with unilateral tumors. Patients eligible for renal-sparing surgery on this protocol include those with a solitary kidney, a predisposition syndrome where tumors are found at a smaller size, and patients with an increased risk for developing renal failure (14,15). Several small single institution reports have documented the feasibility of partial nephrectomy in select cases of “low-risk” unilateral tumors, where nephron preservation is not imperative and where the risk of metachronous tumor formation is low (16). With respect to laparoscopy, there are reports in children with unilateral nonmetastatic Wilms tumor who received preoperative chemotherapy (17). However, the role of laparoscopy prior to chemotherapy may be limited because of large tumor size and risk of intraoperative spillage.

Tumor histology and stage are the most important determinants of prognosis in patients with Wilms tumor. Tumor grade, particularly the presence of anaplasia, is the most important prognostic factor and portends a poorer prognosis compared to favorable histology. The staging system used by the Children’s Oncology Group is presented in Table 85.1 and is based on various intraoperative and pathologic findings.

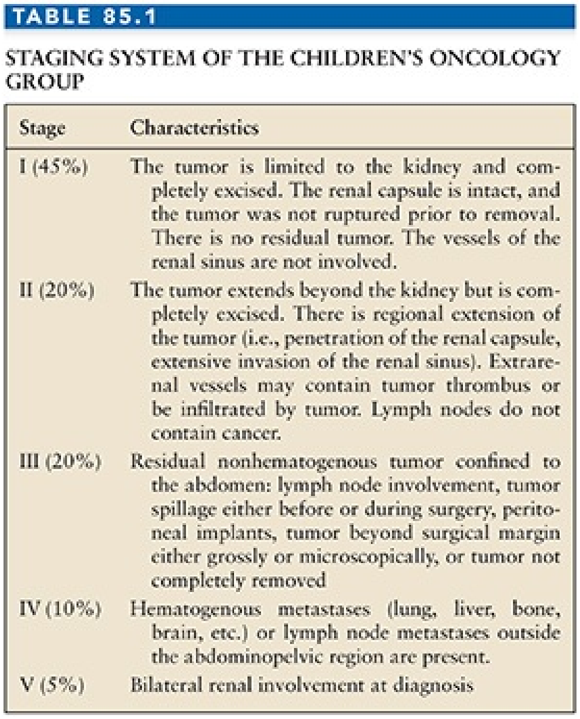

TABLE 85.1

STAGING SYSTEM OF THE CHILDREN'S ONCOLOGY GROUP

Stage	Characteristics
I (45%)	The tumor is limited to the kidney and completely excised. The renal capsule is intact, and the tumor was not ruptured prior to removal. There is no residual tumor. The vessels of the renal sinus are not involved.
II (20%)	The tumor extends beyond the kidney but is completely excised. There is regional extension of the tumor (i.e., penetration of the renal capsule, extensive invasion of the renal sinus). Extrarenal vessels may contain tumor thrombus or be infiltrated by tumor. Lymph nodes do not contain cancer.
III (20%)	Residual nonhematogenous tumor confined to the abdomen: lymph node involvement, tumor spillage either before or during surgery, peritoneal implants, tumor beyond surgical margin either grossly or microscopically, or tumor not completely removed
IV (10%)	Hematogenous metastases (lung, liver, bone, brain, etc.) or lymph node metastases outside the abdominopelvic region are present.
V (5%)	Bilateral renal involvement at diagnosis

PREOPERATIVE CONSIDERATIONS

The International Society of Pediatric Oncology (SIOP) advocates preoperative chemotherapy for all patients with Wilms tumor regardless of the extent of disease (18). Preoperative treatment can produce dramatic reduction in the size of the primary tumor, facilitating surgical excision. The SIOP trials have demonstrated that the incidence of tumor rupture is lower after preoperative therapy. There is no survival advantage over a primary surgical approach. The Children's Oncology Group (COG) recommends preoperative chemotherapy in children with bilateral tumors, tumors inoperable at surgical exploration, or IVC extension above the hepatic veins. All other patients are recommended to undergo primary excision of the tumor. This allows precise staging of patients with modulation of treatment for each individual, thereby decreasing the intensity of treatment when possible while maintaining excellent overall survival.

SURGICAL TECHNIQUE

The recommended surgical approach for Wilms tumor is through a transperitoneal transabdominal incision. An extraperitoneal flank incision should be avoided because it does not allow for proper staging. A generous transverse abdominal incision allows for inspection and exploration of the abdominal cavity. The patient is placed in a supine position with mild flexion of the lumbar spine to facilitate the exposure of retroperitoneal structures. The incision is made approximately two fingerbreadths above the umbilicus beginning in the midaxillary line on the side of the neoplasm. The extent to which the incision is extended across the midline will vary with the size of the tumor and amount of exposure needed. The incision may be extended into a thoracoabdominal approach by continuing through the bed of the 9th or 10th rib, if necessary. The muscle layers are divided sequentially to facilitate exposure. The peritoneal space should be opened carefully. The tumor may compress the colon and/or small bowel against the anterior abdominal wall, inadvertently resulting in enterotomy. A thorough exploration of the abdomen is performed. The peritoneal cavity is assessed for evidence of preoperative tumor rupture and peritoneal implants. The liver is carefully examined, as liver metastases may not be identified on preoperative imaging studies. An assessment of tumor extent is performed next, including palpation of the IVC and assessment of regional lymphadenopathy, perinephric extension, and tumor mobility. Formal exploration of the contralateral kidney is not needed if preoperative imaging does not demonstrate bilateral lesions (19).

Following exploration of the abdominal cavity, the colon is reflected medially by incising the white line of Toldt. The colonic mesentery is mobilized, with care taken to preserve the colonic vessels that may be draped over the tumor. The colon can then be retracted medially to expose the renal vessels (Fig. 85.1). For right-sided tumors, the posterior peritoneum can be incised up to the base of the mesentery. This will allow reflection of the entire colon and small bowel, which provides excellent exposure of the retroperitoneal vessels. Early ligation of the renal vessels before manipulation is ideal. The renal vessels are identified and encircled individually with vessel loops. The artery can be identified with careful retraction of the vein. The renal vein and IVC should be carefully palpated for the presence of Wilms tumor thrombus, which occurs in 4% and 0.7% of patients, respectively. Prior to ligation of the vessels, the contralateral renal vessels and superior mesenteric artery are identified to avoid injury to these structures. Large tumors can significantly distort vascular anatomy. The renal vessels are then doubly ligated and divided. The renal artery should be ligated prior to the renal vein in order to avoid distention of the vein, which can dislodge the ligature. Early ligation of the renal vessels also decreases the theoretical risk of tumor dissemination. Preliminary ligation of the renal vessels should not be pursued if technically difficult or dangerous.

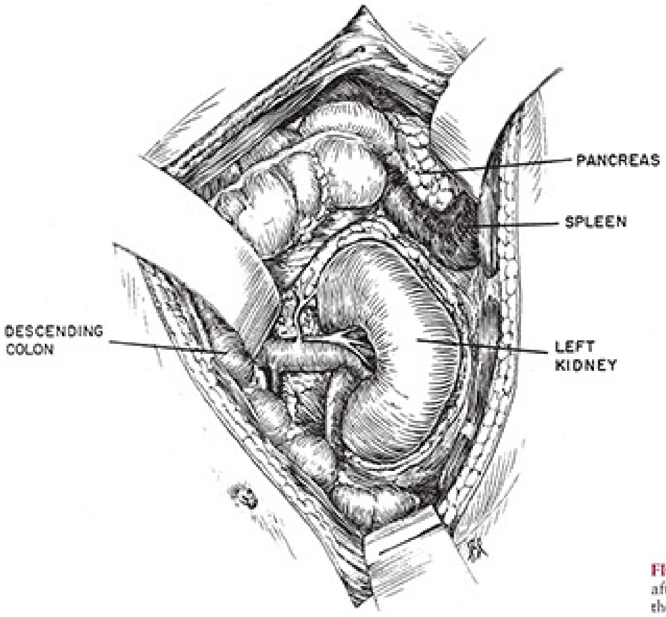

FIGURE 85.1 Descending colon retracted medially after incising of the line of Toldt and mobilizing of the mesocolon off the anterior surface of the tumor.

An alternative for management of the renal vein is to place a Satinsky clamp on the vena IVC just proximal to the insertion of the renal vein. This maneuver can be valuable when the vein is short or if there is tumor extension beyond the renal vein. The tumor thrombus is gently milked back prior to placement of the Satinsky clamp. The renal vein is then divided and the venous stump is oversewn with continuous 5-0 Prolene in two layers (Fig. 85.2).

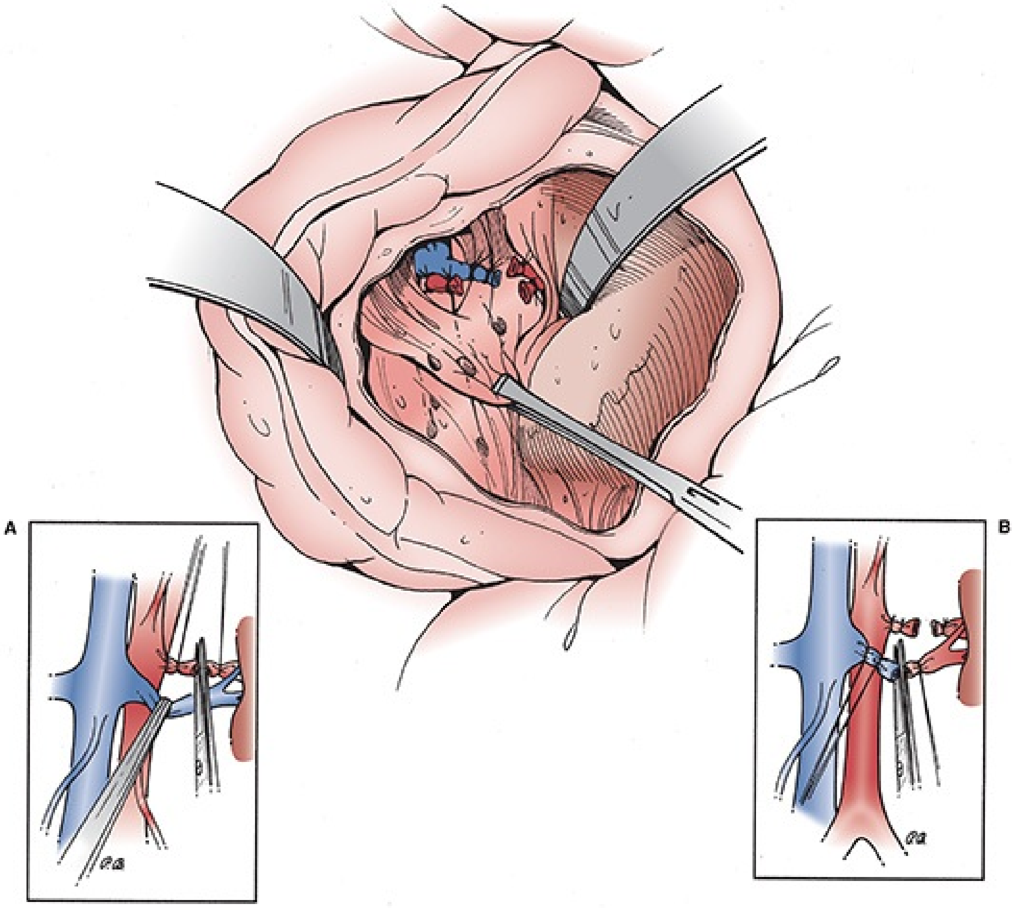

FIGURE 85.2 Mobilization of left-sided Wilms tumor by blunt dissection after ligation and division of the (A) renal artery and (B) vein.

If tumor thrombus is present in the IVC, additional surgical exposure is warranted. Both proximal and distal vascular control is necessary. For minimal thrombus extension below the level of the hepatic veins, the inferior edge of the liver can be retracted to expose the infrahepatic vena cava.

For a tumor that extends more cephalad, mobilization of the liver is required. Division of the triangular and coronary ligaments of the liver allows rotation and exposure of the retrohepatic vena cava. Additional exposure can be gained by dividing the lesser hepatic veins. The contralateral renal vein and infrarenal IVC are controlled with vessel loops. The IVC is then vertically incised just medial to the entrance of the renal vein. If the thrombus is free-floating, it is manually extracted at this point. In many cases, the thrombus is adherent to the wall of the IVC. A Fogarty or Foley balloon catheter can be passed beyond the level of the hepatic veins and then inflated. The catheter is then pulled inferiorly, thus displacing the adherent thrombus into the cavotomy. The IVC is allowed to fill by releasing the vessel loops on the distal cava and contralateral renal vein. This will displace the air from within the IVC. The cavotomy is then clamped with a Satinsky clamp and oversewn with a continuous 5-0 Prolene suture (Fig. 85.3). In rare instances, tumor thrombus invades the wall of the IVC, precluding thrombectomy, and this may necessitate partial resection of the IVC.

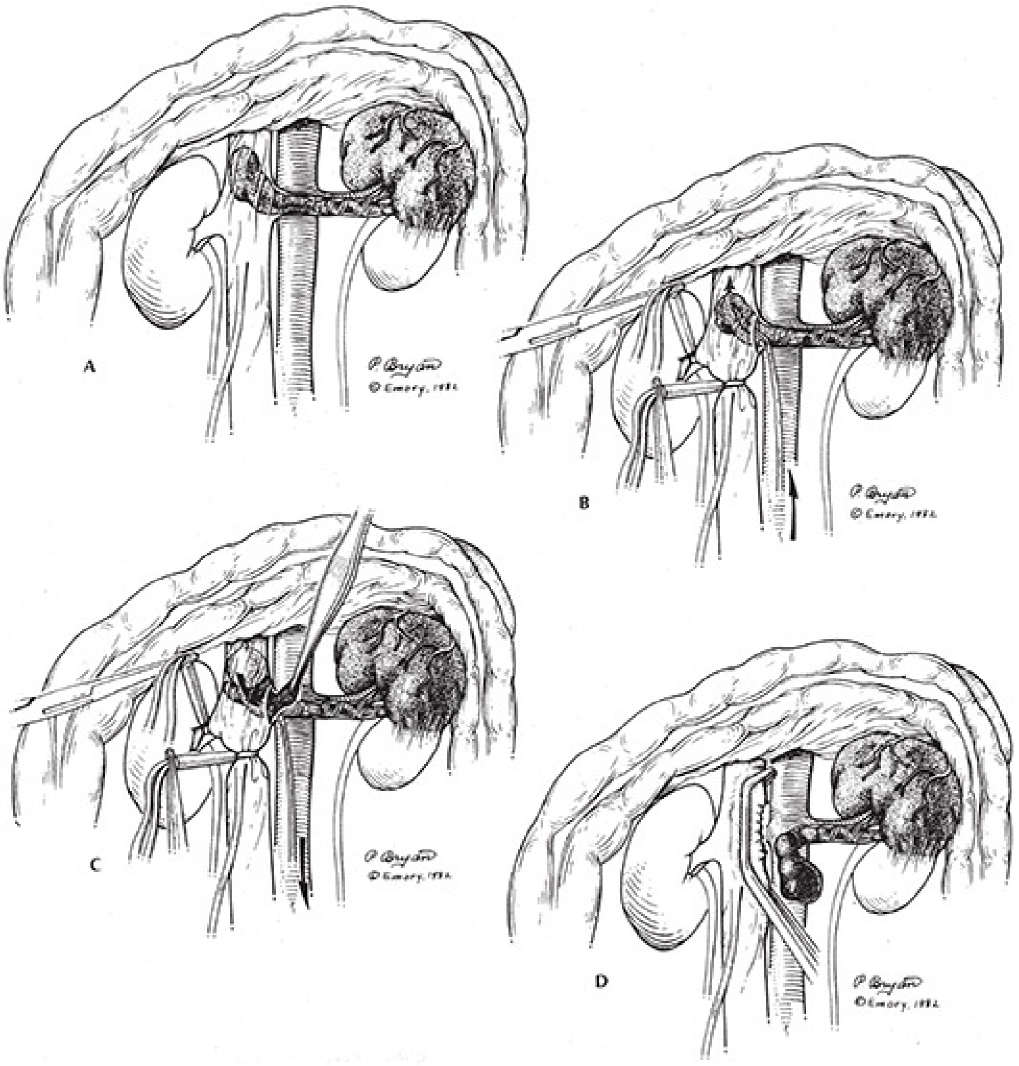

FIGURE 85.3 Surgical technique to manage tumor extension through the renal vein. **A:** Tumor extension into the vena cava (limited to the infrahepatic level). **B:** After exposure of the vessels, the infrarenal vena cava and contralateral renal vein are controlled with vessel loops, and the vena cava is incised vertically at the intersection with the renal vein. A Fogarty catheter (*arrow*) is passed superior to the tumor thrombus **C:** The balloon of the Fogarty catheter is inflated and traction placed downward (*arrow*) to pull the thrombus from the cava. **D:** The vena cava is flushed of air and a Satinsky clamp is placed to allow closure of the cavotomy.

Patients with IVC extension above the level of the hepatic veins or atrial thrombus remain a difficult surgical challenge. Pretreatment with chemotherapy is recommended to decrease surgical morbidity. If this fails to shrink the thrombus or if a primary surgical approach is chosen, the procedure may require cardiopulmonary bypass and benefit from a combined abdominothoracic approach with a pediatric cardiothoracic surgeon. Suprahepatic or atrial involvement is best approached through a median sternotomy. This can be performed in conjunction with a subcostal incision or a midline abdominal incision required for nephrectomy.

After the vessels are controlled, a dissection plane is established outside of the fascia of Gerota by sharp and blunt dissection. The perforating vessels can be quite large and should be ligated individually. Gentle manipulation of the tumor should be emphasized. Wilms tumors are very soft and may easily rupture, leading to tumor spill and an increased risk of local recurrence (20). It is not necessary to remove the adrenal gland with the specimen if there is no evidence of direct involvement with tumor. Involvement of the adrenal gland has been noted in 4% of patients but is noted more often with higher stage disease (21).

The ureter is palpated to rule out intraureteral extension before it is divided as distally as possible (9). Formal lymph node dissection is not required, but all suspicious lymph nodes should be biopsied. Lymphatic tissue in the renal hilum and adjacent precaval and preaortic areas is generally removed with the specimen. Failure to sample lymph nodes will mandate increased therapy due to an increased risk of local recurrence secondary to incomplete staging (22). Lymph node involvement and microscopic residual disease were the stage III criteria that were most predictive of event-free and overall survival in the NWTS-5 (23). After extraction of the intact tumor, the wound is copiously irrigated and hemostasis is assessed. Drains are not routinely placed unless a portion of the pancreas or liver has been resected. The displaced colon is replaced in the tumor bed.

Bilateral Tumors

Synchronous bilateral Wilms tumor occurs in 4% to 6% of patients with Wilms tumor (24). Children with bilateral Wilms tumors should not undergo initial radical nephrectomy; rather, they should receive preoperative chemotherapy with the goal of tumor shrinkage and renal preservation. Children treated with preoperative chemotherapy will have more renal units preserved. This is important because the risk of renal failure in patients with bilateral disease approaches 15% at 15 years posttreatment (14,25).

The current COG-AREN0534 protocol for patients with bilateral Wilms tumor recommends a 6-week regimen of vincristine, dactinomycin, and doxorubicin prior to surgery (24). Tumor response is evaluated with CT or MR after 6 weeks. Patients with tumors amenable to renal-sparing procedures can proceed with surgery. If there has not been a good response, biopsy of the tumor(s) is recommended to determine the histology. Additional chemotherapy is then given, but all patients should proceed to surgical resection within 12 weeks of starting therapy.

At the time of definitive surgery, partial nephrectomy or wedge excision of the tumor is preferred but only if complete removal of the tumor can be achieved. The kidney with the lower tumor burden is addressed first. If complete excision of tumor from this kidney can be performed leaving a viable and functioning kidney, then surgery of the contralateral kidney with more extensive tumor involvement is done. Enucleation of the tumor may be considered in lieu of a formal partial nephrectomy. This will usually be considered for large centrally located tumors where removal of a margin of renal tissue would compromise the vascular supply to the kidney. Even when very large bilateral masses remain after initial chemotherapy, a high percentage of children can be successfully managed with renal-sparing surgery (26). It is easy to underestimate the amount of renal parenchyma that can be salvaged due to compression by the tumor; therefore, renal-sparing surgery should be entertained in all patients. One concern regarding enucleation of large centrally located tumors is the potential for positive surgical margins. Kieran et al. (27) reported a 23% incidence of positive surgical margins in a cohort of patients with bilateral Wilms tumor undergoing renal-sparing surgery. They did not demonstrate an increased risk of local recurrence, but this was a small number of patients with all receiving postoperative radiation.

Adjuvant Therapy

All clinical trials for children with Wilms tumor strive to tailor treatment to individual risks for tumor recurrence and reduce the overall morbidity of treatment. The latter will allow clinicians to reduce treatment-related side effects. Current treatment recommendations of the COG are listed in Table 85.2 (28). All renal tumors are eligible for enrollment in COG protocols, including renal cell carcinoma and congenital mesoblastic nephroma.

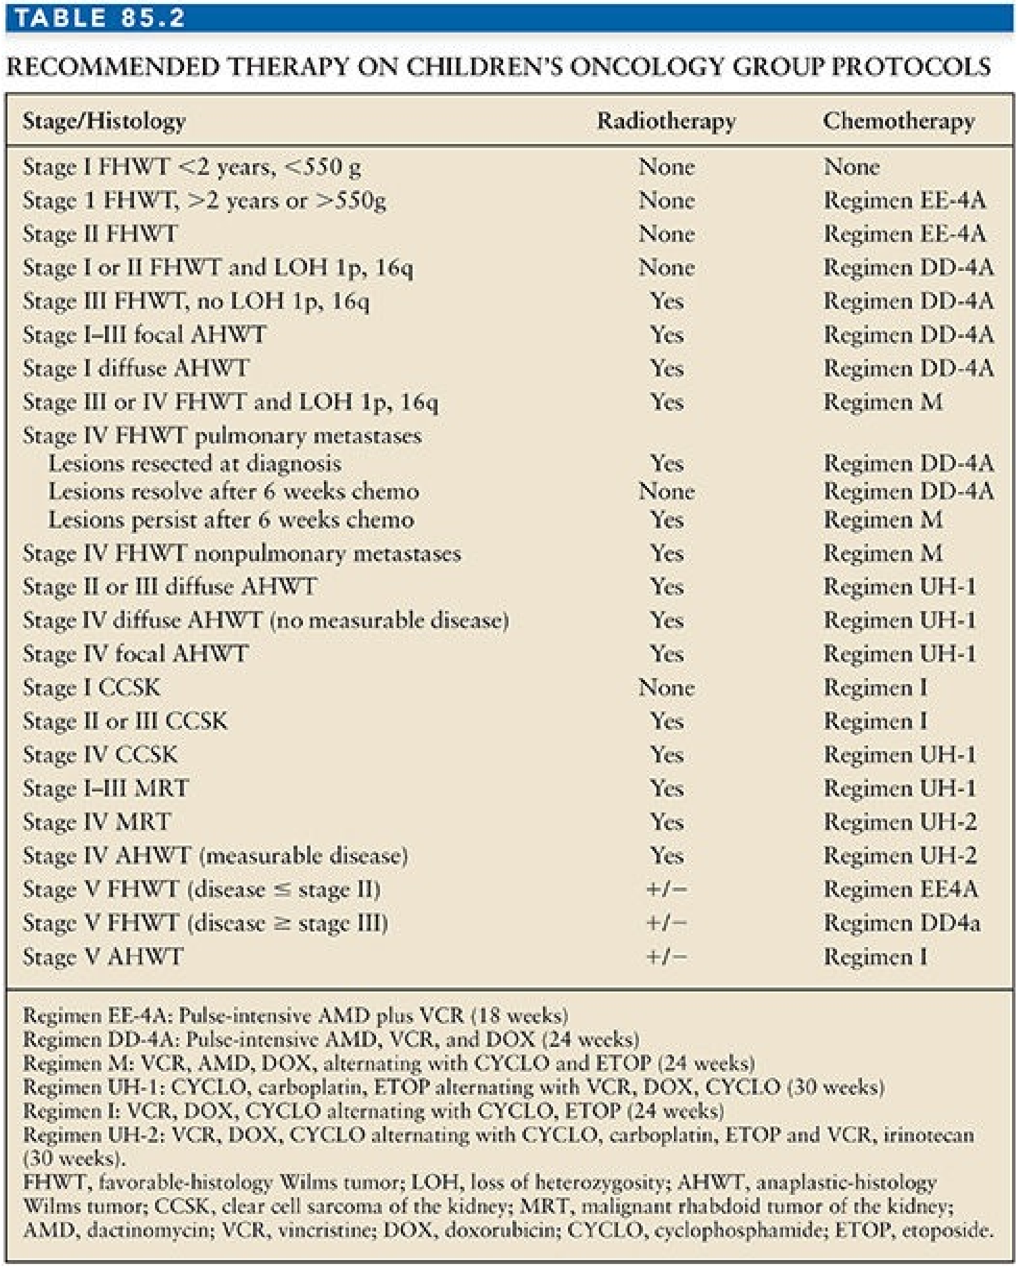

TABLE 85.2

RECOMMENDED THERAPY ON CHILDREN'S ONCOLOGY GROUP PROTOCOLS

Stage/Histology	Radiotherapy	Chemotherapy
Stage I FHWT <2 years, <550 g	None	None
Stage 1 FHWT, >2 years or >550g	None	Regimen EE-4A
Stage II FHWT	None	Regimen EE-4A
Stage I or II FHWT and LOH 1p, 16q	None	Regimen DD-4A
Stage III FHWT, no LOH 1p, 16q	Yes	Regimen DD-4A
Stage I–III focal AHWT	Yes	Regimen DD-4A
Stage I diffuse AHWT	Yes	Regimen DD-4A
Stage III or IV FHWT and LOH 1p, 16q	Yes	Regimen M
Stage IV FHWT pulmonary metastases		
Lesions resected at diagnosis	Yes	Regimen DD-4A
Lesions resolve after 6 weeks chemo	None	Regimen DD-4A
Lesions persist after 6 weeks chemo	Yes	Regimen M
Stage IV FHWT nonpulmonary metastases	Yes	Regimen M
Stage II or III diffuse AHWT	Yes	Regimen UH-1
Stage IV diffuse AHWT (no measurable disease)	Yes	Regimen UH-1
Stage IV focal AHWT	Yes	Regimen UH-1
Stage I CCSK	None	Regimen I
Stage II or III CCSK	Yes	Regimen I
Stage IV CCSK	Yes	Regimen UH-1
Stage I–III MRT	Yes	Regimen UH-1
Stage IV MRT	Yes	Regimen UH-2
Stage IV AHWT (measurable disease)	Yes	Regimen UH-2
Stage V FHWT (disease ≤ stage II)	+/−	Regimen EE4A
Stage V FHWT (disease ≥ stage III)	+/−	Regimen DD4a
Stage V AHWT	+/−	Regimen I

Regimen EE-4A: Pulse-intensive AMD plus VCR (18 weeks)
Regimen DD-4A: Pulse-intensive AMD, VCR, and DOX (24 weeks)
Regimen M: VCR, AMD, DOX, alternating with CYCLO and ETOP (24 weeks)
Regimen UH-1: CYCLO, carboplatin, ETOP alternating with VCR, DOX, CYCLO (30 weeks)
Regimen I: VCR, DOX, CYCLO alternating with CYCLO, ETOP (24 weeks)
Regimen UH-2: VCR, DOX, CYCLO alternating with CYCLO, carboplatin, ETOP and VCR, irinotecan (30 weeks).
FHWT, favorable-histology Wilms tumor; LOH, loss of heterozygosity; AHWT, anaplastic-histology Wilms tumor; CCSK, clear cell sarcoma of the kidney; MRT, malignant rhabdoid tumor of the kidney; AMD, dactinomycin; VCR, vincristine; DOX, doxorubicin; CYCLO, cyclophosphamide; ETOP, etoposide.

The first generation of COG studies (2006 to 2013) grouped patients by risk for recurrence (very low, low, standard, and high). The COG again examined the role of surgery-only treatment for patients with stage I FHWT weighing <550 g and age <2 years. Children with stage I or II FHWT and LOH of 1p and 16q were treated with vincristine (VCR), dactinomycin (AMD), and doxorubicin (DOX) without radiotherapy. Patients with stage III FHWT disease without LOH of 1p and 16q were treated with VCR, AMD, and DOX and irradiation of the flank or abdomen. The COG evaluated a response-based approach for management of children with pulmonary metastases. Those with resolution of the pulmonary lesions on chest CT after 6 weeks of chemotherapy were treated with VCR, AMD, and DOX. Patients who did not have resolution of the pulmonary lesions by week 6 received more intensive chemotherapy and pulmonary irradiation. Children with stage I to III focal anaplastic-histology Wilms tumor (AHWT) and stage I diffuse AHWT were treated with AMD, VCR, DOX, and abdominal irradiation. Patients with stage II, III or IV (no measurable disease) diffuse AHWT, stage IV focal AHWT, stage IV clear cell sarcoma, and stage I to III malignant rhabdoid tumor were treated with a new chemotherapy regimen to try to improve overall survival. All of the COG studies are closed to patient accrual with results not yet reported.

OUTCOMES

Complications

The most common intraoperative complication of nephrectomy for Wilms tumor is bleeding. Major vascular injuries and injury to other organs are less frequent. Following surgery, the most common complication is small bowel obstruction, which occurs in about 5% of patients (29). The surgical complication rate of nephrectomy for Wilms tumor has declined over the past three decades.

Preoperative chemotherapy may influence surgical complication rates by producing tumor shrinkage (30). A recent report from the United Kingdom Children’s Cancer Study Group compared the complication rate for patients undergoing immediate nephrectomy compared to delayed nephrectomy performed after 6 weeks of chemotherapy (31). They found significantly fewer complications in those undergoing delayed nephrectomy (1% versus 5.8%). They also noted a much higher rate of tumor rupture/spill in those undergoing immediate nephrectomy (14.6% versus 0%). This is similar to the rate of intraoperative tumor spill following immediate nephrectomy recently reported by the COG (32).

A mortality rate of 0.5% related to surgical complications was reported from NWTS-3. However, a higher intraoperative mortality rate of 1.5% has been reported from other centers. The latter may reflect that intraoperative deaths may not be reported to the cooperative groups since study enrollment occurs after surgery. Factors that have been associated with an increased risk for surgical complications are higher tumor stage, tumor size >10 cm, incorrect preoperative diagnosis, thoracoabdominal incision, intracaval tumor extension, and resection of other visceral organs.

Tumor Recurrence

Common sites of recurrence are the lungs, liver, and renal fossa. Approximately 15% of children with favorable histology Wilms tumor and up to 50% of children with anaplastic elements will develop recurrent disease. Tumor histology and clinical stage are the most important predictors of outcome. There is an increased risk for local recurrence in the setting of unfavorable histology and intraoperative tumor rupture (20). Omission of lymph node biopsy also correlates with recurrence and is attributed to understaging. Preventing local recurrence is important as the survival after abdominal recurrence is poor (5-year survival rate of 60%) (33,34). Current trials continue to refine chemotherapeutic regimens to improve survival, in particular for higher risk populations with unfavorable histology. The use of biologic factors to further stratify patients for therapy may further advance survival and minimize late effects of treatment.

CHAPTER 86 RENAL FUSION AND ECTOPIA

ROSS M. DECTER AND AMY S. BURNS

Abnormalities of renal position and fusion predispose to infection, hydronephrosis, stone disease, and, in some instances, neoplasia. Although clinical problems associated with these anomalies present infrequently in urologic practice, an understanding of the deviations from standard urologic techniques required to address them is important.

The ureteral bud branches from the wolffian duct and extends toward the metanephric blastema during the fourth and fifth weeks of gestation. The ureteral bud induces the metanephric blastema to form the functioning kidney. The exact mechanism of renal ascent is not known, but during normal development, the kidneys ascend and rotate. The renal pelvis rotates from its initial anterior position 90 degrees toward the midline until it reaches its final medial position. Migration and rotation occur simultaneously between the fourth and eighth or ninth weeks of gestation. The blood supply to the kidney is derived from successively higher levels of the aorta and its branches during ascent.

The most common anomaly of renal position is malrotation: incomplete rotation of the kidney to its final position. The renal pelvis in a malrotated kidney in general lies anterior to the parenchyma, as opposed to its normal medial location. Simple malrotation of a normally positioned kidney is often an incidental finding. The pyelocaliceal systems of malrotated kidneys are morphologically abnormal, but functionally, they usually drain without impairment. Malrotation occurs occasionally in orthotopically positioned kidneys, and it is commonly observed in ectopic kidneys.

Close approximation of the two proliferating renal blastemas prior to significant ascent is a normal embryologic finding (1). If there is any disturbance of separation of the closely approximated renal blastemas, fusion anomalies of the kidneys may develop.

The most common fusion anomaly is the horseshoe kidney. The horseshoe kidney in general ascends until the upper border of the isthmus is at the level of the inferior mesenteric artery. Horseshoe kidney occurs in 1 in 400 to 1 in 1,800 births (2). There is a male predominance for the condition (3). The fusion in horseshoe kidney almost always occurs at the lower poles; cases of upper pole fusion are recorded rarely (3). The isthmus of the horseshoe kidney lies just below the inferior mesenteric artery at the L4 vertebral level. The blood supply to these kidneys is variable (Fig. 86.1).

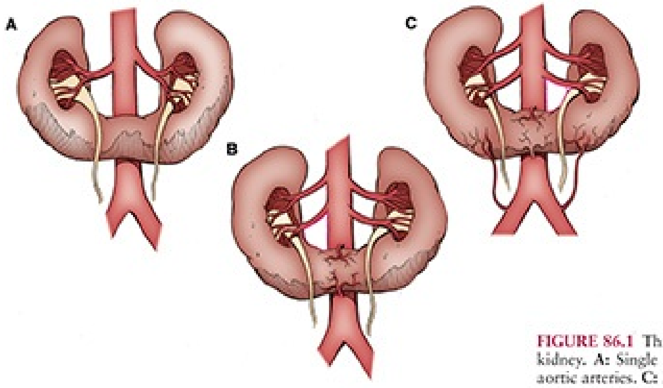

FIGURE 86.1 Three common variants of blood supply in horseshoe kidney. **A:** Single renal arteries arising from the aorta. **B:** Multiple aortic arteries. **C:** Multiple aortic and iliac arteries.

Crossed fused ectopia is the second most common fusion anomaly. This abnormality occurs when the developing kidney crosses from one side to the other during its ascent or when the ureteral bud from one side crosses to the contralateral side and induces abnormal development of that metanephric blastema. Crossed ectopia with fusion may occur in a variety of forms (Fig. 86.2). Although crossed ectopia occurs most frequently with fusion, the anomaly may occur without fusion (Fig. 86.3). The diagnosis should be considered in patients with a prenatal diagnosis of solitary kidney or an empty unilateral renal fossa (Fig. 86.4).

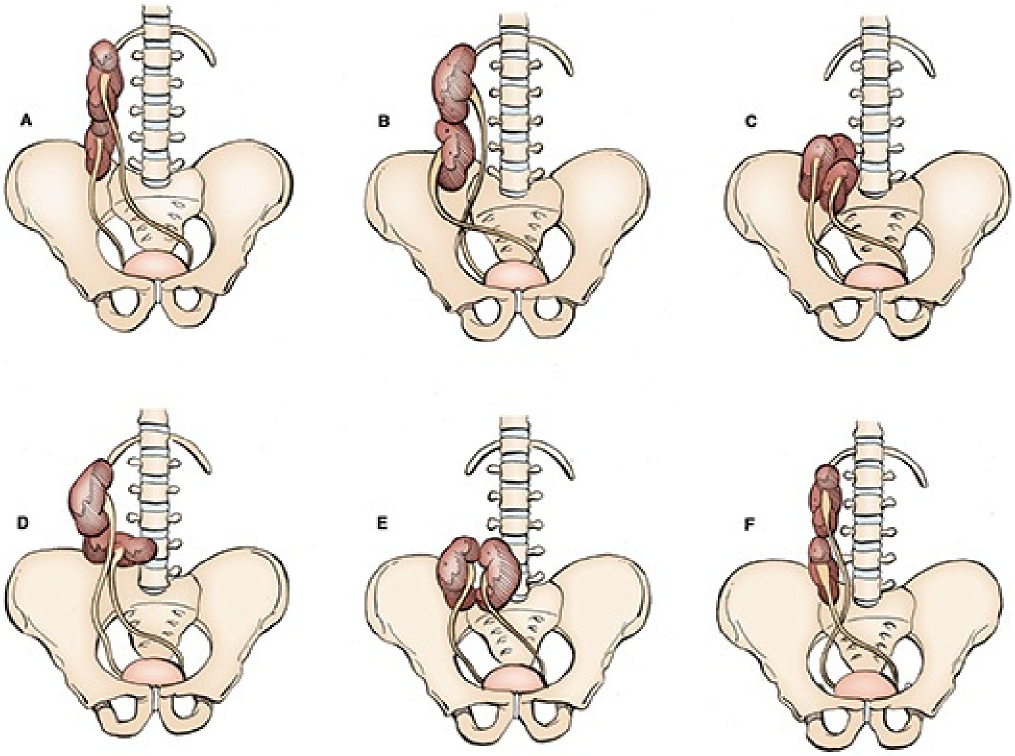

FIGURE 86.2 Six types of crossed renal ectopia with fusion. **A:** Ectopic kidney superior. **B:** Sigmoid or S-shaped kidney. **C:** Lump kidney. **D:** L-shaped kidney. **E:** Disk kidney. **F:** Ectopic kidney inferior. (Modified with permission from McDonald JH, McClellan DS. Crossed renal ectopia. *Am J Surg* 1957;93:995. Copyright © 1957 Published by Elsevier Inc.)

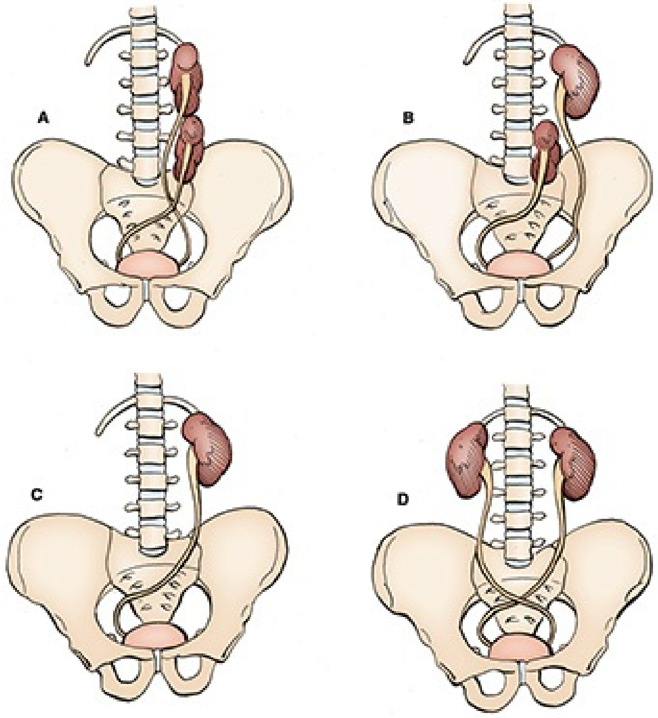

FIGURE 86.3 Types of crossed renal ectopia. A: Fused. B: Nonfused. C: Solitary. D: Bilateral. (Modified with permission from McDonald JH, McClellan DS. Crossed renal ectopia. *Am J Surg* 1957;93:995. Copyright © 1957 Published by Elsevier Inc.)

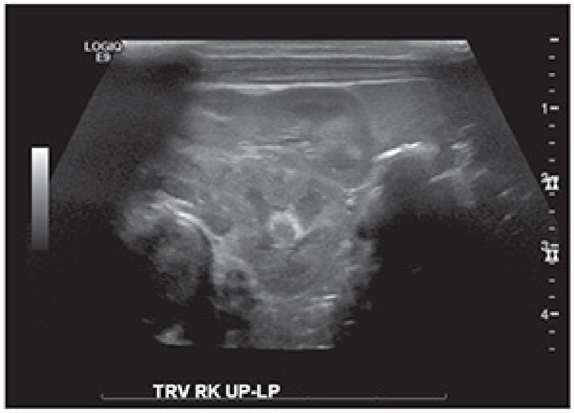

FIGURE 86.4. Crossed fused ectopia. Prenatal sonogram detected presumed solitary kidney. Postnatal sonogram revealed two distinct, but fused, renal units are seen in the right renal fossa, whereas no other renal unit was identified within the abdomen on surveillance sonography.

An ectopic kidney lies outside of the normal position in the renal fossa. The kidney, in simple ectopia, in general, lies in the ipsilateral retroperitoneal space at a position that is lower than normal (Fig. 86.5). In crossed ectopia, the kidney crosses the midline and is frequently fused to its contralateral mate. The autopsy incidence of renal ectopia is about 1 in 1,000 cases, and the condition often is totally asymptomatic (4). Reviews of renal ectopia show that the left kidney is affected slightly more frequently than the right. Ectopic kidneys occur bilaterally around 10% of the time, and the most common position of the ectopic kidney is in the pelvis. Pelvic ectopia was reported in about 55% of patients in one series of ectopic kidneys, crossed fused ectopia occurred in 27%, lumbar ectopia occurred in 12%, non–crossed fused ectopia occurred in 5% of patients, and a thoracic kidney was recorded only 1% of the time (4). Rarely, a solitary pelvic kidney occurs. Obstruction or infection in the previously undiagnosed pelvic kidney can be mistaken for other intra-abdominal pathology, such as appendicitis. Furthermore, this kidney suffers the risk of injury during pelvic surgical procedures and on occasion has been reported as an unusual cause of giant hydronephrosis.

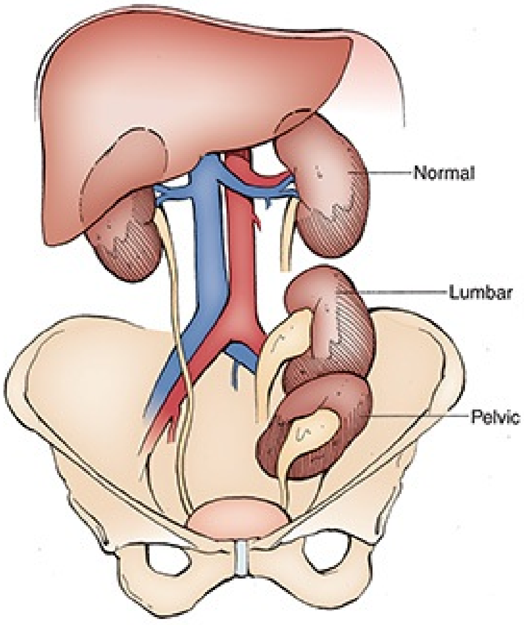

FIGURE 86.5 Location of lumbar and pelvic ectopically positioned kidneys in relation to the normally positioned kidney.

Ectopic kidneys are smaller than their orthotopically positioned mates (5). The blood supply to the pelvic kidney, the most common of the ectopic kidneys, is variable. The arterial supply may arise from the distal aorta or bifurcation, the ipsilateral common iliac, or the hypogastric vessels. In general, the lower the kidney is in its pelvic location, the greater the likelihood that multiple arterial vessels will supply it (6).

DIAGNOSIS

Horseshoe Kidney

Historically, 25% to 33% of patients with horseshoe kidneys who survived beyond the newborn period were asymptomatic (3). The advent of prenatal ultrasound screening makes it likely that an even larger proportion of these kidneys are asymptomatic. Patients with symptoms typically present with urinary tract infections (about 50% of the time), an abdominal mass, hematuria, or abdominal pain (approximately 10% each). Stone prevalence in horseshoe kidneys ranges from 20% to 50% (7).

The initial diagnostic evaluation in children is usually a renal ultrasound (RUS); however, sonographic detection of a horseshoe kidney can be difficult unless an isthmus is seen. Among 34 patients with known horseshoe kidney in one study, only 27 had a detectable isthmus on sonography. Other sonographic features suggesting the presence of a horseshoe kidney were low-lying renal units (78%), malrotation with anteriorly pointing pelvis (36%), bent or curved configuration of the kidney in the long axis (58%), tapering and elongation of the lower pole (60%), and a poorly defined inferior border of the kidney (84%) (8). In instances of hydronephrosis and obstruction, nuclear medicine imaging may detect presence of an isthmus not visualized on sonography (9). Because of the variability in detection of horseshoe kidney via imaging studies typically employed in children, a high index of suspicion should be maintained when performing renal surgery in children when aberrant or unexpected anatomy is encountered intraoperatively.

Symptomatic adults typically undergo computerized axial tomography (CT) where the isthmus is typically readily visible. Historically, many adults underwent intravenous pyelography (IVP) as their initial study, and the IVP features of the horseshoe kidney are typical. The renal axis is abnormal, being either vertically orientated or tilted laterally. The renal pelves tend to be located anteriorly and the ureters course ventral to the isthmus. The lower calices are oriented caudally or even medially as opposed to laterally.

Kidneys with fusion anomalies are subject to a high incidence of vesicoureteral reflux, variably reported between 20% and 50%. Voiding cystourethrography (VCUG) is therefore suggested during the evaluation of children with a horseshoe kidney.

The diagnosis of a ureteropelvic junction (UPJ) obstruction in a horseshoe kidney is straightforward when the patient's symptoms lead to an RUS, IVP, or CT that reveals significant pyelocaliectasis. In other instances, with less severe dilation, and especially when there is coexistent stone disease, we find the diuretic renal scan a valuable adjunct in assessing the drainage of these systems and assessing whether the hydronephrosis is functionally significant.

Ectopic Kidney

Patients with a symptomatic ectopic kidney frequently present with a urinary tract infection, or the ectopic kidney is discovered in the evaluation of abdominal pain. The workup of a palpable abdominal mass and the discovery of the abnormal renal position during the evaluation of other anomalies each account for the diagnosis in about 20% of cases. Hematuria, incontinence, renal insufficiency, and nephrolithiasis are less common presenting complaints. It is important to emphasize that the majority of patients with ectopic kidneys are asymptomatic.

The evaluation in children is usually by RUS, while older patients will in general have an IVP or CT scan. The ectopic kidney can be difficult to detect on the IVP because the pyelocaliceal system often overlies the bony pelvis. Ectopic kidneys have a high incidence of associated vesicoureteral reflux, so a VCUG is a suggested part of the evaluation of these patients. Functional evaluation of the ectopically positioned kidney can be performed with a renal scan. Because the ectopic kidney is in a different plane from the orthotopic kidney, it is necessary to calculate a geometric mean from both posterior and anterior views in order to obtain an accurate differential renal function. Typically, these studies demonstrate decreased function in the ectopic kidney when compared to the normally positioned contralateral kidney. The true use, however, of a functional study is questionable, particularly if there is no evidence of reflux or hydronephrosis suggesting possible obstruction as management of these patients is not impacted. Thus, a functional study is not compulsory.

INDICATIONS FOR SURGERY

The indications for surgical intervention in the ectopic or horseshoe kidney are similar to those in a normally positioned kidney. Pyeloplasty is required in patients with symptomatic UPJ obstruction or when the evaluation suggests that the abnormality at the UPJ may affect ultimate renal function. Symptomatic stone disease needs to be addressed using open, endoscopic, laparoscopic, or extracorporeal techniques. If the evaluation of infections in a horseshoe kidney reveals vesicoureteral reflux, operative management, either subureteral injection of Deflux or ureteral reimplantation, may be warranted if clinically indicated.

ALTERNATIVE THERAPY

The alternative to surgical intervention for reflux is nonoperative management, usually consisting of observation either with or without antibiotic prophylaxis.

Surgery is the only viable option for patients with significant UPJ obstruction, sizeable stones, and tumors. Endopyelotomy has been utilized to treat UPJ obstruction in horseshoe kidneys. The initial results of endopyelotomy performed in adults by experienced surgeons are encouraging; however, formal pyeloplasty is the initial procedure for UPJ obstructions in children.

SURGICAL TECHNIQUE

Pyeloplasty

Pyeloplasty is the most common open procedure performed on the horseshoe kidney. Division of the isthmus with nephropexy had been considered to be an important part of the procedure, but previous experience suggests that isthmus division or symphysiotomy is rarely necessary in the correction of UPJ obstruction. Pyeloplasty may be performed either open or laparoscopically. Laparoscopic procedures can be accomplished with or without robotic assistance. Laparoscopic and robotic-assisted laparoscopic pyeloplasty is more widely practiced in orthotopic renal units and is also a viable option in addition to open pyeloplasty in abnormally positioned kidneys (10–12).

The surgical exposure of the horseshoe kidney can be achieved through a midline transperitoneal, anteriorly positioned flank extraperitoneal, or transverse transperitoneal approach. We prefer the transverse transperitoneal exposure as it seems to provide the widest exposure with a cosmetically acceptable scar. We perform a retrograde ureteropyelogram at the time of pyeloplasty so we can position the incision accurately. The incision generally extends from the anterior axillary line on the affected side to the midline several centimeters below the umbilicus. It can be extended laterally in either direction if necessary. For a right-sided UPJ obstruction, the posterior peritoneum may be incised medial to the inferior mesenteric vein, then inferior and laterally along the small bowel mesentery around the cecum, and up along the line of Toldt. The small bowel and cecum can then be reflected upward out of the operative field and packed in the upper abdomen. For a left-sided UPJ obstruction, the sigmoid colon may be mobilized if necessary to afford better exposure. Exposure is maintained with a ring retractor.

Repair of UPJ obstruction in the horseshoe kidney can be performed by a Foley Y-V plasty or a dismembered pyeloplasty. Although the Foley Y-V repair is nicely suited to the typical high-insertion obstruction seen in horseshoe kidneys (Fig. 86.6D), we prefer the dismembered technique because it provides more flexibility. During the conduct of the pyeloplasty, care must be taken to avoid inadvertent division of small vessels to the parenchyma and excessive dissection of the ureter or pelvis. As much adventitial tissue is left on the ureter as possible, and no vessels to the ureter are sacrificed unless their division is necessary to provide for adequate mobilization.

After the proximal ureter and renal pelvis are adequately exposed using sharp dissection, two stay stitches of 5-0 chromic are positioned in the ureter just below the UPJ (Fig. 86.6). The ureter is divided between these stitches and carefully mobilized. A pelvic flap is then created by orienting a wide-based inverted V-shaped incision on the renal pelvis, with the apex of the inverted V at the UPJ. The flap is designed such that it will provide a dependent portion of pelvis for the anastomosis. It is important that the base of the V be wide to avoid ischemia of the flap. The flap is opened with tenotomy scissors and the tip is trimmed minimally to smooth the point of the V. The ureter is then positioned so the length and position of the spatulation can be judged. The spatulation is positioned on the posterior aspect of the ureter using Potts scissors such that the ureter will not be twisted when it is laid on the dependent pelvic flap. It is critical that the flap and the spatulated ureter are approximated in a tension-free fashion. If the repair is performed under tension, an anastomotic stricture may result.

It is also important that the upper ureter or anastomosis is not compressed by any of the renal vessels, as they may obstruct the repair (13). The anastomosis and dissection are performed with the aid of 2.5× optical magnification. We perform the anastomosis using 7-0 Vicryl in younger children and 6-0 Vicryl in adolescents.

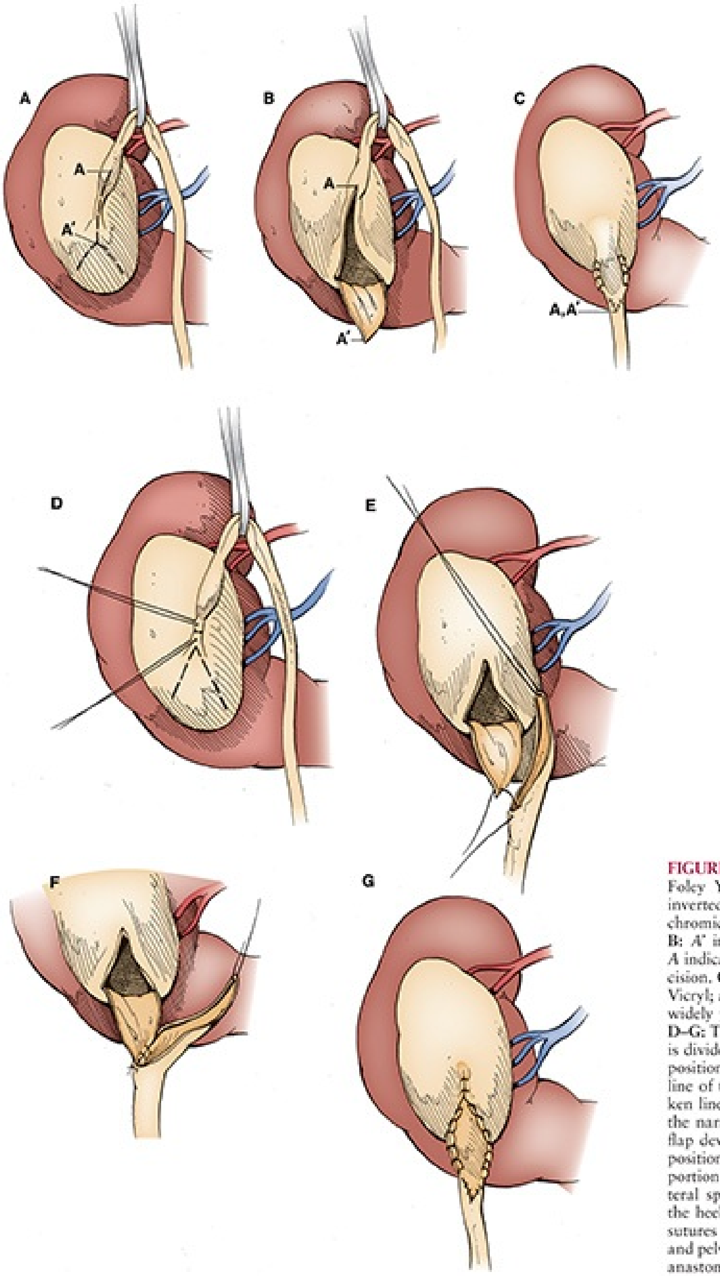

FIGURE 86.6 Pyeloplasty techniques. A–C: The Foley Y-V technique. A: Broken lines indicate inverted Y-shaped incision. Stay sutures of 5-0 chromic help define the margins of the incision. B: *A'* indicates the tip of the renal pelvic flap. *A* indicates the inferior margin of the ureteral incision. C: *A* and *A'* are sutured together with 7-0 Vicryl; as the remainder of the repair is closed, a widely patent dependent anastomosis is created. D–G: The dismembered technique. D: The ureter is divided distal to the UPJ after stay stitches are positioned. The inverted V, indicating the outline of the pelvic incision, is indicated by a broken line. E: The ureter has been spatulated after the narrowed segment is excised and the pelvic flap developed. The initial stitch of 7-0 Vicryl is positioned to approximate the most dependent portion of the pelvic flap to the heel of the ureteral spatulation. F: Interrupted sutures around the heel are completed. G: The running locking sutures extending between the spatulated ureter and pelvis are completed, creating a widely patent anastomosis.

The fact that the ureter is dismembered and freely mobile allows the surgeon to position it so that the ureteral spatulation can extend into a relatively wide portion of the ureter and simultaneously the ureter can be oriented to avoid torsion or redundancy that might kink the ureter distal to the repair. The anastomosis in the dismembered pyeloplasty seems technically easier than the Foley Y-V because the ureter is not fixed at two points.

We begin the anastomosis at the heel, suturing the most dependent portion of the V-shaped incision to the apex of the ureteral spatulation. The initial portion of the anastomosis is performed using interrupted sutures, in general, one at the apex and two on either side of the apex. Each stitch must be precisely positioned to avoid postoperative leakage and/or compromise of the lumen. After the apex is anastomosed, the remainder of the pyeloplasty is performed using a running locking 7-0 Vicryl suture up one side of the spatulated ureter and then up the other side. Prior to complete closure, the patency of the anastomosis is tested by passing a 5Fr and 8Fr feeding tube through the repair. No stent or diversion is in general employed in children. A Penrose drain is positioned near the anastomosis and made to exit through a separate stab wound. The abdominal wall closure is performed using running 3-0 or larger polydioxanone suture (PDS). We close the skin with a subcuticular pull-out stitch of 3-0 Prolene. Most children are discharged the day after surgery. The skin suture is removed between 6 and 8 days postoperatively, and the drain is removed at that time if drainage is minimal.

Ureterocalicostomy

A ureterocalicostomy is usually performed to salvage a failed prior pyeloplasty, but it can be considered as the primary procedure for UPJ obstruction when there is a small intrarenal pelvis or in other instances with significant lower pole caliectasis and thin overlying parenchyma (13) (Fig. 86.7). This can be performed either via an open approach or laparoscopically with or without robotic assistance (14). When the open technique is employed, the ureter is carefully separated from the pelvis as described earlier, and if feasible, a pyelotomy is performed. We find that a finger inserted into the open renal pelvis and positioned in the lower pole calyx aids in the dissection. The parenchyma over the dilated lower pole calyx is incised with electrocautery; the capsule is incised and the parenchyma resected to allow adequate exposure of the calyx. Hemostasis is achieved using cautery and/or sutures of 4-0 chromic through the edge of the resected parenchyma. The ureter is spatulated and the anastomosis between the ureter and the opened calyx is performed as described in the figure. We divert the urine by using a nephrostomy tube (a 10Fr or 12Fr Malecot catheter) and either a ureteral stent (usually a 5Fr feeding tube) or a double-J stent. A ureterocalicostomy as it would appear in a horseshoe kidney is shown in Figure 86.8.

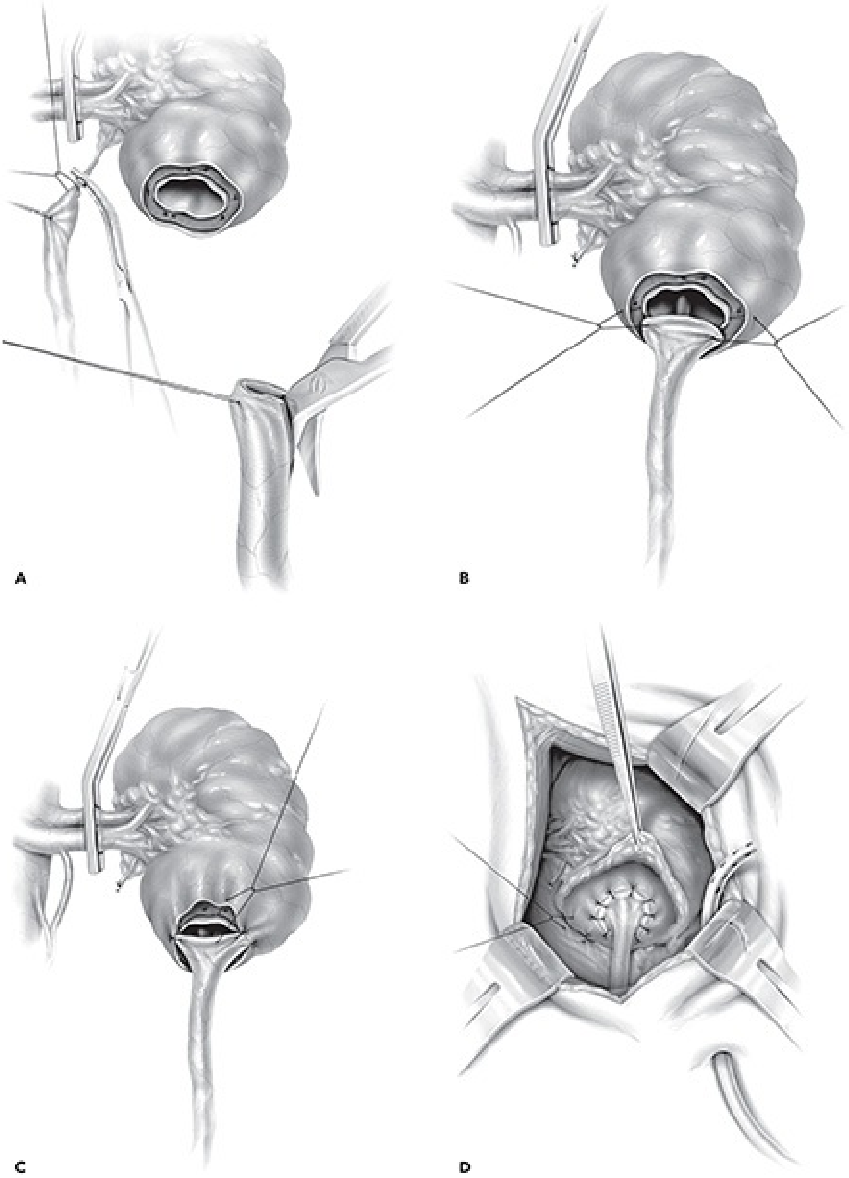

FIGURE 86.7 Ureterocalicostomy for correction of ureteropelvic obstruction after a prior failed pyeloplasty. **A:** The scarred ureter is divided and spatulated widely. Thin cortex over the dilated lower pole calyx has been excised and hemostasis achieved. **B:** The spatulated ureter is anastomosed to the open lower pole calyx. The sutures of 4-0 chromic catch the capsule, calyx, and ureter (the end of a double-J stent is visualized in the pelvis). **C:** The anastomosis is completed with interrupted sutures. A nephrostomy tube (not visualized) should be used. The surgeon may irrigate through the nephrostomy tube to ensure a watertight repair. **D:** Place one or two nephropexy sutures to obviate kinking of the repair. Replace the perirenal fat and place a perinephric drain. (Modified with permission from Steffens J, Humke U, Haben B, et al. Open ureterocalycostomy. *BJU Int* 2008;101[3]:397–407. Surgery for Tumors

Renal cell carcinoma and renal pelvic tumors are reported in horseshoe kidneys (15). Wilms tumor occurring in a horseshoe kidney represented 0.48% of tumors in the National Wilms Tumor Study; this incidence is about twice that expected in the general population (16). When Wilms tumor involves a horseshoe kidney, the involved portion of the kidney and isthmus are generally resected in the course of removal of the tumor. If the tumor occurs in the isthmus, some authors have recommended bilateral lower pole heminephrectomy. If the Wilms tumor is bilateral at presentation, management is the same as for bilateral Wilms tumors in orthotopically positioned kidneys.

Tumor surgery of the horseshoe kidney deserves special mention because excision of the involved kidney will necessitate division of the isthmus. If the isthmus is composed of a band of fibrous tissue, it can be readily divided using cautery; however, if it is functioning parenchyma, it must be carefully addressed to avoid excessive blood loss and necrosis of the remaining parenchyma, with the risk of secondary bleed and urinary fistula. The area must be carefully dissected and arteries to the isthmus sequentially occluded with bulldog clamps to assess the line of demarcation. Once this line is established, the capsule is divided sharply and the parenchyma divided. Bleeding from the cut parenchyma is controlled with 4-0 chromic sutures. Any exposed calices are closed with running locking 4-0 or 5-0 chromic sutures, and the capsule and parenchyma are closed with carefully positioned horizontal mattress sutures of 2-0 chromic (Fig. 86.9).

The isthmus blood supply is from the left iliac. **A:** After identification of the line of demarcation, an incision is made around the capsule of the isthmus. **B:** The capsule is peeled back. **C:** The parenchyma of the isthmus is transected in a wedge fashion to facilitate closure. **D:** Horizontal mattress sutures of absorbable 2-0 material are used to close the parenchyma for hemostasis. **E:** The capsule is closed over the parenchyma with a continuous absorbable suture.

Stone Surgery in the Horseshoe Kidney

Pyelolithotomy had been utilized in past decades to clear calculi from horseshoe kidneys, but currently, percutaneous and extracorporeal techniques are employed almost exclusively. Extracorporeal shock wave lithotripsy (ESWL) in the horseshoe kidney has not enjoyed the success rate that it provides in orthotopically positioned kidneys. Most series note the requirement for an increased number of shocks, an increased need for retreatment, and a somewhat decreased stone clearance rate in horseshoe kidneys compared to stones in normally positioned kidneys. One series recorded a 73% stone-free rate in horseshoe kidneys using ESWL after multiple treatments (17). One of the reasons for difficulties treating stones with ESWL is that the anterior position of the stone makes it harder to position the stone at the F2 focus; often, the surgeon will have to employ the blast path to try to fragment the stone. Some investigators have used prone positioning to overcome this problem.

Alternatively, percutaneous endoscopic treatment of calculi in horseshoe kidneys is safe and effective. After appropriate CT planning, percutaneous access to the horseshoe kidney is best achieved using an upper pole posterior calyx. Stones in any calyx can be managed through this access, although often a long nephroscope and flexible instrumentation are required (18,19). Reports comparing ESWL of stones in horseshoe kidneys to percutaneous nephrostolithotomy conclude that the percutaneous technique provides superior stone clearance rates (18). One series reported an 82% overall stone-free rate when treating staghorn calculi with percutaneous nephrolithotomy (20).

A final option for management of stones in the horseshoe or ectopic kidney is via a transperitoneal pyelolithotomy via laparoscopic approach (21). This approach is safe and feasible with the added benefit of allowing for removal of intact stones, which may decrease stone recurrence (22).

When calculus disease complicates obstruction of the UPJ in a horseshoe kidney, the stone is removed at the time of pyeloplasty. In these instances, there may be considerably more reaction around the pelvis and ureter, so the use of a nephrostomy tube and ureteral stent is prudent. An antegrade study can be performed 10 to 12 days postoperatively prior to nephrostomy tube removal to confirm drainage through the UPJ and integrity of the repair.

Robotic Pyeloplasty for Ectopic Kidneys

Technique

The technique for robotic-assisted laparoscopic pyeloplasty (RALP) has been described by Lee et al., and robotic pyeloplasty for horseshoe or ectopic kidneys can be performed in a similar fashion with adjustments in port placement, robot location, and patient positioning as needed depending on the location of the renal pelvis (23). It is worth noting that RALP in these abnormal kidneys provides the additional advantage of allowing improved visualization of the surrounding operative field.

Briefly, the technique for robotic pyeloplasty for pelvic kidney in children is described in the following text (Fig 86.10). Following optional cystoscopy with retrograde ureterograms and double-J stent placement, a bladder catheter and placement of a nasogastric tube and rectal tube are inserted and the patient is secured to the table in the supine position to allow for lateral rotation as well as head down positioning. The child’s feet should be positioned at the end of the table. A tall child or adult can be positioned in the lithotomy position. This allows the robot to be brought in from the foot of the bed. Alternatively, the patient can be positioned in the flank position, and the robot can be positioned at the side of the bed in instances where the kidney is located higher in the pelvis. The child is then prepped from the anterior thigh to the nipple line and to the posterior axillary line on either side and draped in the usual sterile fashion.

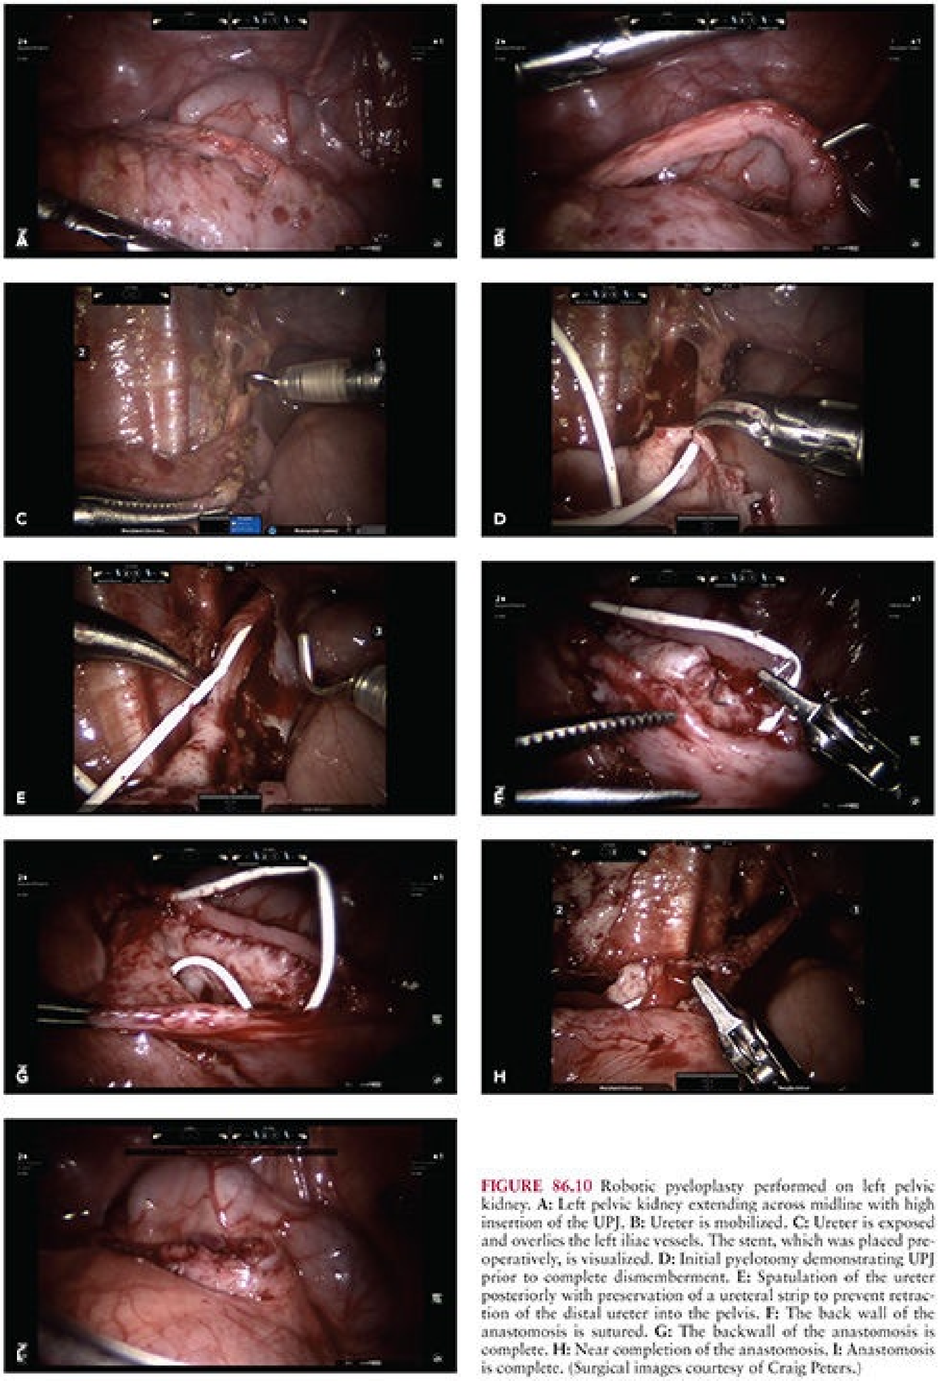

FIGURE 86.10 Robotic pyeloplasty performed on left pelvic kidney. **A:** Left pelvic kidney extending across midline with high insertion of the UPJ. **B:** Ureter is mobilized. **C:** Ureter is exposed and overlies the left iliac vessels. The stent, which was placed preoperatively, is visualized. **D:** Initial pyelotomy demonstrating UPJ prior to complete dismemberment. **E:** Spatulation of the ureter posteriorly with preservation of a ureteral strip to prevent retraction of the distal ureter into the pelvis. **F:** The back wall of the anastomosis is sutured. **G:** The backwall of the anastomosis is complete. **H:** Near completion of the anastomosis. **I:** Anastomosis is complete. (Surgical images courtesy of Craig Peters.)

First, the 8-mm or 12-mm camera port is inserted using an open Hasson technique in the inferior fold of the umbilicus. The camera is inserted, and the peritoneal cavity is inspected following appropriate insufflation. Under direct visualization, two working ports, either 5-mm or 8-mm, are inserted lateral to the umbilicus approximately four fingerbreadths away from midline. Following the port incisions, 2-0 Vicryl U-stitch fascial sutures are placed at each site for easy postprocedure closure of all port sites (24). The table is then rotated and the patient is placed in the head-down position to allow the intestines and colon to fall away from the kidney. The robot is brought from the foot of the bed and the arms are engaged to the ports.

Dismembered pyeloplasty is performed via transperitoneal approach similar to that as described by Lee et al. (23). Briefly, hook electrocautery and graspers are used for mobilization and dissection (Fig. 86.10A–C). The colon is either mobilized medially and cephalad to expose the renal pelvis and ureter which are then mobilized. Cold scissors are used to incise the pelvis parallel to the ureter, and the ureter is spatulated for a side-to-side anastomosis (Fig. 86.10D and E). The excised pelvis tissue/tissue at level of UPJ can serve as a handle for retraction and thus grasping of the ureteral tissue that has been spatulated is limited. The anastomosis is carried out using 5-0 or 6-0 Monocryl suture in an interrupted or running fashion (Fig 86.10F and G). If a double-J stent was not placed preoperatively, a large angiocatheter can be placed through the anterior abdominal wall, and a wire and double-J stent can be placed in an antegrade fashion down the ureter. Following placement of several initial sutures, the excess ureteral and pelvis tissue is excised. With the stent in place, the pelvis anastomosis is completed (Fig. 86.10H).

Surgical Options for the Ectopic Kidney

The ectopic kidney can be affected by any of the processes that occur in a normally positioned kidney. Overall, the evaluation and surgical management of these conditions will follow the lines of those discussed with horseshoe kidney. Vesicoureteral reflux, if it mandates operative treatment, is addressed by a standard ureteral reimplantation or, alternatively, subureteral injection of a bulking agent.

On occasion, one has to address the problem of a failed pyeloplasty in a patient who has an ectopic pelvic kidney. Ureterocalicostomy is one alternative in management of this problem; another is the use of a pyelovesicostomy. Pyelovesicostomy has been performed in renal transplant recipients after ureteral loss due to ischemia and/or rejection and has proven to be a viable salvage procedure.

OUTCOMES

Complications

Complications of pyeloplasty, such as prolonged urine leakage and poor anastomotic drainage, occur somewhat more frequently in horseshoe kidneys than in normal kidneys. The risk of renal ischemia caused by damage to an aberrant vessel is increased in the horseshoe or ectopically positioned kidney.

Results

Pyeloplasty in the horseshoe kidney is in general a successful procedure. A higher rate of complications was experienced in the era when division of the isthmus was employed.

CHAPTER 87 TRANSURETEROURETEROSTOMY

AARON D. MARTIN AND H. GIL RUSHTON

Ureteral surgery and various conditions, including trauma, stricture, neoplasm, or a previous failed surgical procedure, can render a ureter inadequate for successful ureteroureterostomy or ureteroneocystostomy. Transureteroureterostomy (TUU), first described by Higgins (1) in the 1930s, has gained increased prominence in pediatric urology as a method to compensate for a lacking or defective distal ureter. In some cases, bridging the midureter to the contralateral ureter via TUU may salvage a renal unit, especially in cases when an ipsilateral psoas hitch and/or Boari flap are insufficient to accomplish this task. In other situations, TUU can be performed as a salvage procedure following previous failed ureteral surgery (2,3). More recently, TUU has been employed in complex reconstructive procedures that entail harvesting of the distal donor ureter for alternative purposes, including augmentation ureterocystoplasty or as a continent catheterizable conduit (2).

DIAGNOSIS

In the majority of cases in pediatric urology, TUU is employed as part of a planned reconstruction. The preoperative workup requires thorough assessment of bilateral renal function and drainage, knowledge of the anatomy of both the donor and recipient ureters, and careful evaluation of bladder function. Differential renal function and drainage are most objectively determined by preoperative MAG-3 renal scintigraphy. Sonography can aid in determining the presence and severity of hydronephrosis. Contrast imaging with intravenous, retrograde, or antegrade pyelography may be necessary in select cases when detailed anatomic definition of the ureters is required. Contrast voiding cystography is the best modality to assess for the presence of vesicoureteral reflux, which, when present, provides a "free" retrograde ureteropyelogram. In cases involving children with abnormal or neuropathic bladder function, preoperative urodynamics is required to evaluate bladder capacity, compliance, and emptying.

Less commonly in children than in adults, initial recognition of a ureteral injury requiring a TUU occurs intraoperatively during resection of a tumor or during exploration for trauma. Fortunately, in the majority of these cases, one can usually anticipate a normal recipient ureter and bladder.

INDICATIONS FOR SURGERY

The primary goal of a TUU is to reestablish nonobstructive, nonrefluxing drainage of the ureter. Historically, TUU in children has been performed either to salvage a failed ureteral reimplantation or in conjunction with cutaneous ureterostomy for urinary diversion (4–6). Because TUU requires only one ureter for reimplantation, this procedure was commonly employed in the 1980s for urinary undiversion of conduits or in the construction of continent urinary reservoirs (3,7). In the majority of these cases, TUU was used simultaneously with reimplantation of the recipient ureter, many of which required tapering or tailoring frequently with a psoas hitch and/or bladder augmentation. TUU has also been used as an adjunct to reimplant procedures complicated by an abnormal bladder, which precludes reimplantation of more than one ureter, or as a salvage procedure for failed ureteral reimplantation surgery (3). More recently, indications for TUU have been broadened to allow for harvesting the distal donor ureter to construct a continent ureteral conduit for clean intermittent catheterization or for unilateral ureterocystoplasty in cases where there is sufficient ureteral dilatation (2).

Ureteral reconstruction with TUU may not be possible if there is insufficient donor ureter (approximately one-half the original length) for a tension-free anastomosis. Any disease process that has the potential to affect contralateral renal function or drainage is also a contraindication, such as retroperitoneal fibrosis, high-dose radiation therapy, calculus disease, recurrent pyelonephritis, and urothelial malignancy. Although size disparity between ureters has been regarded as a relative contraindication in the past, successful TUU has been accomplished by use of a longer vertical ureterotomy in the recipient ureter to accommodate a larger-caliber donor ureter (3,5,7).

ALTERNATIVE THERAPY

Other procedures to be considered in lieu of TUU include ureteroneocystostomy with a psoas hitch or Boari flap, nephropexy to allow ureteroneocystostomy or ureteroureterostomy, ileal substitution, and autotransplantation. Other alternatives to TUU include mitigating or temporizing procedures such as cutaneous ureterostomy, pyelostomy, nephrostomy drainage, and ureteral stenting. Nephrectomy should also be considered in cases of marginal donor renal function.

SURGICAL TECHNIQUE

The patient is placed supine with such options as kidney rest elevation, retroflexion of the surgical bed, and Trendelenburg positioning to enhance retroperitoneal exposure. A midline vertical incision is usually made in the abdomen, extending from just above the umbilicus to the pubic symphysis. However, in cases of distal TUU following a failed reimplantation, a Pfannenstiel incision may be sufficient. A choice of exposure approaches is then available.

Transperitoneal Approach

Wide transperitoneal exposure is indicated in cases that require complex adjunct procedures such as tapered reimplantation of the recipient ureter or bladder augmentation as well as when there is a long segment of diseased distal donor ureter. This approach would also be preferred when a high TUU is necessary for the distal donor ureter to be used as a continent catheterizable channel or for augmentation of the bladder.

The bowel is packed and retracted superiorly to allow for further dissection. Once the ureters have been visualized as they pass over the iliac vessels, two options for opening the retroperitoneum have been described (8): (a) two 5-cm vertical incisions may be made over the ureters where they cross the iliac vessels, creating a window on each side (Fig. 87.1), and (b) wider retroperitoneal exposure can be achieved through a single curved incision that opens the retroperitoneum from over the left distal ureter, extending across the midline along the small bowel mesentery and cecum and up the right side along the line of Toldt (Fig. 87.2). This technique allows for more extensive mobilization of the bowel in an upward direction.

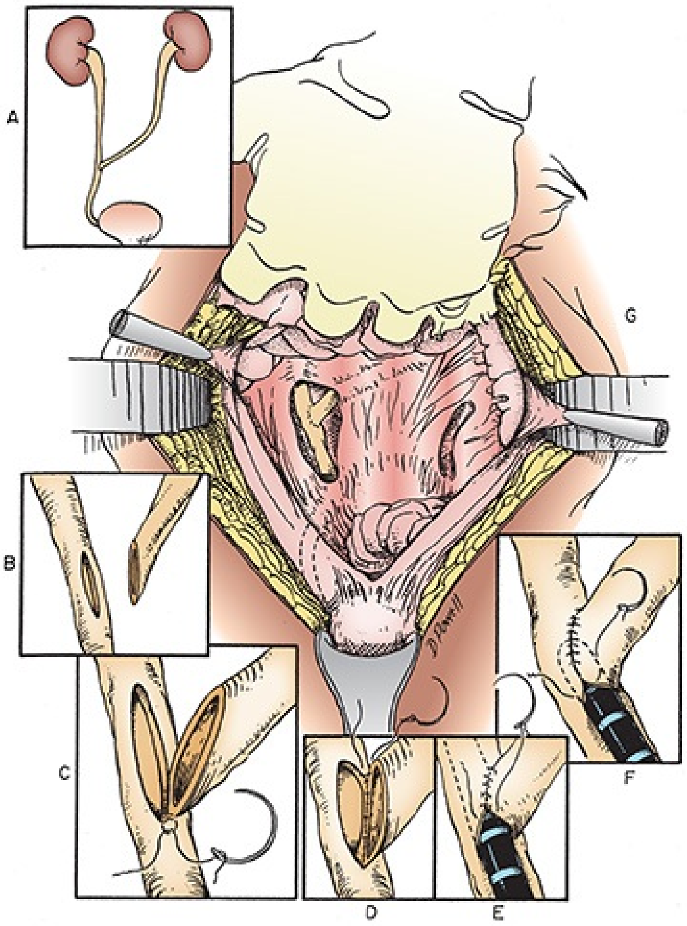

FIGURE 87.1 TUU approached by two incisions in the posterior peritoneum. **A:** Schematic diagram of left-to-right TUU. **B:** The donor ureter is approximated to the vertical ureterotomy on the anteromedial aspect of the recipient ureter. **C and D:** The anastomosis is begun at the apex and is extended to the posterior aspect of the TUU, using either running or interrupted absorbable sutures. **E and F:** The anterior aspect of the anastomosis may be performed over a catheter or feeding tube removed prior to the last stitch. **G:** Completed TUU in situ.

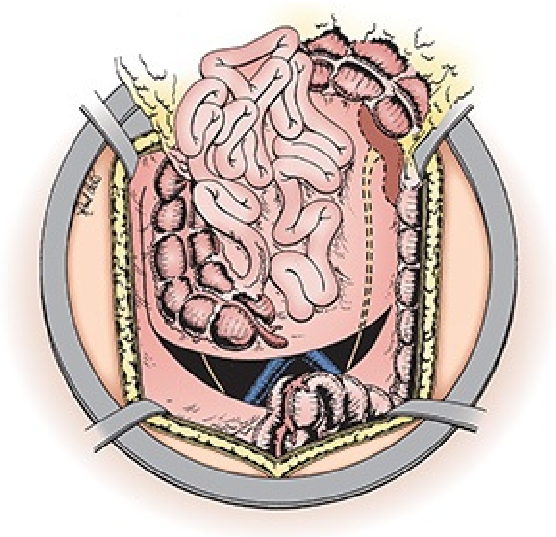

FIGURE 87.2 Approach for single curvilinear incision in the posterior peritoneum to mobilize the bowels and mesentery and expose the retroperitoneum.

Once the ureters are adequately exposed, the retroperitoneal tunnel is created by blunt dissection beneath the posterior peritoneum, anterior to the great vessels and superior to the inferior mesenteric artery (IMA). The angle between the aorta and IMA may kink or even obstruct the donor ureter. The position of the IMA should therefore be noted and avoided in calculating the path of the donor ureter to the contralateral retroperitoneum. Rarely, it may be necessary to ligate the IMA to prevent donor ureteral compression.

Retroperitoneal Approach

This technique provides the benefit of preventing complications associated with intraperitoneal procedures. The author prefers this approach for a more distal TUU, which requires less mobilization of the donor ureter. Other authors have also described this method as a viable alternative to the transperitoneal approach (9). Most commonly, this approach would be used in salvage procedures for failed ureteral reimplantation.

After the transversalis fascia is incised, the extravesical space is mobilized on each side of the bladder. The ureters are identified crossing beneath the obliterated umbilical arteries. After dividing these vessels with Vicryl or silk ties, the peritoneal sac is retracted superiorly to further expose the retroperitoneum. The peritoneal sac may also be reflected medially to expose the area of interest.

Once adequate exposure of the ureters has been achieved, blunt finger dissection is then used to create an ample retroperitoneal tunnel. In cases of a low TUU using a retroperitoneal approach, the tunnel is created beneath the posterior peritoneum just superior to the posterior wall of the bladder and anterior to the sacral promontory.

Transureteroureterostomy

Adjunct procedures required for the recipient ureter, such as tapering and reimplantation, should be undertaken prior to the anastomosis of the donor and recipient ureter. For a standard TUU, mobilization of the donor should be sufficient to create a tension-free anastomosis. Because preservation of blood supply is essential for the success of TUU, great care is taken to avoid unnecessary disruption of the adventitia. The ipsilateral gonadal vessel may be tied off with a 3-0 silk suture to provide even greater mobilization with adventitial preservation. If even greater donor ureteral length is necessary, the donor kidney may be gently mobilized, moved inferiorly, and pexed to the psoas muscle using interrupted 3-0 Vicryl or 3-0 polydioxanone sutures.

After dividing the donor ureter as distal as possible, a long tagged 4-0 chromic or Vicryl suture is then placed on the most distal aspect of the divided donor ureter to allow the ureter to be brought through the retroperitoneal tunnel. A right-angle clamp can then be passed from the recipient to the donor side to grasp the stay suture on the donor ureter and pull the donor ureter through the tunnel. Care must be taken to avoid twisting or kinking of the ureter, and the ureter should reach easily to the other side without tension.

With respect to the recipient ureter, mobilization should be minimized. To enable touch-free manipulation of the recipient ureter, stay sutures consisting of 4-0 or 5-0 chromic may be placed in the recipient ureteral adventitia, superior and inferior to the intended area of anastomosis. A vertical ureterotomy at least 1.5 cm in length on the anteromedial wall of the recipient ureter is then performed at the site of the anastomosis. The donor ureter is then spatulated to accommodate the recipient ureterotomy. However, spatulation may not be necessary if the donor ureter is sufficiently dilated. The anastomosis is performed using interrupted (Fig. 87.3) or running 4-0 or 5-0 absorbable sutures, beginning with the superior and inferior apices, followed by the approximation of the more posterior wall of the anastomosis. At this juncture, a ureteral catheter or infant feeding tube may be helpful in some cases to facilitate the anterior wall anastomosis. This tube may be removed just prior to the final anastomotic stitch (see Fig. 87.1).

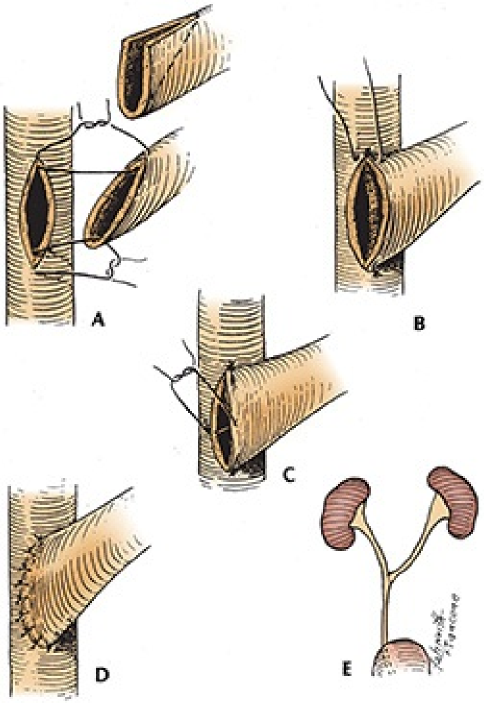

FIGURE 87.3 TUU anastomosis performed with interrupted absorbable sutures. **A and B:** After aligning the distal donor ureteral lumen and recipient ureterotomy, apical sutures are placed and tied. **C:** Subsequent intervening interrupted sutures are placed halfway between previously placed sutures. **D:** Completed anastomosis. **E:** Schematic diagram of completed TUU.

The use of an indwelling ureteral stent is mandatory only when the recipient ureter distal to the anastomosis has been altered in some fashion, such as in reimplantation. A 5Fr or 8Fr feeding tube or a double-J stent may be used. In addition, nephrostomy drainage of the recipient ureter may be employed if extensive mobilization or tapering of the recipient ureter and/or kidney is required to complete the reconstruction (3). In all cases, it is vital to drain the retroperitoneal space using either a Penrose or closed suction drain. Furthermore, with the transperitoneal approach, it is recommended to close the posterior peritoneum to avoid drainage of urine into the peritoneal cavity. Finally, a suprapubic catheter or urethral catheter should be placed to keep the bladder decompressed, as an overly distended bladder in the early postoperative period may stress the TUU anastomosis.

Approximately 2 months postoperatively, the patient should undergo a renal sonogram and/or a diuretic renal scan to assess drainage and/or renal function. Depending on the results, imaging may be repeated in 3 to 9 months until a trend of progression has been established. Renal function by creatinine measurements should also be followed, particularly if these levels were elevated preoperatively.

Laparoscopic/Robot-Assisted Approach

Laparoscopic TUU has recently been described in children (10). Initially, cystoscopy is performed for a retrograde pyelogram with stent and/or wire placement. The patient is then placed supine and redraped. After gaining periumbilical access to the peritoneal cavity, working ports (3 to 5 mm) are placed under laparoscopic vision in the hypogastrium and in the right and left anterior axillary line. The position is adjusted according to patient size and the level of the expected donor ureter transection but typically at the level of the umbilicus or higher. The patient is placed in the Trendelenburg position with the donor ureter side elevated 30 to 45 degrees and the surgeon standing on the contralateral side.

The donor ureter is exposed and dissected distally by incising the peritoneum at the pelvic brim. The dissection is carried down to the bladder, taking care not to damage the vas deferens in males. The ureter is transected at the level of the bladder obliquely and the distal stump/bladder is closed with an absorbable suture. The donor ureter is further mobilized proximally while maintaining ample periureteral vascularization. The surgeon can then switch to the patient’s opposite side and roll the table to elevate the recipient ureter side to aid in preparation of the recipient site at the pelvic brim in a similar fashion.

Using blunt dissection, a rectosigmoid mesenteric window can be created through which to pass the donor ureter. A stay suture or atraumatic grasper can be used to facilitate this transfer. It is critical that the donor ureter is not compressed, twisted, or kinked in the tunnel and reaches the recipient site easily without tension. Otherwise, further proximal dissection is necessary. Next, a medial longitudinal ureterotomy is made in the recipient ureter corresponding to the size of the donor ureter lumen. The recipient ureteral stent can be left in place and used to aid in visualization of the anastomosis. The anastomosis can be accomplished with two running 5-0 absorbable monofilament sutures. A drain can be left via one of the port sites near the anastomosis if desired. The Foley catheter can be removed on postoperative day 1 or 2 with the drain to follow after the patient has voided and there are no concerns for leakage. Typically, the ureteral stent is removed 2 to 4 weeks after surgery.

Although no reports of robot-assisted laparoscopic transureteroureterostomies have been published to date, certainly the same technique described earlier can be applied with the advantage of increased dexterity when suturing the anastomosis. Either a three-port or four-port technique can be used with the optional fourth port used for an assistant port or the fourth robotic arm for help with retraction and passing the ureter through the tunnel. Alternatively, a pure laparoscopic approach can be used for ureteral mobilization and transposition with the robot brought in strictly for the anastomosis while using the same trocar arrangement.

OUTCOMES

Complications

Postoperative complications include urinoma, pyelonephritis, prolonged anastomotic drainage, and stricture (11). The risk of any of these complications is heightened by tenuous ureteral blood supply from excessive mobilization or from previous radiation (12). Patients with neuropathic or abnormal bladders may be more at risk for developing new vesicoureteral reflux or distal ureteral stenosis in cases that involve reimplantation of the recipient ureter (13). Early anastomotic obstruction leading to persistent drainage may be initially treated conservatively with placement of a double-J ureteral stent or percutaneous nephrostomy.

Late complications include small bowel obstruction but only in cases involving the transperitoneal approach. A TUU performed in the context of neoplasm may suffer from late ureteral obstruction. Subsequent stone disease can potentially obstruct the common segment, rendering the patient anuric and mandating emergent percutaneous nephrostomy drainage or ureteral stenting. Rarely, compression of the donor ureter by the IMA can develop years after TUU if precautions to avoid the artery during donor ureter tunneling were not taken. However, despite potential problems and the possible need for reoperation, several series have shown that TUU anastomotic revision is rarely, if ever, necessary. Also, donor renal loss due to chronic infection or obstruction has proven infrequent, with rates ranging from 0% to 6% (2,3,5). Recipient kidney loss is even less common, reportedly occurring only after extensive mobilization required in complex reconstructions (3,7).

Results

Numerous studies have shown excellent results after TUU. Damage to the recipient kidney and ureter has rarely been observed, and successful preservation of both renal units occurs in >90% of cases. TUU performed in the correct setting, with meticulous attention to maintaining ureteral blood supply and a tension-free anastomosis, is clearly an important component of the urologist’s repertoire of reconstructive ureteral surgery.

CHAPTER 88 PYELOPLASTY

MEGAN S. SCHOBER, KEVIN M. FEBER, AND EVAN J. KASS

Improved antenatal ultrasonography techniques have clearly been a factor in identifying collecting system dilation in the neonatal period. Obstruction is not necessarily the cause of hydronephrosis in the neonate; however, ureteropelvic junction (UPJ) obstruction is the most common cause of significant renal pelvis dilation in this age group (1). An exact etiology of UPJ obstruction has yet to be determined, but multiple hypotheses exist as to the cause of the obstruction. Incomplete recanalization of the proximal ureter, functional or anatomic obstruction, and developmental arrest are a few theories as to why obstruction occurs at the UPJ. Although the etiology of the obstruction may be unknown, the classification of obstruction can be divided into three categories: intrinsic, extrinsic, and secondary. Intrinsic UPJ obstruction is usually characterized by a stenotic or adynamic segment of ureter. Less commonly, intrinsic obstruction can be caused by mucosal folds or “flaps” (2). It has been estimated that 60% to 80% of persistent hydronephrosis in infants is secondary to intrinsic obstruction. Extrinsic obstruction most often occurs from an aberrant crossing vessel typically traveling to the lower pole of the kidney. This is a more common presentation in older children and adults. Secondary obstruction is rarer than extrinsic or intrinsic obstruction. It occurs when the ureter is severely dilated and tortuous from vesicoureteral reflux causing a “kink” in the ureter that acts as an impediment to urine flow. Over time, this area can become the site of significant periureteral scarring requiring surgical correction.

DIAGNOSIS

Before routine prenatal ultrasonography, the most common presentation of an infant with UPJ obstruction was with a palpable abdominal mass. Prenatal ultrasound has significantly increased the number of infants diagnosed with asymptomatic hydronephrosis. Prior to maternal ultrasonography, children with UPJ obstruction presented later in childhood with flank pain, hematuria, recurrent urinary tract infections, abdominal mass, or urolithiasis. Extrinsic compression of the UPJ by crossing vessels is more commonly seen in older children and accounts for the second peak of UPJ obstruction diagnosis in later childhood and adolescents. These children are usually diagnosed after multiple episodes of periodic flank pain accompanied by nausea and vomiting. Neonates with a history of antenatal hydronephrosis should undergo postnatal renal ultrasound. If prenatal hydronephrosis was unilateral and mild to moderate, postnatal renal ultrasound should be performed at 1 to 2 weeks of life because transitory dehydration of the newborn usually lasts about 48 hours after birth and can underestimate the degree of hydronephrosis visualized. However, if the hydronephrosis detected prenatally was severe, bilateral, or associated with oligohydramnios, postnatal ultrasound should not be delayed. When the diagnosis of hydronephrosis has been confirmed postnatally, a voiding cystourethrogram (VCUG) is typically performed to exclude vesicoureteric reflux as the cause and also to determine if there are any other associated findings.

Once the diagnosis of UPJ obstruction is suspected after completion of renal ultrasound and VCUG, a diuretic renal scan is the next study that should be performed. Mercaptoacetyl triglycine (MAG-3) with furosemide is the preferred test in this situation to determine relative renal function and if delayed drainage is present. There has been much debate regarding the use of calculated half-times in response to furosemide administration and half-time should not be the sole determining factor in the clinical decision-making process regarding UPJ obstruction (3).

INDICATIONS FOR SURGERY

Indications to proceed to pyeloplasty at our institution include the following: severe hydronephrosis (Society for Fetal Urology grade III or IV) detected postnatally accompanied by <40% differential renal function with no response to furosemide on renal scan, worsening hydronephrosis on serial ultrasound, symptomatic UPJ obstruction, loss of relative renal function on serial renal scans (>10%), or persistent delay in drainage on serial diuretic renography in a child with severe hydronephrosis.

ALTERNATIVE THERAPY

Multiple treatment options currently exist for the treatment of UPJ obstruction ranging from endopyelotomy to robotic pyeloplasty. At this time, endopyelotomy is not commonly performed in neonates and infants but has been used in preadolescent and adolescent children with some degree of success. It has also been demonstrated that endopyelotomy appears to be more successful as a secondary technique for failed pyeloplasty in children. However, more recent data suggest that redo pyeloplasty or ureterocalicostomy are more successful secondary treatments than endourologic procedures (4,5).

Pure laparoscopic or robotic-assisted laparoscopic pyeloplasty has gained significant popularity in the last decade, as the success rates, operative times, and hospital length of stay of these procedures are becoming comparable to open pyeloplasty (6,7). Robotic assistance has significantly decreased the learning curve for minimally invasive pyeloplasty by making intracorporeal knot tying a much simpler process. Although robotic pyeloplasty in small infants has been shown in the literature to be a successful operation, the open Anderson–Hynes pyeloplasty continues to be the gold standard for clinically significant UPJ obstruction in neonates and small infants with reported success rates consistently >90% to 95%. The most important factors in a successful pyeloplasty of any technique include formation of a funnel at the UPJ with dependent drainage and a tension-free anastomosis.

SURGICAL TECHNIQUE

The patient is placed in the flank position using a rolled towel and/or table flexion with elevation of the kidney rest depending on the size of the child (Fig. 88.1). Incision is made in a transverse fashion medial to the tip of the 12th rib and carried anteriorly. Subcutaneous tissues and musculofascial layers are opened with electrocautery (Fig. 88.2). The lumbodorsal is divided and the peritoneum is swept medially taking care to remain extraperitoneal. Gerota fascia is then identified and opened.

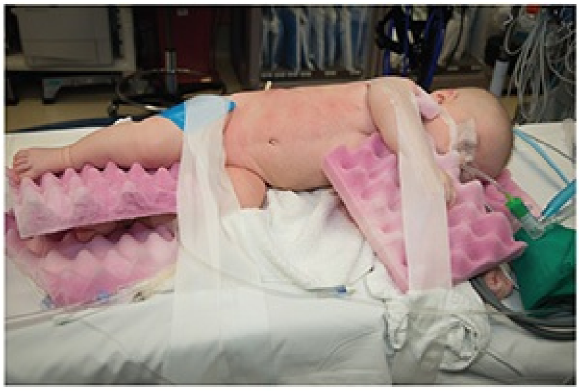

FIGURE 88.1 Surgical positioning for open pyeloplasty in flank position.

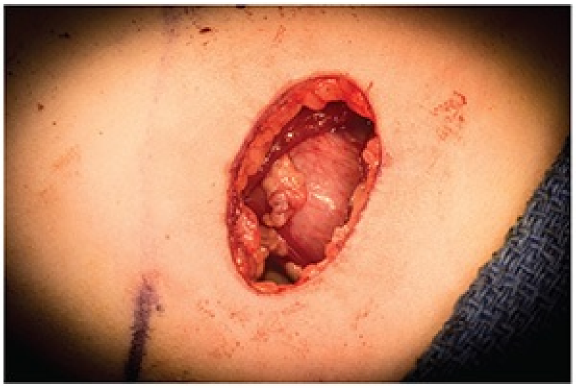

FIGURE 88.2 Flank incision medial to the tip of the 12th rib.

Once Gerota is entered, the lower pole and renal pelvis should be identified and the UPJ should be sharply dissected (Fig. 88.3). At this point, one should be able to determine the etiology of the obstruction. Care should be taken to preserve the blood supply to periureteral tissues and the ureter. Stay sutures are placed cephalad to the UPJ and in the ureter to minimize manipulation of the ureteral tissues. The renal pelvis is incised circumferentially at the UPJ to decompress the collecting system (Fig. 88.4). The proximal ureter is then mobilized and the atretic segment is identified and excised. Excessive trimming of the renal pelvis is avoided but can be performed in the case of a severely redundant pelvis. The proximal ureter is then spatulated and assessed to ensure that the ureter is healthy appearing (Fig. 88.5). A 5Fr feeding tube is then inserted into the ureter to begin the ureteropelvic anastomosis. Anastomosis is performed at the most dependent portion of the renal pelvis with interrupted polydioxanone suture (PDS) (Fig. 88.6). Running suture can be used; however, placing interrupted sutures decreases the likelihood of the suture "bunching up" and causing subsequent narrowing of the anastomosis. In infants, we use 7-0 PDS. Extreme care is taken to avoid any twisting or kinking of the anastomosis. Optical magnification with a 3.0× to 4.5× loupe facilitates precise suture placement. If there is any remaining pelvis tissue open after suturing the anastomosis, it is closed with running 6-0 PDS suture (Fig. 88.7).

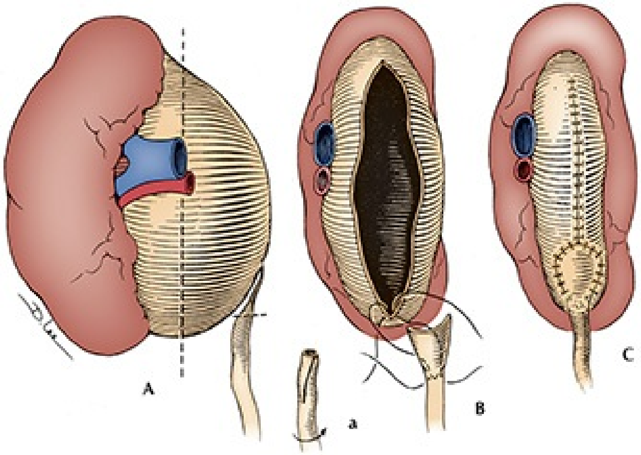

FIGURE 88.4 Dismembered pyeloplasty. **A:** The renal pelvis is incised, redundant tissue excised, and the ureter divided distal to the atretic segment. **B:** The ureter is spatulated and brought to the most dependent portion of the pelvis. **C:** The remaining pelvis is closed with running sutures.

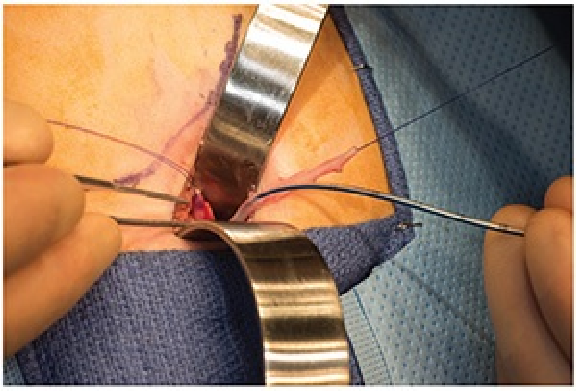

FIGURE 88.5 Proximal ureter is spatulated; feeding tube placed into ureter.

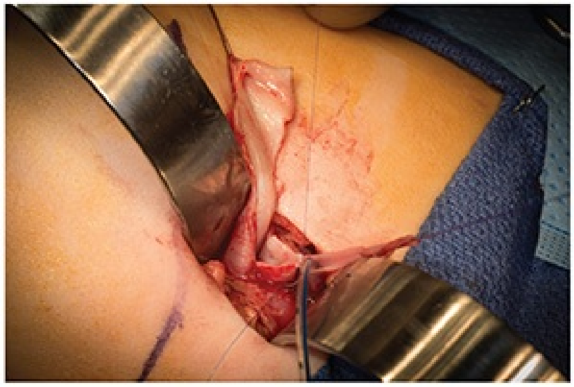

FIGURE 88.6 Anastomosis of spatulated ureter to renal pelvis with 7-0 PDS.

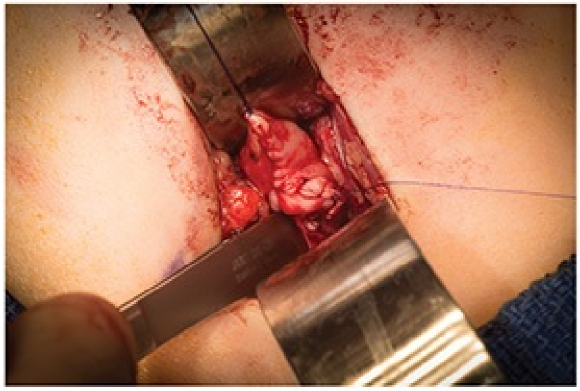

FIGURE 88.7 Completed repair.

Of note, if the UPJ obstruction is found to be secondary to a crossing vessel, the divided ureter is brought anterior to the vessel, and the ureter and pelvis are anastomosed in this anterior location (Fig. 88.8).

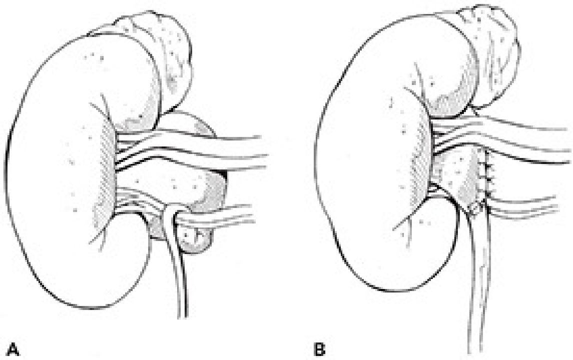

FIGURE 88.8 Dismembered pyeloplasty with accessory vessels. A: Vessels causing ureteral compression and hydronephrosis. B: Anastomosis performed anterior to crossing vessels. Pelvic tailoring as needed.

A 0.25-inch Penrose drain is placed in the perirenal space and brought out through the skin in a separate more caudal puncture (Fig. 88.9). The musculofascial layers are closed with 3-0 polyglactin suture. Subcutaneous tissues reapproximated with 4-0 plain gut suture and the skin is closed with a running subcuticular 5-0 poliglecaprone suture.

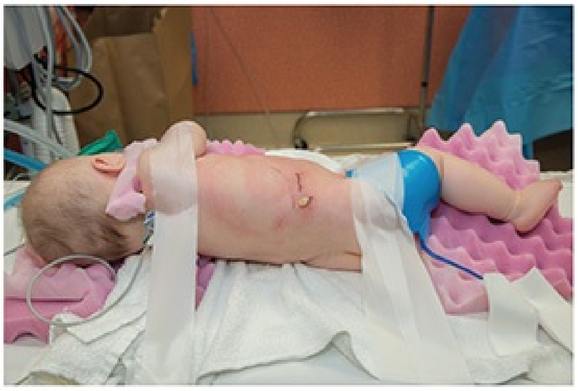

FIGURE 88.9 Completed procedure showing positioning, incision, and Penrose drain.

The use of ureteral stents and nephrostomy tubes continue to be a controversial issue and is surgeon-dependent. At our institution, we generally do not use a stent or nephrostomy tube. Indications for ureteral stenting include solitary kidney, renal insufficiency, extensive renal pelvis tailoring, or those undergoing redo pyeloplasty. Disadvantages of ureteral stenting or nephrostomy tube usage include patient discomfort and stent removal in the operating room under a second anesthetic. A nephroureteral catheter such as a Pippi Salle stent allows removal in the office, thus avoiding a second anesthetic. These stents can be removed as early as 1 to 2 weeks postoperatively. If a double-J ureteral stent is used, removal in the operating room is generally recommended 4 to 6 weeks after surgery.

Postoperatively, the patients are kept on intravenous antibiotics until the Penrose drain is removed, which typically occurs on postoperative day 1 or 2 if there is no evidence of a urinary leak. If high drain output is observed or if there is clinical concern for delayed urinary leak, we advocate leaving the Penrose drain in place for 1 to 2 weeks. Pain is controlled with ketorolac 0.25 mg per kg for the first 24 to 48 hours. We have found that narcotic pain medications are rarely needed when ketorolac is used. Children are typically discharged home within 24 hours of surgery. Follow-up renal ultrasound is performed 4 weeks postoperatively. MAG-3 renal scan is performed after pyeloplasty if there is clinical evidence of continued obstruction or no improvement in hydronephrosis postoperatively. If MAG-3 demonstrates loss of renal function, early intervention such as percutaneous nephrostomy drainage or ureteral stenting should be considered to avoid further renal damage.

OUTCOMES

Complications

As with any type of operation, bleeding is always a risk of this procedure. Although very rare, when significant bleeding occurs, it is typically from an aberrant vessel. This complication can be avoided by careful dissection and identification of any abnormal anatomy during the procedure. Retroperitoneal leaks can occur but usually resolve spontaneously. If the leak persists, antegrade or retrograde stenting can be useful. Other complications after open pyeloplasty include obstruction associated with lack of improvement in renal washout as well as diminished renal function. Fortunately, these complications are rare but will require a second surgical procedure such as ureterocalicostomy or redo pyeloplasty.

Results

At our institution, we have found open dismembered pyeloplasty to be curative for UPJ obstruction in >95% of our patients.

CHAPTER 89 MEGAURETER

CHRISTOPHER J. LONG, J. CHRISTOPHER AUSTIN, AND DOUGLAS A. CANNING

Megaureter is a relatively rare congenital anomaly of the urinary tract. We define a megaureter as having a diameter that is 8 mm or greater. The upper limit width for a normal ureter in a full-term newborn is 7 mm. Megaureter is a broad term and is further subdivided into four categories: (a) refluxing; (b) obstructed; (c) both refluxing and obstructed; and (d) nonobstructed, nonrefluxing megaureter. The Pfister-Hendren classification stratifies the ureter based on appearance: in type I, dilation is limited to the distal ureter with no pelvic dilation; type II involves dilation of both the ureter and the pelvis; and type III has severe dilation of the ureter and pelvis with tortuosity of the ureter. Further, megaureters can be either primary or secondary; secondary causes of megaureter include posterior urethral valves, high-volume vesicoureteral reflux, neuropathic bladder resulting in higher detrusor pressure, or less commonly an acquired condition such as external compression of the ureter from a mass lesion or retroperitoneal fibrosis. Primary megaureters, in contrast, are isolated physical abnormalities of the ureter or ureterovesical junction resulting in a dilated ureter.

Prior to the widespread use of screening prenatal ultrasonography, most children with megaureters presented with urinary tract infection, flank pain, urolithiasis, abdominal mass, or hematuria. Most cases today are detected in asymptomatic infants with hydroureteronephrosis in utero. This earlier presentation has led to changes in the approach to management.

The pathophysiology of obstructive megaureters lies not within the dilated segment of the ureter but in the distal, nondilated segment. This segment of ureter is characterized by a deficiency in muscle fiber cross-linking and increased collagen deposition, although this segment is not usually narrowed compared with the normal ureter. These changes compromise the ureter’s ability to effectively propagate the urine bolus as it descends toward the bladder. When the bolus of urine encounters the aperistaltic segment, only a portion of the urine passes into the bladder; the remainder ascends back up the ureter in a yo-yo fashion. This process constantly repeats itself and results in the characteristic appearance of fusiform dilation in which the distal ureter is more severely affected. Proximal dilation and hydronephrosis may develop when the amount and force of the bolus are sufficiently large that it dilates the entire ureter and reaches the renal pelvis.

DIAGNOSIS

The primary goal when evaluating a megaureter is to distinguish an obstructed megaureter from the nonobstructed entities. These ureters demonstrate a spectrum of severity rather than separate conditions. The diagnostic workup depends on the presenting signs and symptoms and may vary from patient to patient. For the child with prenatal hydroureter (width 8 mm or above), the usual evaluation includes a renal/bladder ultrasound, a voiding cystourethrogram (VCUG), and a renal scintigram (renal scan) depending on the degree of dilation. Hydroureteronephrosis is identified with the renal ultrasound. Severe hydronephrosis warrants antibiotic prophylaxis upon initial diagnosis and should be continued for at least 6 to 12 months if no surgical intervention occurs. The dilated ureter is usually visible in the pelvis and is posterolateral to the bladder. If the ureter is dilated inferior to the level of the trigone, an ectopic ureter may be present rather than a primary megaureter with a pseudoureterocele visualized in the bladder. The VCUG separates children with refluxing megaureters from those without reflux and will identify a ureterocele if present. The renal scan in the newborn should be performed with mercaptoacetyl triglycine (MAG-3) with diuretic washout. The scan will estimate the relative function of each kidney and measure the effectiveness of renal clearance of radiotracer from the collecting system. In the past, the $t_{1/2}$ (time required for half of the radiotracer to clear from the renal pelvis) had been used as an indicator of obstruction. However, in practice, the use of the $t_{1/2}$ alone to estimate obstruction is not always reliable and can be delayed simply by the presence of a dilated ureter or pelvis. Because the clearance is variable based on the patient's prestudy hydration level, age, renal function, and response to the diuretic, we prefer to follow trends in the relative renal function, reserving surgery for those with increasing $t_{1/2}$ or decreasing relative renal function. A differential renal function of <40% or a change in split function >10% should be considered clinically significant.

In children who are symptomatic, the presenting symptom(s) determines the subsequent workup. Hematuria, rarely noted in children with megaureter, is normally evaluated initially with a renal/bladder ultrasound. The finding of hydroureteronephrosis should be followed by a renal scan or intravenous pyelogram. If there is suspicion of renal or ureteral stone, a noncontrast computerized tomography scan should be performed. The renal scan may be required to provide a baseline estimate of relative renal function. If the anatomy is unclear, magnetic resonance urography (MRU) can identify both aberrant anatomy and differential function and can help distinguish between an obstructed megaureter and an ectopic ureter.

If there is impaired function of the affected kidney and the child is undergoing surgical correction, cystoscopy should be performed at the beginning of the reconstructive procedure to evaluate the position of the ureteral orifice. The orifice is normally positioned in an obstructed megaureter, whereas an ectopic ureter will distort the trigone and an ectopic orifice can often be visualized in the urethra.

INDICATIONS FOR SURGERY

Relative indications to proceed with surgical repair include poor initial relative function (<40% of differential renal function by renal scan), progressive hydronephrosis, decreasing function (>10%) in serial renal scans, persistent severe hydroureteronephrosis, bilateral megaureters, or failure of conservative management (the development of symptoms such as pain localized to the side of the megaureter or febrile urinary tract infection). In older children with megaureter, we tend to operate on those who present with symptoms of intermittent flank pain or urinary tract infection.

In infants with indications for intervention, we consider alternative approaches given the infant's small, thin-walled bladder and the technical difficulties of reimplanting a large, hydronephrotic ureter into the small infant bladder. Options in these patients include endoscopic stenting, a staged reconstructive approach with temporary diversion to an end-cutaneous ureterostomy, and construction of a refluxing ureteral reimplantation, or, rarely, diverting pyelostomy should be given consideration instead of primary surgical repair (1,2).

Prior to surgery, we evaluate the child for voiding dysfunction. Rarely, children develop a secondary megaureter from high-pressure bladder storage that is transmitted to the ureter and renal pelvis. Ureteral dilation can be detected in association with neuropathic bladder dysfunction, posterior urethral valves, or severe voiding dysfunction. Appropriate treatment of the posterior urethral valves or the bladder dysfunction may result in improvement or resolution of ureteral dilation. Dysfunctional bowel elimination can have a significant impact on bladder emptying and should be assessed in every patient evaluated for dysfunctional voiding. Failure to recognize bladder and bowel dysfunction before surgical intervention increases complication rates including persistent obstruction or vesicoureteral reflux.

ALTERNATIVE THERAPY

Because most patients are asymptomatic and identified on prenatal ultrasound, the great majority of children with primary megaureters do not require surgical correction. Ureteral dilation does not always indicate obstruction. Dilation in some boys and girls may represent the residuum of in utero obstruction that has resolved. The long-term experience at the Children's Hospital of Philadelphia (CHOP) has been that the majority of children with megaureter maintain renal function and ureteral dilation often improves with time, albeit with close observation for renal function preservation. In a series of 27 children with megaureters treated conservatively with a mean follow-up of 6.8 years, hydronephrosis completely resolved in 53% and was improved or stable in the rest. Only 10% of patients required surgical correction, while 90% were followed with serial radiologic studies. A single patient from this cohort developed progression of hydronephrosis and diminished function at age 14 (3). Likewise, in a series of 53 patients with 67 megaureters, only 17% required surgery for poor initial function or progressive loss of function; in addition, the dilation completely resolved by ultrasound in 34% (4). These two series are concordant with additional literature on primary ureter management and suggest that the majority can be managed conservatively. Because of the rare risk of late progression of obstruction, we recommend that all children with persistent hydronephrosis have extended follow-up.

ENDOSCOPIC TECHNIQUES

One option that deserves consideration is double-J stent insertion with or without dilation of the diseased segment via either endoscopic balloon dilation or laser incision. Cystoscopy is performed to evaluate the appearance of the ureteral orifice. Retrograde pyelogram is performed to assess the area of narrowing and the proximal ureter. If balloon dilation is performed, the ureter is intubated with a 14Fr endoscopic balloon and inflated to 14 atmospheres for 3 minutes. For narrowing that extends beyond 2 cm, a ureteroscope can be inserted to perform laser incision of the ureter at the 12 o'clock position, followed by balloon dilation of the ureter. A double-J stent is left in place for 2 months postoperatively. One additional option is double stenting of the ureter, with the theory that the constant sliding of the stents against one another allows the ureter to heal at a wider caliber.

The endoscopic approach has several advantages. It can be performed as an outpatient procedure and if failure occurs, a formal reimplant remains an option although some groups have reported inflammation and subsequent ureteral scarring after stent placement. Its use in infants younger than 1 year of age has increased, acting to temporarily relieve the obstruction until bladder growth allows for a more definitive formal reimplant.

SURGICAL TECHNIQUE

The surgical correction is similar for refluxing and obstructed megaureters. Obstructed megaureters have a distal ureteral segment of variable length with a normal or narrowed caliber that does not contract normally and should be excised. Refluxing megaureters are dilated to the level of the ureterovesical junction. Distal segment excision is not always required.

The child is positioned supine on the operating room table. In boys, the lower abdomen and genitalia are fully prepped and draped. Females are placed in a mild frog-legged position with gel bolsters under the knees to permit intraoperative access to the urethra if needed. The bladder may be left full during the initial surgical exposure. A Pfannenstiel incision is made in the abdominal skin crease. The rectus fascia is opened transversely along the course of the incision and the flaps of fascia are elevated off the muscle superiorly to just below the umbilicus and inferiorly to the pubis. The rectus muscles are separated in the midline. The space of Retzius is entered, exposing the bladder.

Intravesical Approach

At this point, depending upon the surgeon’s preference, the dissection of the ureter begins either intravesically or through an extravesical exposure. It has been our preference to begin intravesically. The bladder is opened via a midline cystotomy. The bladder dome is packed with damp sponges and a Dennis–Brown retractor is placed to provide exposure of the trigone. A 5Fr feeding tube is passed up the ureter and secured at the orifice with a 4-0 suture. The urothelium surrounding the orifice is divided using electrocautery. With the mucosa divided circumferentially, the ureteral catheter is gently pulled to expose the medial and inferior attachments of the trigonal musculature. These attachments are divided with electrocautery. At this point, the dissection proceeds to carefully divide the muscular attachments of the ureter through the plane of Waldeyer sheath. This dissection will free the distal ureter, which should have a normal or narrowed caliber. The surgeon should recognize the blood supply of the ureter, as shown in Figure 89.1. As the dissection proceeds more proximally, the blood supply of the ureter originates from medial branches of the hypogastric (male) or cervical (female) arteries. These vessels should be preserved, as should the longitudinal blood supply, by taking care to prevent dissection too close to the ureteral wall. When the ureter is free from its intramural attachments, the mobilization should proceed extravesically. The ureter at this point can be passed through the bladder wall, and the dissection proceeds more proximally. When the dilated region of the ureter is reached, dissection should continue until an adequate length for reimplantation has been mobilized, again paying attention to preserving the blood supply. An ischemic distal ureter may lead to fibrosis and obstruction.

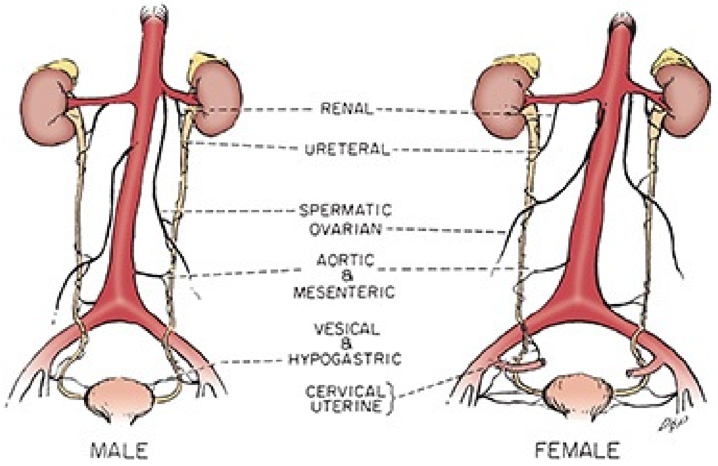

FIGURE 89.1 Major arterial supply to the ureter. It is not necessary to sacrifice any medially based blood supply for primary megaureter repair.

At this point, the surgeon must decide whether to taper the ureter. In general, if the lumen of the ureter is significantly larger than 10 mm, it should be tapered prior to reimplantation. This improves reimplant effectiveness by achieving an appropriate ratio of tunnel length to ureteral width. There are two techniques used to taper the size of the ureter: (a) excisional tapering and (b) tapering by folding. We will review the three most commonly used procedures. The goal of tapering is to provide a distal ureter with a small enough diameter that postoperative vesicoureteral reflux will be prevented with a reasonable length of intramural tunnel. The tapering needs to extend for only a short distance beyond the bladder wall rather than the whole length of the ureter. The dilation of the proximal ureter should improve postoperatively with the relief of obstruction and/or reflux. The decision to perform an excisional versus a folding technique depends on the preference of the surgeon and the size and thickness of the ureter. Folding a very dilated, thick-walled ureter will leave a large amount of residual bulk, making the creation of the submucosal tunnel difficult. In general, the taper should not be aggressive. In a bladder that functions well, reflux is less hazardous than persistent obstruction. In general, an intravesical reimplant should be pursued when a ureter meets criteria for tapering.

Excisional tapering (Fig. 89.2) begins with careful examination of the ureter. Without twisting the ureter, the surgeon observes the pattern of blood supply to the ureter. In most cases, the longitudinal vessels are predominately located along the medial aspect of the ureter. Usually, the excised segment of ureter is taken from the opposite side along the lateral border. The distal nondilated ureteral (aperistaltic) segment is excised. A 12Fr catheter is passed up the ureter. With this in place, the wedge to be excised is identified and outlined. Aggressive tailoring may result in obstruction and should be avoided. The process of excising and suturing the ureter will result in considerable contraction of the ureteral lumen. The tailored segment should gradually widen as the ureter is reconstructed proximally. The ureter is then closed. The mucosa and the muscularis of the ureter are closed with absorbable interrupted or running fine suture. A second layer if desired may incorporate the muscularis and adventitia with a series of interrupted absorbable fine sutures. The ureter is then reimplanted in a cross-trigonal fashion. If possible, the ureteral suture line should be positioned facing the detrusor muscle to prevent the development of a ureterovesical fistula and reflux. The 12Fr catheter is replaced with a 5Fr or 8Fr feeding tube or a double-J stent. The advantage to leaving an open-ended ureteral catheter is that a retrograde ureteral study can be performed postoperatively to demonstrate ureteral drainage, and the catheter can be removed in the office. The internal stent is easy to care for and leaves the patient free of external tubes; however, it requires a general anesthetic for removal. All tapered reimplants should be stented, regardless of which type of stent is used.

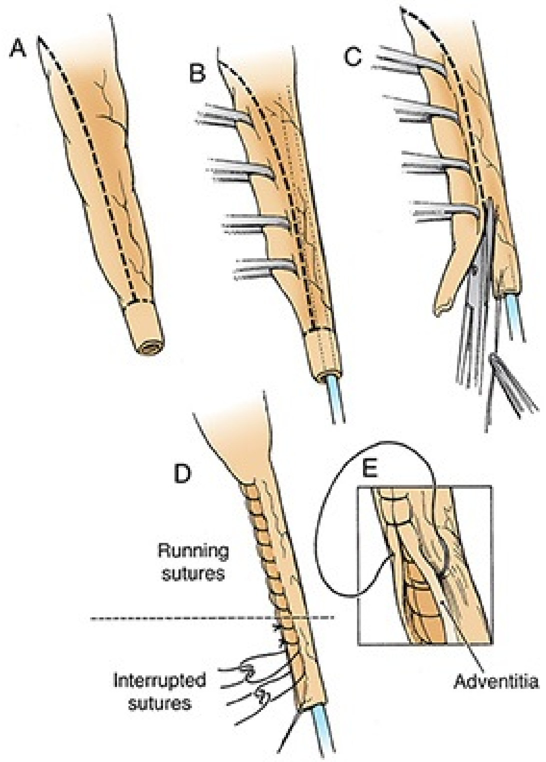

FIGURE 89.2 A and B: The wedge of ureter to be excised is secured with Allis or Hendren clamps. C: The outlined segment of ureteral wall is excised sharply. D and E: The ureter is closed in two layers. Distally, interrupted sutures are placed to allow for trimming of the end of the ureter at the time of reimplantation.

There are two techniques commonly employed for tapering by ureteral folding: (a) the Starr plication and (b) the Kaliscinski technique. Both techniques are similar to excisional tapering with regard to the length of ureter to be narrowed and the choice of the segment of the wall based upon the intrinsic blood supply. Starr plication (Fig. 89.3) reduces the diameter of the ureter by infolding the ureteral wall with interrupted Lembert sutures of 5-0 polyglyconate or polydioxan. The tapering begins proximally and gradually reduces the caliber of the ureter until the diameter approaches that of the 12Fr catheter. Care should be taken to ensure the wedge of folded ureter stays in the same position of the ureteral wall as you proceed distally and does not spiral from lateral to medial as the sutures are placed more distally. The ureter is reimplanted with the plication sutures facing the detrusor muscle as described with excisional tapering. The Kaliscinski technique (Fig. 89.4) begins with a running horizontal mattress suture of 5-0 or 6-0 chromic that runs the length of the segment to be tapered, creating a defunctionalized wedge of ureter that is then wrapped around the ureter and secured posterior with interrupted absorbable sutures. The ureter is reimplanted with the imbricated segment against the muscularis. Again, ureteral stents are placed in both repairs as with excisional tapering.

D: Excluded portion of the ureter is folded over and wrapped around the intubated ureter. E: Final appearance in cross section.

Extravesical Approach

Several authors have reported good results with the extravesical approach to megaureter repair (5,6). We avoid this technique in bilateral megaureter. In cases of bilateral megaureters, a high rate of voiding dysfunction postoperatively has been reported that may require intermittent catheterizations for a period following surgery. A Foley catheter is placed at the beginning of the procedure. The catheter may be attached with a Y-connector for intraoperative filling and emptying. The ability to regulate the bladder volume aids in the dissection. The incision and initial approach is identical as for the intravesical approach until the bladder is exposed. The dissection then proceeds into the lateral extravesical space. The obliterated umbilical artery is divided to expose the ureter. The ureter is carefully dissected free and encircled with a vessel loop. The ureter is dissected distally to the ureterovesical junction. With the bladder full, a detrusorotomy is made in a line extending from the bladder neck cephalad and circumscribing the detrusor adjacent to the ureter. The length of the incision should be 3 to 4 cm.

The ureter is freed from all detrusor attachments, keeping the mucosal attachments intact. The edges of the detrusor incision are then dissected free of the urothelium to form flaps that can be closed over the ureter. If the urothelium is perforated during the dissection, it can be repaired with 6-0 or 7-0 chromic. The most distal region is ligated and the ureter divided proximal to the ligature. The aperistaltic segment of the ureter is resected. The dilated ureter is then tapered as necessary. An indwelling stent is placed if the ureter is tapered. The bladder is partially emptied and the ureter is then directly anastomosed to the urothelium at the distal apex of the detrusorotomy using 5-0 absorbable sutures. With this accomplished, this advancement stitch fixes the distal ureter to the detrusor with 5-0 polyglyconate horizontal mattress sutures at the apex. The detrusor is then closed over the ureter with 4-0 polydioxan sutures. The hiatus should be approximated but not closed too tightly. A Foley catheter is left indwelling postoperatively and a Penrose drain is placed during closure.

Robotic Reimplant

The robotic approach has reached nearly all facets of intra-abdominal surgery within pediatric urology. Its use in ureteral reimplant for vesicoureteral reflux has made dismembered reimplant for an obstructed megaureter an easy transition. Positioning is either supine or dorsal lithotomy, dependent on patient size. Taller children require the lithotomy position to allow robot docking from the foot of the bed. All pressure points are padded with gel pads and tape is placed across the chest and midthigh to prevent patient migration during the procedure. Cystoscopy is performed and an internal double-J stent is placed. Pneumoperitoneum in the pediatric population should be obtained via an open technique. A semicircular incision is hidden within the umbilicus and an 8.5-mm Hassan trocar is inserted as a camera port. Two additional 5-mm robotic trocars are placed under direct vision on either side of the umbilicus along the midclavicular line. We prefer to use the 5-mm ports with the Maryland and the hook cautery. Alternatively, 8-mm robot ports can be used for larger children or if the surgeon prefers to use the hot scissors. The patient is then placed in steep Trendelenburg to mobilize the abdominal contents cephalad. The initial approach differs based on patient gender, as care must be taken to preserve the vas deferens and uterine structures during mobilization. The ureters can typically be visualized through the thin peritoneum, which is incised posterior to the bladder to expose the ureter. The ureter is exposed by gently grasping the adventitia with a Maryland instrument, then tenting it anteriorly with the hook to bluntly dissect the ureter for 5 or 6 cm proximal to the ureterovesical junction (Fig. 89.5A). This dissection will ultimately allow the ureter to lie in the detrusor trough without tension. An 0 Prolene suture is placed through the suprapubic region as a hitch stich on the bladder. The needle is straightened and inserted under vision then passed through the bladder both medial and anterior to the apex of the trajectory of the detrusor trough. Tension is placed on the stitch to pull the bladder anteriorly toward the abdominal wall. This alignment facilitates detrusor dissection, particularly at the UVJ. Next, the detrusor layer is incised with hook electrocautery and the Maryland dissector, taking caution to avoid violation of the mucosal layer. Bladder filling to increase bladder pressure can facilitate this dissection. Dissection continues until the mucosa bulges throughout the incision for the length of the intended tunnel to the UVJ (Fig. 89.5B). The ureter is then sharply incised distal to the narrowed segment and the mucosa spatulated. The diseased segment is then excised until healthy ureter is encountered (Fig. 89.5C). The anastomosis is then approximated in a running fashion, taking care to leave the double-J stent in place. Once completed, the ureter is placed in the trough and the detrusor edges are approximated over the ureter with advancement stitches at the apex of the trough. Care is taken not to extend the trough too far or too tight, as iatrogenic obstruction must be avoided. The remaining detrusor defect is closed over the ureter with absorbable suture (5-0 polydioxanone or poliglecaprone) in an interrupted fashion (Fig. 89.5D). We recommend closing the fascia at all port sites due to hernia risk. A Foley catheter is left overnight as in the open approach and we typically leave a Jackson-Pratt (JP) drain. The ureteral stent is removed 2 months postoperatively.

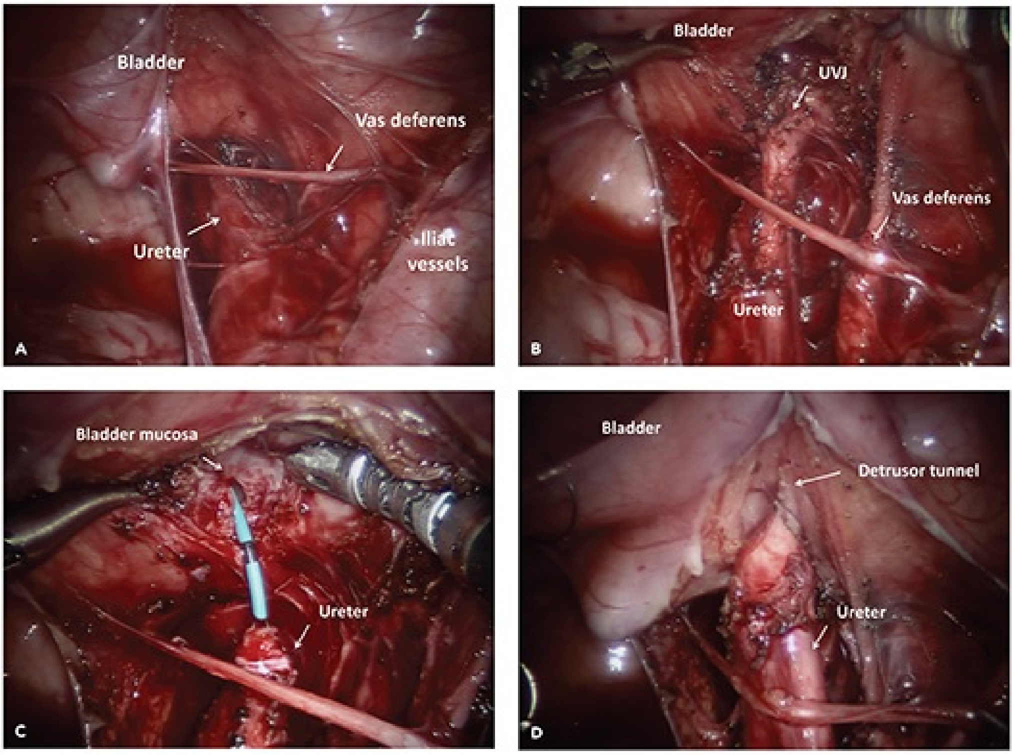

FIGURE 89.5 **A:** Peritoneum is incised over the iliac vessels and along the course of the ureter. In males, care is taken to mobilize the vas deferens so that it is not injured. In females, the peritoneum is incised anterior to the fallopian tube. **B:** The ureter is mobilized to the level of the UVJ and the narrowed diseased segment is visualized. The detrusor is incised, exposing the mucosa. Filling the bladder places tension on the muscle fiber and facilitates dissection. We prefer to use a Maryland and hook cautery via 5-mm ports. **C:** The ureter is incised distal to the diseased segment and the bladder mucosa is spatulated. The narrowed segment of ureter is excised and a running anastomosis is performed to the healthy ureter. **D:** Detrusorrhaphy is performed in an interrupted fashion to provide a gentle tunnel. The redundancy of the ureter is removed to improve drainage.

Staged Approach

Although repair of megaureters has been performed safely in newborns and young infants, there is a reasonable concern about reimplanting a markedly dilated ureter into the thin bladder wall of an infant (1,7). In some infants where severe dilation and diminished relative function (<35%) exists, end-cutaneous ureterostomy is a good alternative to reimplantation with tapering (7). The infant bladder often empties with high pressure, and postponing the definitive reimplantation while decompressing the obstructed ureter may reduce complications. In this case, one option is an end-cutaneous ureterostomy with resection of the distal stump. This provides reliable decompression of the kidney and usually improves the degree of ureteral dilation prior to reimplantation. In some cases, the ureterectasis recovers enough to avoid the need for tapering. This temporary measure will allow the reimplantation to be delayed until the infant is older and the bladder has grown. The takedown of the ureterostomy and ureteral reimplantation is usually done when the child is 12 to 18 months of age and can be performed intravesically or extravesically. If the initial function is poor and the kidney fails to recover following decompression, a nephrectomy rather than reimplantation may be preferred as the second procedure.

An alternative to the cutaneous ureterostomy that we use at CHOP is a refluxing ureteral reimplant. The ureter is mobilized and dismembered proximal to the narrowed segment. It is then reimplanted in a nontunneled fashion into the bladder. This has two functions: It preserves the continuity of the urinary tract and relieves the obstructive process and its sequelae to the kidney. We find this technique particularly useful in the infant bladder and have found that the great majority of these patients undergo a formal ureteral reimplant when age appropriate.

POSTOPERATIVE CARE

A catheter drainage is used for 24 to 48 hours. The externalized ureteral stent is left in place for 10 to 14 days. Children are discharged from the hospital on prophylactic antibiotics. Contrast injection of external stents at low pressure by gravity infusion with antibiotic coverage is performed to document drainage. If there is not prompt drainage around the stent, it is left for another 10 to 14 days and the stentogram is repeated. Internal stents are removed 4 to 6 weeks postoperatively. Patients are evaluated with a renal ultrasound 1 month after surgery or stent removal. If hydronephrosis is not improved, a renal scan should be obtained to rule out obstruction. A VCUG and renal scan should be performed 3 months after surgery, and the ultrasound is repeated at 1 year.

OUTCOMES

Complications

The most common complication related to surgery for megaureters is new or persistent reflux. This complication is more common when the surgery is performed for refluxing megaureters than for obstructed megaureters. Management options include observation with prophylaxis, endoscopic injection, or rarely, surgical revision. Obstruction is a rare complication, with reported rates of 0% to 4% (4,5,7). It should be initially evaluated endoscopically, as on occasion, a synechia has been reported to narrow the orifice. Strictures can be assessed by retrograde pyelography. Initial management with dilation and stenting may be successful, but failures will require formal surgical revision. Complications unique to endoscopic management include stent migration, stone formation, and stent colic, reported to occur in up to 31% of patients. Balloon dilation and/or laser incision can result in ureteral perforation, although these are rare occurrences in the literature. Because in most cases surgery is to relieve obstruction, patients with persistent vesicoureteral reflux do well and rarely need revision.

Results

Most series report success rates >90% (1,7–9). In a series of infants treated with reimplantation, 20% had reflux postoperatively; however, with time, a few patients had spontaneous resolution of their reflux, lowering the rate to 12.5% (10). Extravesical reimplants had rates of postoperative reflux similar to intravesical rates (12%). When performed bilaterally for megaureters, two-thirds of patients treated with extravesical reimplantation required intermittent catheterization for a period of 1 to 4 months (5). Success rates with endoscopic management are quite variable with rates (defined as no need for further intervention after stenting) ranging from 51% to 67%.

CHAPTER 90 PRUNE BELLY (TRIAD) SYNDROME

DAVID B. JOSEPH

Triad syndrome—the clinical association of a thin flaccid abdominal wall, undescended testes, and bladder hypertrophy with hydroureters—was originally described in 1895 by Parker (1). Shortly thereafter, Osler (2) presented a similar constellation of findings in a child he described as having the appearance of “a wrinkled prune.” From that point, “prune belly” has unfortunately become synonymous with this syndrome. This clinical manifestation is also known as the Eagle–Barrett syndrome and the abdominal muscular deficiency syndrome. By classic description, the triad syndrome occurs in boys. However, 5% of patients are girls presenting with similar physical findings, with the obvious exception of the gonadal abnormality. The incidence of triad syndrome in the United States is approximately 1/26,000 live births of which 50% are white, 31% African American, and 10% Hispanic (3). Most cases are sporadic, although a familial occurrence has been described and might be influenced by the HNF1β gene (4,5).

Approximately three quarters of children with classic triad syndrome will have other associated anomalies. Urethral abnormalities, including atresia and megalourethra, have been reported but are not required as part of the triad. Urethral atresia is usually associated with a patent urachus. The most common skeletal abnormality is a thoracic deformity resulting in a protruded upper sternum, depressed lower sternum, and splayed ribs. Other less frequent skeletal deformities include talipes equinovarus, congenital hip dislocation, calcaneus valgus, polydactyly, syndactyly, arthrogryposis, scoliosis, and lordosis. Intestinal malformations are noted in approximately one-third of children and most often are due to defective fixation or malrotation of the midgut. Cardiac atrial or ventricular septal defects, patent ductus, and teratology of Fallot have been reported in approximately 15% of children (4). Oral manifestations that included enamel hypoplasia and jaw bone abnormalities have become recently appreciated and possibly due to chronic renal insufficiency (6). The perinatal mortality remains substantial most often due to prematurity and pulmonary complications (3).

DIAGNOSIS

The diagnosis of triad syndrome can be established in utero with fetal sonography. However, similar findings can be identified in a fetus with posterior urethral valves or the megacystis–megaureters syndrome. Close inspection for thinned, deficient, or absent abdominal wall musculature should hedge the differential diagnosis to that of the triad syndrome. In utero diagnosis allows for a planned neonatal investigation. Triad syndrome is typically obvious at birth with the pathognomonic physical findings of a loose, lax, wrinkled abdominal wall; flared chest; and undescended testes.

Several classifications of the triad syndrome have been established based on severity and initial clinical presentation. There is no single classification system that incorporates the total spectrum of this syndrome. For practical purposes, children can be grouped into severe, moderate, or mild presentations. With a severe presentation, survival is often limited by significant respiratory compromise due to pulmonary immaturity and dysplasia, as well as extensive renal dysplasia, resulting in a Potter-like syndrome. Children described with moderate involvement have combined renal and respiratory insufficiency, mandating close observation and early intervention to minimize the sequelae of pulmonary and renal compromise. The combination of increased bilateral renal echogenicity on sonography, chronic urinary tract infections (UTIs), and a nadir serum creatine of >0.7 mg per dL are prognostic for renal failure (7). Monitoring of the urinary system is necessary to prevent progressive renal deterioration due to stagnation of urinary flow, UTIs, and possible urinary tract obstruction. Urinary tract reconstruction may play an important role in limiting long-term morbidity. Children with mild involvement do not suffer from respiratory or renal compromise. While long-term follow-up is necessary, operative intervention is often limited to orchiopexy and abdominal wall reconstruction.

A team approach consisting of a pediatric urologist, neonatologist, nephrologist, pulmonologist, and cardiologist is required to maximize the outcome. The initial cardiorespiratory status of the neonate must be established. The baby should undergo a chest X-ray and, when indicated, cardiac sonography. Urologic evaluation commences with abdominal sonography and a baseline chemistry profile. Both the upper and lower urinary tract should be assessed. Attention should be placed on the degree of hydronephrosis, the volume of renal parenchyma, and its echogenicity. Often, there will be a disproportionate degree of distal ureteral dilation and megacystis compared to dilation of the proximal ureter and kidney. On occasion, a marked transition of ureteral dilation is noted. If the infant is clinically stable with normal renal function and is voiding per urethra or draining through a patent urachus, further diagnostic testing can be placed on hold.

Children with renal insufficiency require further imaging to differentiate renal dysplasia and stagnant urine flow from true obstruction. The MAG-3 renal scan has limitations in the newborn period but remains the most objective diagnostic tool. The voiding cystourethrogram can assess vesicoureteral reflux and the effectiveness of bladder emptying. The neonate with triad syndrome and hydroureteronephrosis is susceptible to bacteriuria and can quickly become symptomatic. Bacteriuria is often persistent and difficult to clear. Therefore, it is of utmost importance that any invasive lower urinary tract imaging be performed in a sterile environment, with the child receiving pre- and postprocedural antibiotics.

Megalourethra has been classified as scaphoid and fusiform (Fig. 90.1). The more common scaphoid defect is confined to the penile portion of the corpus spongiosum, resulting in a variable length of massively enlarged ventral, anterior urethra similar in appearance to a saccular diverticulum. The fusiform variety encompasses a defect of the corpus spongiosum and deficiency of one or both of the corpus cavernosum, resulting in circumferential ballooning of the urethra and generalized penile flaccidity. Megalourethra is usually an isolated defect but can present with upper urinary tract changes, including hydronephrosis, vesicoureteral reflux, and renal dysplasia. It has been reported to occur with the triad syndrome, which may represent a continuation of the abnormal mesodermal theory of development related to the triad syndrome.

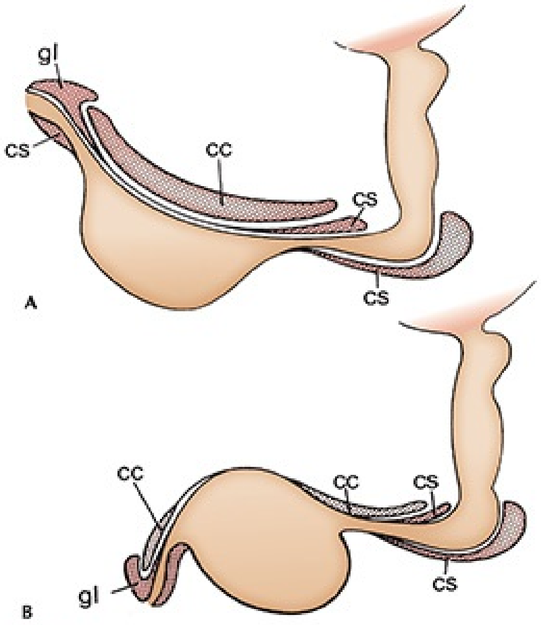

FIGURE 90.1 **A:** Scaphoid megalourethra. Corpora spongiosum (*CS*) is deficient throughout the ventral aspect of penile urethra. Corpora cavernosum (*CC*) is normal. **B:** Fusiform megalourethra. Both corpora spongiosum and cavernosum are deficient. Glans (*gl*) is normal in both variants.

INDICATIONS FOR SURGERY

Each child presents with a unique constellation of problems resulting in its own set of considerations and requires individualized care (8). Therefore, no one treatment plan is appropriate for all children. In general, operative management can be divided into three broad areas: reconstruction of the urinary system, reconstruction of the abdominal wall, and transfer of the intra-abdominal testes to the scrotum.

Urinary Tract Reconstruction

Controversy surrounds the need for aggressive urinary tract reconstruction. Early aggressive operative intervention for all children is countered by the fact that renal dysplasia may be inherent, thus preventing any intervention from improving the functional status. In addition, imaging studies depicting significant hydroureteronephrosis do not always correlate with obstruction or the potential for symptoms, and hydroureteronephrosis by itself does not mandate reconstruction. Urinary tract reconstruction is beneficial in a child who has a component of obstructive uropathy and has been shown to have improved renal function with decompression of the urinary system. Reconstruction is also of benefit in the child who has progressive hydroureteronephrosis associated with increasing renal compromise and in the child who has recurrent symptomatic UTIs due to stagnant urine flow.

Urinary diversion plays an initial temporary role in the management of acute renal failure or sepsis. Often, children with urethral atresia or obstruction will present with a patent urachus, effectively emptying their lower tract. Infants with associated posterior urethral abnormalities resulting in obstruction or poor bladder decompression, who are not candidates for intermittent catheterization, benefit from a vesicostomy. A vesicostomy, however, may not adequately drain the upper urinary tract due to a relative obstruction of the ureter at the level of the bladder or poor urinary transport secondary to a highly compliant, adynamic ureter. Vesicostomy should be undertaken only when bladder catheterization has been shown to provide effective decompression of the upper urinary tract. Otherwise, temporary diversion of the upper urinary tract will be required.

Nephrostomy tube drainage is helpful to stabilize an acute problem but long-term effectiveness is limited, resulting in a need for a more formal upper urinary tract diversion. There is a theoretical advantage in performing upper tract diversion as proximal as possible. This should maximally relieve stress to the kidney and limit stagnation of urine in a dilated tortuous ureter. However, there is often a disproportionate degree of distal versus proximal ureteral dilation that can prevent easy access of the proximal ureter.

It is compelling to perform a reduction cystoplasty during urinary reconstruction in a child with triad syndrome. However, long-term follow-up has been mixed regarding identifiable objective advantages (9–11). With time, the bladder will often regain its large size and lose its tone, resulting in inadequate emptying. For these reasons, it is not practical to proceed with reductive cystoplasty as the primary indication for urinary reconstruction. If a large, poorly contracting bladder results in inadequate urinary emptying, intermittent catheterization would be a more appropriate form of initial management. However, when undertaking formal urinary reconstruction with upper tract ureteral tailoring, reductive cystoplasty is practical and may provide limited improved bladder emptying (11).

Reconstruction of the Abdominal Wall

Several techniques have been devised to maximize the cosmetic benefits of abdominal wall reconstruction in children with triad syndrome. There is evidence indicating that the muscular defect is more pronounced centrally and caudally. Initial reconstructive efforts were based on removal of this abnormal tissue. While the appearance of the abdomen was improved, it was not ideal and resulted in a transverse incision and loss of the umbilicus. Monfort described preservation of the umbilicus, and others have added various modifications (12–17). Based on these approaches, abdominal wall reconstruction now allows for an excellent cosmetic and functional outcome (15–18). The benefit of abdominal wall reconstruction is dependent on the degree of abdominal wall laxity. The timing for this procedure should be based on the need for other operative intervention. If it is obvious that the child will not require upper urinary tract reconstruction, abdominal wall reconstruction can be undertaken at any time. If, however, there is the potential for upper urinary tract reconstruction, abdominal wall reconstruction should be deferred until the time of that intervention.

Orchiopexy

The timing for orchiopexy can be individualized based on the child’s need for urinary reconstructive surgery. If urinary reconstructive surgery is required, orchiopexy can be performed at the same time. If urinary reconstructive surgery is not required, then the timing and approach are variable. Placement of the testes within the scrotum is important for maintaining hormone function, allowing for pubertal development and sexuality, but unfortunately fertility is not improved (19). Biopsies of testes have shown limited sperm production, atypical germ cells and features consistent with Sertoli-cell-only, Leydig cell hyperplasia significantly limiting future fertility, and raising concern for malignant potential (20–22). Recently, case reports indicate that intracytoplasmic sperm injection may be feasible (23,24).

Urethral Reconstruction

Correction of the megalourethra is dependent on presenting symptoms of urinary dribbling and/or urinary infections. Most often, operative correction is undertaken because of the unusual appearance of the megalourethra. Urethral tapering is an appropriate treatment.

ALTERNATIVE THERAPY

Alternative therapy relates to conservative medical management and observation. The floppy abdominal wall and poor musculature can be supported with use of an elastic corset.

SURGICAL TECHNIQUE

Vesicostomy

A vesicostomy is placed between the symphysis and umbilicus. A 2- to 3-cm incision is made down to the rectus fascia. A triangular segment of fascia is removed, which will help limit problems of stenosis. The rectus is separated, the space of Retzius is entered, and the dome of the bladder is identified along with the urachus and umbilical ligaments. The bladder is opened in this region to decrease the risk of prolapse. The bladder wall is secured to the rectus fascia with 4-0 polyglactin sutures, and the bladder epithelium is approximated to the skin with 4-0 chromic gut.

Distal Cutaneous Ureterostomy

When there is minimal proximal dilation, a low distal cutaneous ureterostomy provides adequate decompression with relief of stagnated urine flow and stabilization of renal function. The ureter can be approached from a small (2.5-cm) incision placed in a low inguinal location. The muscles are split to enter the retroperitoneum. The ureter may have the appearance of bowel due to its large size. When in doubt, a 21-gauge needle should be passed, aspirating contents to confirm urine. Once confirmed, the ureter is opened at the level of the medial umbilical ligament (obliterated umbilical artery). The size of the ureter usually prevents postoperative stenosis, allowing for either an end or loop ureterostomy. An advantage of distal diversion is noted at the time of definitive urinary reconstruction: the proximal urinary system will have remained uncompromised, allowing for easier mobilization and greater flexibility when tailoring the ureter.

Ureteral Reconstruction

When definitive primary urinary reconstruction is necessary, the initial approach to the ureter can be extravesical. The ureter is isolated at the level of the bladder and proximal dissection ensues. If there is an obvious transitional phase noted on imaging between the dilated distal ureter and the normal proximal ureter, the dissection should be continued proximal to the transition point. During dissection, the adventitial tissue surrounding the ureter is preserved to prevent devascularization. All of the distal ureter is excised when there is adequate length for the proximal ureter to be tapered if needed and reimplanted in the bladder in a standard fashion or with the assistance of a psoas hitch.

If total proximal and distal ureteral tailoring is necessary due to massive dilation, full mobilization of the ureter will be required. This can be accomplished via a retroperitoneal approach, but in most children, it is helpful to enter the peritoneum and reflect either the descending or ascending colon along the white line of Toldt. The dilated ureter is often exceedingly redundant and tortuous. Straightening of the ureter without devascularization is required. The functional capability of the ureter for peristalsis and transmission of urine into the bladder parallels the degree of hydroureter. Therefore, ureteral tapering may enhance urinary flow into the bladder. Multiple techniques exist for ureteral tailoring, including ureteral imbrication and formal ureteral excision as with any megaureter (Fig. 90.2). Ureteral imbrication is appropriate for marginally dilated ureters. But, when massive ureteral dilation is present, which is usually the reason for reconstruction, formal excision is preferred, eliminating the bulky tissue that results from the large imbricated ureter.

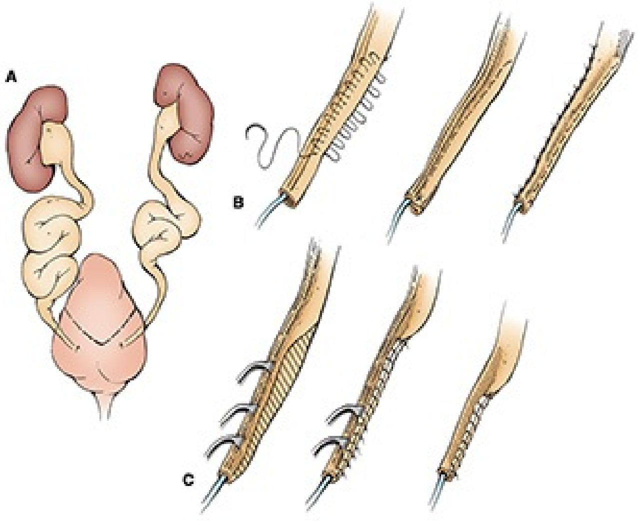

FIGURE 90.2 **A:** The tortuous dilated ureter is carefully straightened without compromising blood supply. The redundant portion is excised and the remaining distal segment tapered if necessary. **B:** Ureteral folding over a 10Fr or 12Fr ureteral catheter. **C:** Formal ureteral tapering with excision and closure. *Note:* The continuous running closure stops 1 to 2 cm from the end of the segment, followed by interrupted suture placement, allowing for excision of the distal end of the ureter without compromising the running closure.

The ureter is tapered loosely over either a 10Fr or 12Fr catheter, depending on the child's age and size. The excised ureteral segment may need to take an unconventional course to preserve adequate blood supply to the tailored ureter. If a large, redundant renal pelvis is present in association with a dilated proximal ureter, a reduction pyeloplasty should be performed in line with the ureteral excision. Preservation of the proximal ureteral blood supply is essential.

After excision, the ureter and renal pelvis are closed in a two-layer technique using absorbable sutures. The first running suture line is 5-0 or 6-0 chromic gut, polydioxanone, or polyglactic acid, directly apposing the mucosa and muscularis of the ureter. The second layer reapproximates the adventitial tissue using the same suture material. Both running layers are discontinued a few centimeters from the distal end of the ureter. The very distal portion of the ureter is closed with interrupted sutures. This allows for excision of the distal ureter without interruption of the running suture line. Enough ureteral length should be preserved to allow for a tunneled antirefluxing ureteroneocystostomy in all cases. A ureteral stent will remain for 5 to 10 days postoperatively.

Reduction Cystoplasty

Reductive cystoplasty should include the urachus and the majority of the dome of the bladder (Fig. 90.3). A 2- to 3-cm strip of mucosa is removed from one side of the bladder wall, allowing for a reinforced overlapping suture line. The bladder is closed in three independent layers using a running suture of 3-0 chromic gut, polydioxanone, or polyglactic acid. A suprapubic tube is inserted for postoperative monitoring regarding the effectiveness of bladder emptying.

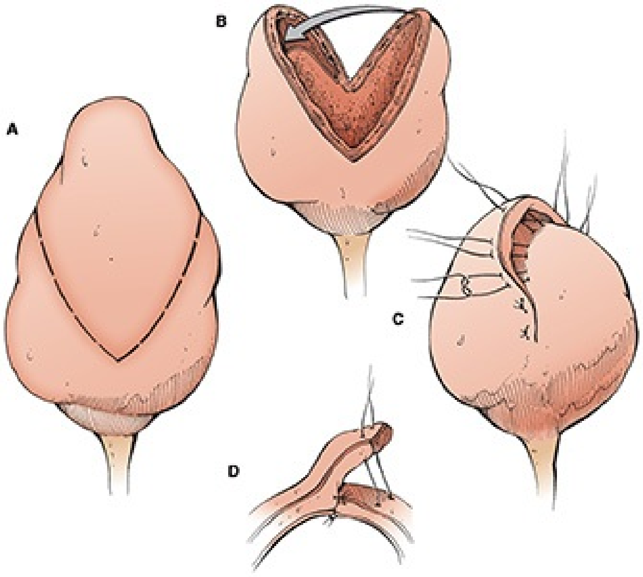

FIGURE 90.3 Reduction cystoplasty. **A:** The dome of the bladder, including any urachal remnant, is removed. **B:** A 2- to 3-cm mucosal strip is then removed from one portion of the bladder. *Arrow* indicates "vest over pants" closure. **C** and **D:** The bladder is closed with overlapping suture lines.

Abdominal Wall Reconstruction

The Monfort approach begins with a midline incision from the tip of the xiphoid process carried inferiorly, circumscribing the umbilicus, leaving an adequate umbilical island of tissue, and ending at the symphysis pubis (Fig. 90.4). A full-thickness skin flap is created bilaterally, elevating the subcutaneous fat from the underlying fascia. The dissection is continued laterally to the anterior axillary line. Often, there will be variability and asymmetry of muscular development. Care must be taken not to enter the peritoneum while mobilizing the skin flaps, in particular, in areas where the fascia is relatively thin. An incision is then made lateral to the superior epigastric artery through the fascia, entering the peritoneum. The incision is continued lateral and parallel to the course of the superior and inferior epigastric arteries from the costal margin to the symphysis pubis. The fascia is then elevated and the contralateral superior and inferior epigastric arteries are identified. A second parallel incision is made lateral to these arteries. The central fascial bridge with the umbilical island is now supported by both sets of epigastric arteries. The two lateral incisions provide excellent exposure for orchiopexy and major urinary tract reconstruction when required. A variation of this exposure has been described using only one incision through the side of greater laxity in an attempt to improve strength and abdominal wall function (15).

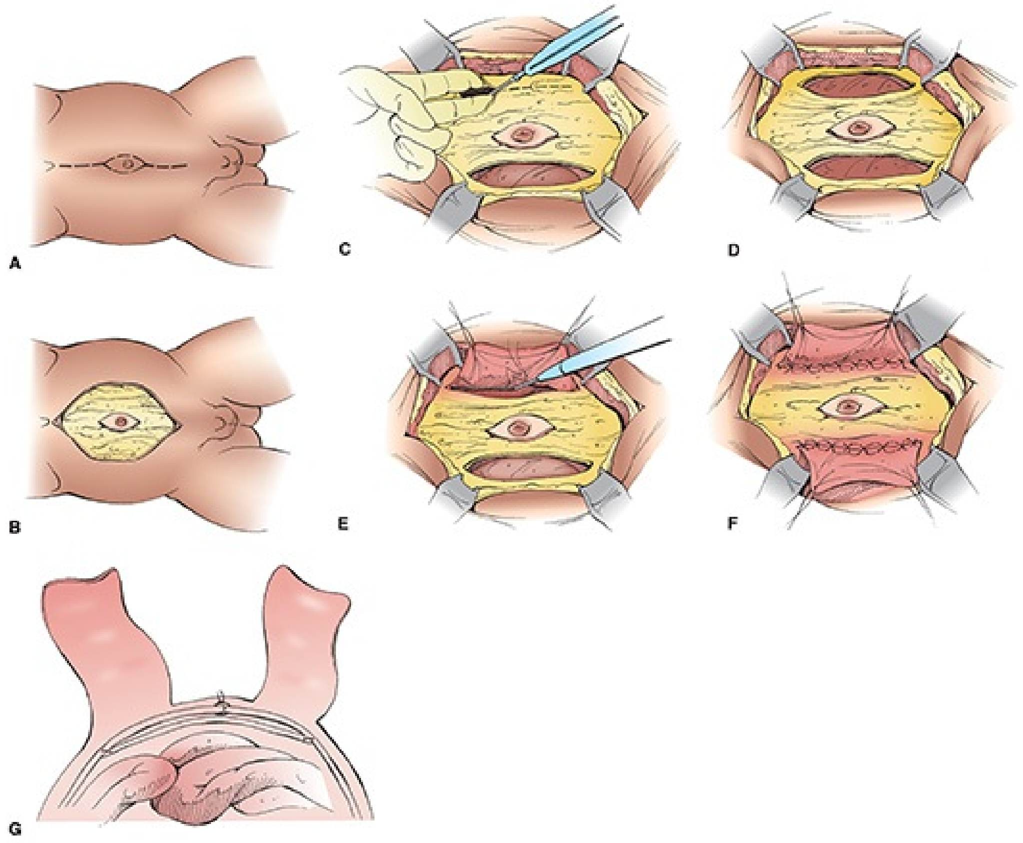

FIGURE 90.4 **A:** An incision is begun at the xiphoid, circumscribing the umbilicus, and carried down to the pubis. **B:** Skin flaps are then elevated, dissecting between the subcutaneous fat and the fascial layer. The lateral extension is the anterior auxiliary line. **C and D:** The umbilicus is supported by the central fascial bridge. Incisions will be made into the peritoneum lateral to the epigastric vessels. The central fascial bridge is easily manipulated to allow for excellent intra-abdominal exposure. **E:** At the time of closure, a line is scored on the peritoneal surface of the fascia. **F:** The central fascial strip is then secured laterally to the scored fascia line with a running suture of 2-0 or 3-0 polyglactin. **G:** The lateral fascia is then secured in the midline above and below the umbilicus with 2-0 or 3-0 polyglactin. Centrally, the fascia is secured directly to the umbilicus. This allows for an overlapping reinforced fascial wall closure. Subcutaneous tissue is closed with 3-0 or 4-0 plain gut and the skin with a running subcuticular 4-0 or 5-0 polyglactin suture.

At the time of abdominal closure, the lateral fascia wall is secured to the central fascial strip with a running 2-0 or 3-0 polyglactin suture. The lateral fascia can be scored with the cautery along the intended suture line to enhance adherence. The edge of the lateral fascia is then overlapped and secured in the midline with figure-of-eight suture placement using 2-0 or 3-0 polyglactin sutures. This pants-over-vest closure provides additional ventral support. When severe laxity is present, additional abdominal support can be achieved with mobilization and transposition of bilateral rectus femoris muscles (17). Two flat 7Fr suction drains are placed between the fascia and the subcutaneous space. The skin flaps are then tailored, removing the excess dermis, allowing for a midline and periumbilical closure. The skin flap is closed in multiple layers, securing the subcutaneous tissue with 4-0 plain gut sutures. The epithelial edge is reapproximated with a running subcuticular suture of 4-0 or 5-0 polyglactin. The drains remain in place for 2 or 3 days for decompression of the dead space. An alternative laparoscopic-assisted approach may allow for improved abdominal wall plication and simultaneous orchiopexy (25).

Orchiopexy

The testicle is usually found closely associated with a dilated distal ureter and should be released from the ureter in order to determine whether it can be delivered into the scrotum without sacrifice of the gonadal artery. If orchiopexy is undertaken early, particularly within the first 6 months of life, there is often adequate vascular length to deliver the testicle directly into the scrotum without transection of the gonadal artery (8). After the testicle is separated from the ureter, an incision is made in the peritoneum lateral to the gonadal artery and directed to the internal ring. A second incision medial to the gonadal vessels is made in the peritoneum and continued caudally along the course of the vessels and vas deferens. It is important not to disrupt the vascular supply of the peritoneal pedicle running on both sides of the vas deferens. If it becomes apparent that the testes will not reach into the scrotum after mobilization, the gonadal artery is sacrificed to obtain adequate length for the testicle to be delivered in the scrotum, as described by Fowler and Stephens (26). The blood supply to the testes is maintained by the vasal artery and small anastomotic channels within the peritoneal flap. A tunnel is then made into the scrotum and an incision placed inferiorly in the scrotum to create a dartos pouch. A clamp is passed from the scrotum to the inguinal canal. The testicle is grasped, pulled down through the tunnel, and delivered to the scrotum. Care must be taken not to twist or place the peritoneal pedicle on tension. If desired, the tunica vaginalis overlying the testicle can be secured to the dartos tissue with a 5-0 polydioxanone suture to reduce tension. When the orchiopexy is approached as an independent procedure, it can be undertaken laparoscopically either in a single or staged fashion (27).

Urethral Reconstruction

Urethral reconfiguration is most effective by formal excisional tapering, as described by Nesbitt (Fig. 90.5). An incision is made in line with the previous circumcision or beneath the coronal sulcus if the patient is uncircumcised. The penile shaft skin is then mobilized to the base of the penis. The anterior urethral wall is usually thin and poorly supported, and care needs to be taken to prevent inadvertent entrance into the urethra. The urethra is split in the midline ventrally. The redundant portion of the urethra is excised, and the urethra is reapproximated over a 10Fr or 12Fr catheter, depending on the child’s age. The urethra is closed in two layers using 6-0 or 7-0 polydioxanone or polyglactic acid sutures. The glanular urethra is usually patent, and the reconstruction is limited to the penile shaft. Because of poor development of the spongiosum, it may be difficult to achieve additional tissue for a second layer of coverage. The penile shaft skin is then secured to the coronal tissue with 6-0 chromic sutures. A urethral stent or catheter is placed for 7 days. The penis is dressed with the personal technique used for a hypospadias repair.

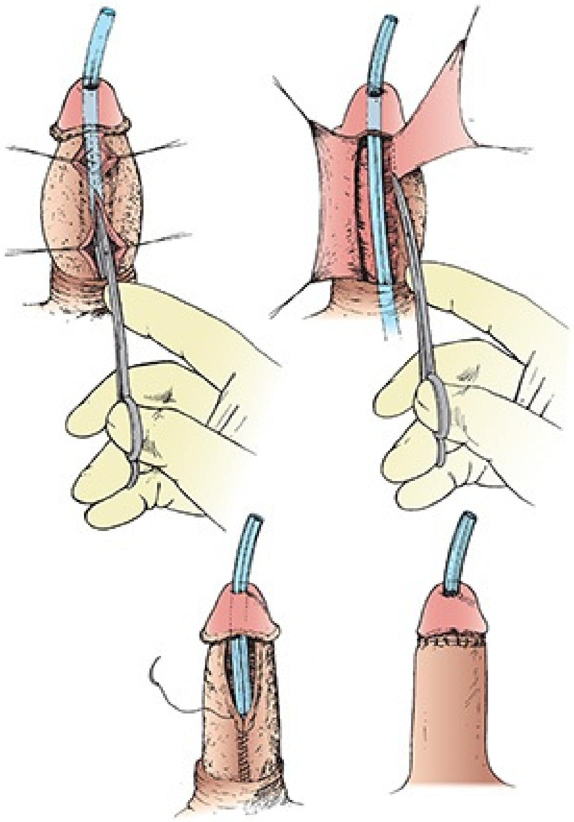

FIGURE 90.5 Nesbitt reduction urethroplasty for megalourethra. **A:** The urethra is opened vertically in the midline, followed by excision of the lateral redundant tissue (B). **C:** Reconstruction is carried out over a 12Fr catheter using two layers of running suture. **D:** The penile skin is reapproximated to the coronal margin circumferentially.

A variant of megalourethra is the “megameatus with an intact prepuce” (MIP). This is corrected using standard hypospadias techniques (Fig. 90.6). The glans is infiltrated with a mixture of 1:200,000 epinephrine for hemostasis. Parallel incisions are made lateral to the urethral plate and extended into the glans, creating two glanular wings. The incisions are continued along the shaft of the penis and connected beneath the urethral meatus. The urethra is then tubularized over an 8Fr, 10Fr, or 12Fr catheter using 6-0 or 7-0 polyglactic or polyglycolic acid sutures. The glans is closed in the midline, reapproximating the deep tissue with 6-0 Vicryl and the epithelium with 6-0 chromic. The penile shaft skin is brought up and the excess excised and then reapproximated to the coronal ring. A urethral stent or catheter can be positioned for 7 days, depending on the length of the defect. The penis is dressed as discussed earlier.

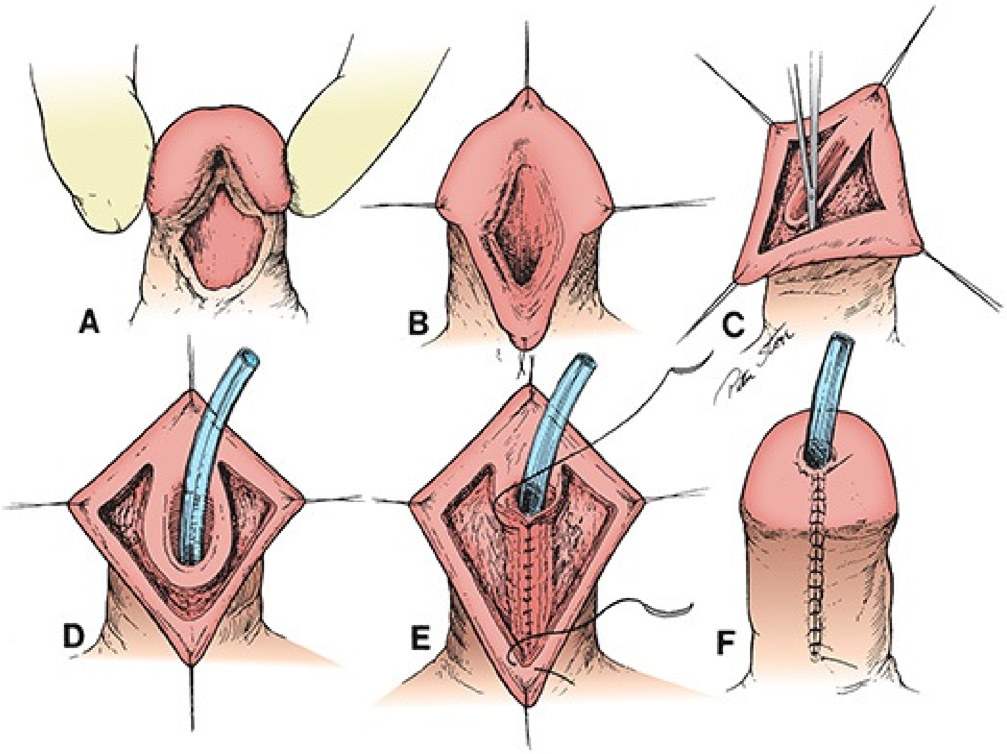

FIGURE 90.6 **A:** Pyramid procedure for repair of the megameatus with intact prepuce variant of hypospadias. **B and C:** Stay sutures are placed and the urethra is mobilized sharply. **D and E:** The urethra is tubularized in a two-layer technique. **F:** Subcutaneous glandular tissue is reapproximated and the skin closed.

OUTCOME

Complications

Ureteral devascularization resulting in ischemia and subsequent obstruction can occur if attention has not been paid to the ureteral blood supply. As with any ureteral reimplantation, vesicoureteral reflux and ureteral obstruction are rare but possible events. The risk of bowel obstruction is present as in any intra-abdominal procedure. Testicular ischemia and atrophy due to a single-stage Fowler–Stephens procedure has been reported to occur in 30% of children. This can be decreased with a staged approach (19,27). More importantly, ischemia may be prevented with early orchiopexy, eliminating the need for sacrificing the gonadal vessels.

The cosmetic appearance following urethral tapering is good and limited only by any residual corpora cavernosa deficiency. Postvoid dribbling can be abolished, and the risk of urinary infections due to stagnant urine can be diminished. The most common complication is that of a urethral fistula due to limited spongiosum tissue for a multiple-layer closure. The circumferential degloving of the penis with subsequent reapproximation of the penile shaft skin to the corona will limit fistula formation. The greatest risk for a fistula is located at the level of the ventral coronal sulcus.

Results

The results of urologic reconstruction can be very gratifying in the initial postoperative period, in particular, the cosmetic appearance of the abdomen and the improvement in upper urinary tract drainage. Voiding function may become more effective due to the benefits of abdominal wall reconstruction and reduction cystoplasty (17,18). However, with time, there can be an increase in both bladder size and ureteral dilation. This is often due to ineffective voiding and is independent of bladder reduction. For those reasons, long-term follow-up of the urinary tract is required. Patients should be prepared for the potential need for intermittent catheterization. Because of normal sensation, children are often unwilling to cooperate with urethral catheterization. Placement of an appendicovesicostomy should be considered if catheterization appears to be a realistic possibility at the time of urinary reconstruction. An appendicovesicostomy provides excellent access to the bladder in a normally sensate child.

CHAPTER 91 CHILDHOOD RHABDOMYOSARCOMA

FRANK J. PENNA AND MARTIN A. KOYLE

Rhabdomyosarcoma (RMS) is the most common soft tissue sarcoma of childhood, accounting for 5% of all cancers in children and about half of all soft tissue sarcomas. RMS is also the most common extracranial neoplasm, following neuroblastoma and Wilms tumor. This tumor is nonencapsulated, grows rapidly, spreads locally to regional lymph nodes, but can also metastasize hematogenously and is not limited to skeletal muscle. In children and adolescents (<20 years of age), the incidence is 4.3 cases per million, with approximately 350 new cases diagnosed annually in the United States (1). Genitourinary RMS, involving the bladder, prostate, paratestis, vagina, and uterus represents 18% to 20% of all cases (1). There is a bimodal age distribution with a peak incidence in the first 2 years of life and again during early adolescence (2).

RMS was first described in 1850 by Wiener (3). Little was published on RMS, until the 1950s when a histologic classification system for the condition was described. Theriault initially described alveolar RMS in children and Stout described pleomorphic RMS (4,5). In 1958, Horn and Enterline created the classification of RMS that reflected varying degrees of embryonic rhabdomyogenesis (6). In fact, RMS is considered one of the “small round blue cell tumors of childhood,” the others being neuroblastoma, Ewing sarcoma, and lymphoma. Once almost uniformly fatal, RMS has become highly curable with multimodal therapy, with the majority of patients achieving long-term survival. These advances were the result of the Intergroup Rhabdomyosarcoma Study Group in exploration of the optimal therapy for childhood RMS.

The Intergroup Rhabdomyosarcoma Study Group (IRSG) initiated studies in the United States in 1972 to achieve better survival with less morbidity in successive coordinated large, multicenter trials. During the first IRSG study (IRSG I) from 1972 to 1978, radical surgical resection was employed with adjuvant chemotherapy, traditionally using vincristine, dactinomycin, and cyclophosphamide (VAC) at the expense of bladder preservation, with a rate of preservation of only 23% at 3 years (3). The second IRSG study from 1979 to 1984 incorporated neoadjuvant chemotherapy and/or radiation prior to surgical excision. In this study, overall survival remained high at 80% with 10% of patients achieving relapse-free survival with chemotherapy alone (3). Early in these studies, when the bladder was involved with tumor, radical exenterative surgery was employed. With the success of chemotherapy, bladder-sparing surgery was then invoked; however, only 25% being left with an intact, functional bladder (3).

The third IRSG from 1985 to 1992 marked the advent of the organ-sparing era. With bladder-sparing surgery, retained bladder function of 60% was noted at 4 years after diagnosis while preserving an 83% survival rate (3). Also during this time, chemotherapy was standardized to include doxorubicin, cisplatin, and etoposide in patients with bladder and prostate RMS. IRSG IV initiated the use of the tumor–node–metastasis (TNM) pretreatment staging system and also concluded that hyperfractionated radiation was not more beneficial compared to standard conformal radiation therapy.

The IRSG is now the Soft Tissue Sarcoma Committee of the Children’s Oncology Group, which has taken over responsibilities for these trials, and is currently investigating new chemotherapeutic options including sorafenib, pazopanib, crizotinib, TH-302, aurora-kinase inhibitors, and anaplastic lymphoma kinase inhibitors (7). Patient survival, which was only 40% to 73% prior to chemotherapy, has improved to 86% in IRSG IV with VAC (8).

PATHOLOGIC FEATURES AND MOLECULAR MECHANISMS

RMS is derived from immature striated skeletal muscle cells in various stages of embryonic myogenesis. There are three variants of RMS as described by the IRSG: embryonal, alveolar, and pleomorphic RMS. Embryonal RMS, the most common subtype, is typically found in infants and young children and includes sarcoma botryoides, a polypoid variant that is found in the hollow organs such as the bladder or vagina and carries a favorable prognosis as well as the spindle cell variant which is common in the paratesticular region and also carries a favorable prognosis (1). Embryonal RMS resembles fetal striated muscle at 7 to 10 weeks gestational age and is composed mainly of spindle-shaped cells with a central nucleus that stains for nuclear transcription factors such as myogenin or MyoD1, surrounded by eosinophilic cytoplasm (3). Embryonal RMS is associated with an 11p15.1 loss of heterozygosity and, in general, carries a favorable prognosis (9).

Alternatively, alveolar RMS is the second most common form and portends a poorer prognosis; it resembles striated muscle at 10 to 21 weeks gestational age, has a vague resemblance to fetal alveoli, with clusters of small round cells adherent to fibrosepta, and is typically diagnosed in older children (1,6). Alveolar RMS also has distinct genetic mutations, including t(2;13) or t(1;13) translocation, which generate the PAX3-FKHR and the PAX7-FKHR gene fusions, respectively. The presence of these gene fusions have been associated with a high rate of relapse and death in patients with metastatic disease, particularly patients who exhibit the PAX3-FKHR mutation, which is present in approximately 70% of alveolar RMS (3). The downstream effect of these mutations results in decreased gene products that play a role in normal myogenic differentiation. These mutations, and not the histologic features, have been implicated as the source of the poorer outcome in this subtype (6). In fact, fusion-negative alveolar RMS behaves more characteristically of embryonal in terms of presentation and clinical outcome.

Pleomorphic is not classically associated with childhood RMS originating from the prostate or bladder (1). Undifferentiated type RMS is remarkably anaplastic and difficult to identify due to nonspecific large round cells with scant cytoplasm and lack of antigenic markers.

RMS is associated with particular familial conditions that result in a genetic predisposition to developing the condition including Li-Fraumeni, Beckwith-Wiedemann, Gorlin syndrome, and neurofibromatosis type 1, with the latter seen commonly with genitourinary RMS with embryonal histology (1). The most common genetic mutations include PAX-FKHR gene fusions, alterations affecting MyoD1 and myogenin expression, as well as the retinoblastoma and p53 pathways (3). There has been much effort put forth on applying the recent advances in molecular biology and bioinformatics to provide more robust criteria for risk stratification, predicting clinical outcome, and tailoring “rational” therapy based on the identification of critical targets in RMS (10).

DIAGNOSTIC EVALUATION AND STAGING

Signs and symptoms are dictated by the primary organ(s) involved. Hence, imaging will vary accordingly. Evaluation of pelvic organs with diagnostic imaging modalities including conventional radiography, ultrasonography, computerized tomography (CT), magnetic resonance imaging (MRI), and nuclear medicine studies such as bone scan, positron emission tomography (PET). MRI has been shown to improve the detection of residual pelvic RMS with well-delineated tissue planes and more accurate assessment of tumor invasion into adjacent structures compared with CT (11). Suspected paratesticular RMS are evaluated initially with scrotal ultrasound. Metastatic workup is completed with a chest X-ray, liver function tests, bone scan, and bone marrow biopsy. The initial staging algorithm is demonstrated in Figure 91.1.

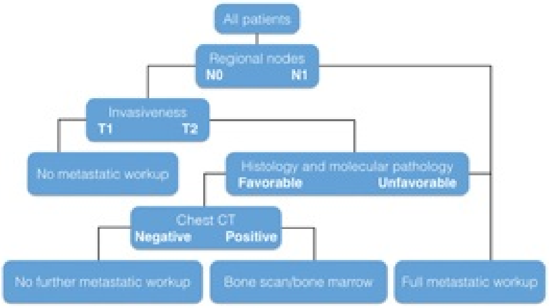

FIGURE 91.1 RMS initial staging algorithm. *CT*, computerized tomography. (Adapted from Weiss AR, Lyden ER, Anderson JR, et al. Histologic and clinical characteristics can guide staging evaluations for children and adolescents with rhabdomyosarcoma: a report from the Children's Oncology Group Soft Tissue Sarcoma Committee. *J Clin Oncol*. 2013;31[26]:3226–3232.)

The mechanism of metastasis for RMS is variable, with local and regional spread via lymphatic channels present in approximately 20% of patients (3). The most common sites of hematogenous metastases include lung, bone marrow, and bone, whereas sites such as the liver or brain are rare. Prognostic factors that are considered unfavorable include primary sites such as bladder or prostate, the presence of distant metastasis at diagnosis, regional lymphadenopathy, primary tumors greater than 5 cm, and age younger than 1 year or older than 10 years (2). A substantial number of patients with low-stage disease are subjected to unavoidable testing so there has been an effort to characterize patients with low-stage, node-negative, and noninvasive RMS disease early to avoid studies such as bone marrow aspirate and bone scan as well as the unnecessary radiation exposure from chest CT (12). The IRSG protocols included both preoperative staging and postoperative grouping (8) (Tables 91.1 and 91.2). The IRSG I to III studies grouped patients based on completeness of resection, introducing biases (shifting patients from group 1 to group 3) that are not seen with the use of the TNM system in IRSG IV and V.

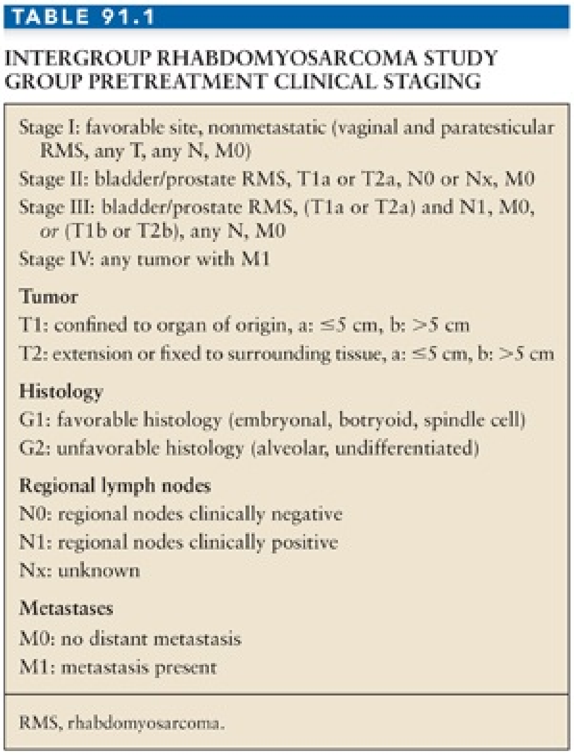

TABLE 91.1

INTERGROUP RHABDOMYOSARCOMA STUDY GROUP PRETREATMENT CLINICAL STAGING

Stage I: favorable site, nonmetastatic (vaginal and paratesticular RMS, any T, any N, M0)
Stage II: bladder/prostate RMS, T1a or T2a, N0 or Nx, M0
Stage III: bladder/prostate RMS, (T1a or T2a) and N1, M0, *or* (T1b or T2b), any N, M0
Stage IV: any tumor with M1

Tumor
T1: confined to organ of origin, a: ≤5 cm, b: >5 cm
T2: extension or fixed to surrounding tissue, a: ≤5 cm, b: >5 cm

Histology
G1: favorable histology (embryonal, botryoid, spindle cell)
G2: unfavorable histology (alveolar, undifferentiated)

Regional lymph nodes
N0: regional nodes clinically negative
N1: regional nodes clinically positive
Nx: unknown

Metastases
M0: no distant metastasis
M1: metastasis present

RMS, rhabdomyosarcoma.

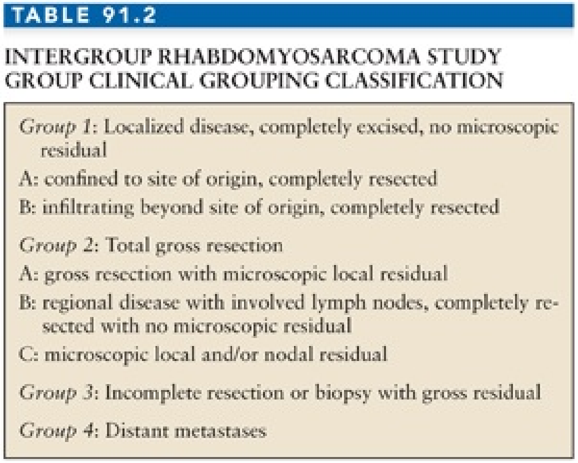

TABLE 91.2

INTERGROUP RHABDOMYOSARCOMA STUDY GROUP CLINICAL GROUPING CLASSIFICATION

Group 1: Localized disease, completely excised, no microscopic residual
A: confined to site of origin, completely resected
B: infiltrating beyond site of origin, completely resected

Group 2: Total gross resection
A: gross resection with microscopic local residual
B: regional disease with involved lymph nodes, completely resected with no microscopic residual
C: microscopic local and/or nodal residual

Group 3: Incomplete resection or biopsy with gross residual

Group 4: Distant metastases

Bladder and Prostate Rhabdomyosarcoma

Bladder and prostate RMS present initially with obstructive urinary symptoms, including urinary frequency, stranguria, hematuria, incontinence, and acute urinary retention, and tend to be located at the trigone and bladder neck. Bladder RMS typically grows intraluminally and usually occurs in the botryoid form. Most present by 10 years of age, whereas neonatal RMS is very rare but has been reported in the literature and detected via prenatal ultrasonography (13).

Prostatic RMS usually presents as a solid mass and carries a poorer prognosis (2). On physical examination, an abdominal mass may be present. Imaging including ultrasonography, CT, or MRI can delineate disease extent including retroperitoneal lymphadenopathy, and cystoscopy can facilitate diagnosis via transurethral biopsy with a pediatric resectoscope or cold-cup biopsy forceps (Fig. 91.2).

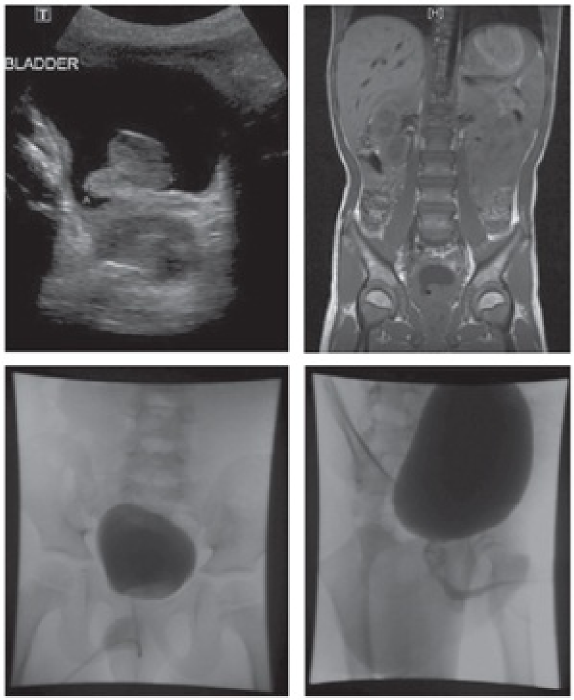

FIGURE 91.2 A 2-year-old boy with RMS demonstrated by ultrasound (**top left**) of the bladder showing mass filling bladder lumen and coronal MRI (**top right**), T1-weighted. voiding cystourethrogram (**bottom left**) showing filling defect in the bladder and ball valving of mass in posterior urethra (**bottom right**).

A study from the late 1980s of 36 children with RMS employed a multimodal approach including conservative surgery when indicated, radiation, and chemotherapy with VAC, with an overall and event-free survival rate of 80% and 74%, respectively (14). The study also emphasizes the importance of urethral biopsies when evaluating bladder and prostate RMS because urethral involvement can be subtle due to submucosal extension and may not be apparent with cystoscopy alone.

Serial imaging with CT or MRI can be used to assess response to treatment, including chemotherapy. Chest CT is useful for evaluating lung metastases, and more recently, PET has been implemented, but its use is still under investigation (3). Based on the tumor site, grade, presence of lymphadenopathy, and metastatic lesions, patients are categorized into low-, intermediate-, or high-risk groups.

Paratesticular Rhabdomyosarcoma

Paratesticular RMS presents as a unilateral painless scrotal mass or with scrotal swelling that is appreciably distinct from the testis. Paratesticular RMS represents 7% to 10% of genitourinary RMS with a peak presentation of 1 to 5 years of age (2). The majority of paratesticular tumors are stage 1 and embryonal in histology, which portends a good prognosis. Imaging, including CT, is recommended to assess for retroperitoneal lymphadenopathy, which can occur in up to 20% of patients. Interestingly, although ultrasonography is the imaging modality of choice for intratesticular pathology, paratesticular RMS on ultrasonography and even MRI may be elusive and often confused with other conditions such as epididymitis, adenomatoid tumor, and leiomyoma (15) (Fig. 91.3).

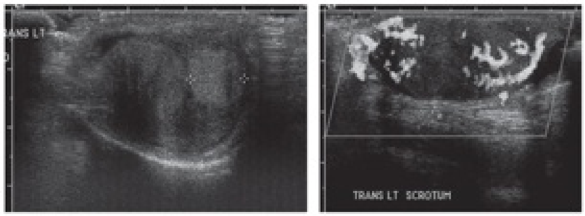

FIGURE 91.3 Scrotal ultrasound of a boy with paratesticular RMS showing mass (left) and flow to mass (right).

Vaginal and Uterine Rhabdomyosarcoma

Vaginal RMS typically presents with a vaginal discharge, bleeding, or a painful, expanding introital, anterior vaginal wall mass in the first few years of life. Uterine RMS typically presents as an abdominal mass originating from the uterine body or with vaginal bleeding from a cervical mass. These lesions carry an excellent prognosis due to their botryoid histology (2). Historically, these patients were treated with aggressive surgical resection with an anterior pelvic exenteration. With the advent of more efficacious chemotherapeutic agents, preservation of the vagina and uterus is paramount, and the patients are surgically resected only if persistence of disease after neoadjuvant chemotherapy, as determined by a postchemotherapy biopsy. Complications of treatment of vaginal and uterine RMS include vaginal stenosis, ureteral obstruction, intestinal stricture or fistula, and ovarian failure (Fig. 91.4).

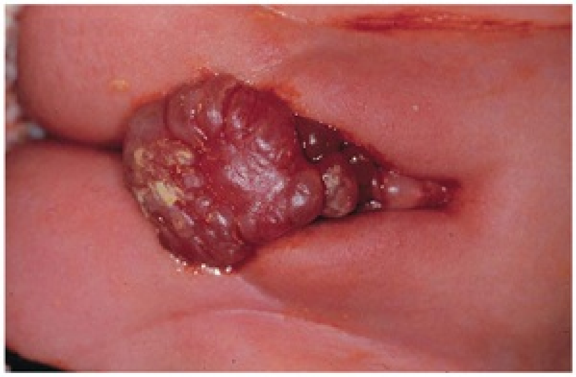

FIGURE 91.4 An 11-month-old in foster care with a 3-month history of enlarging vaginal mass. Resected with total response to chemotherapy. The patient is alive and with no evidence of disease after 17 years.

TREATMENT

The treatment of RMS involves the coordination of multimodal therapy including surgical resection, chemotherapy, and radiotherapy. A number of factors determine the treatment regimen including the specific pathologic and histologic subtype, primary site, biology, clinical stage of disease, and extent of resection. Many cooperative organizations, including the Soft Tissue Sarcoma Committee of the Children's Oncology Group (STS COG), Study for Malignant Mesenchymal Tumors of Société Internationale d'Oncologie Pédiatrique (SIOP-MMT), and Cooperative Weichteilsarkom-Studie (CWS), have defined specific risk-adapted treatment regimens (1).

According to the protocols set by STS COG, surgical resection or adequate biopsy is the initial treatment followed by adjuvant chemotherapy. Adequate tissue for a definitive diagnosis should be obtained, and if possible, the tumor should be removed without removing or potentially damaging the affected and adjacent organs (with the exception of paratesticular RMS, where the testis is removed inguinally with the tumor). This allows for characterization via IRSG risk group and will determine the subsequent treatment algorithm. If excision is not possible, primary chemotherapy should be given. In follow-up staging, a biopsy is needed during the "second-look" operation because the residual mass does not always represent tumor: The cancer can involute more rapidly than the supporting stroma. With pelvic tumors, definitive surgery aims to attain complete disease excision with clear margins but with an organ-sparing goal. If microscopic residual disease is found, it is treated with brachytherapy or external beam radiotherapy. Exenteration is reserved for patients who fail this protocol of chemotherapy, conservative surgery, and radiotherapy. In Europe, the approach is to give primary chemotherapy without initial local control (radiotherapy or surgery) and offer local therapy based on the initial chemotherapy response (16). SIOP treatment regimens advocate for neoadjuvant chemotherapy followed by completion surgical resection depending on the chemotherapeutic response.

Effective local therapy and control is essential for overall survival in patients with RMS (1). The dilemma between radical local treatment and preservation of residual organ function (bladder, vagina, testes/ovaries, and sexual function) is difficult but must be optimally determined to allow for the greatest cancer control and the least disruption of function. Certainly, the potential for bladder dysfunction in bladder-sparing procedures must be considered in the treatment algorithm. Other surgical procedures that have the potential to disrupt innervation and function, including extravesical reimplantation, have been associated with postoperative bladder dysfunction (3).

Radiotherapy, an alternative therapy, has been remarkably successful in decreasing the need for radical surgery to achieve a cure and has allowed for improved local control and relapse prevention (1). Newer therapies such as intensity-modulated radiation therapy, brachytherapy, and proton radiation allow for a minimization of treatment toxicity without compromising efficacy. In fact, multimodal treatment including limited surgical resection in combination with chemoradiation therapy may allow for preservation of function while maintaining cancer control. Radiation therapy has also been associated with bladder dysfunction in a dose-dependent manner, with both acute and chronic effects (3). The early effects include inflammatory changes in the bladder, which result in decreased bladder capacity, but it is typically reversible. The chronic effects are also dose-dependent and include lower urinary tract symptoms such as urgency, frequency, hematuria, and diminished bladder compliance secondary to fibrosis. The fibrosis is due to increased transforming growth factor-β expression resulting in increased collagen deposition in the muscle and subepithelial layers of the bladder. The difficulty with radiotherapy and bladder RMS is that because the tumors tend to be located at the bladder neck, even the lowest dose (41 Gray [Gy]) may significantly affect urinary continence. The long-term risk of radiation vasculitis, which is inevitably progressive, as well as possible bony pelvis deformity in these children is another issue to consider. Therefore, one must sometimes weigh whether preserving a bladder without an outlet is better than removing the bladder entirely (17). The final issue is that postradiation artifact makes subsequent biopsy very difficult to interpret, so it would make sense to delay radiation until the patient is free of gross disease. With radiotherapy, there is also an increased risk of a secondary neoplasm, often another sarcoma, typically in the radiation field. Current attempts at limiting radiation toxicity to adjacent organs involve both conformal radiotherapy and brachytherapy.

Chemotherapy is a mainstay in the treatment of RMS, including the combination of VAC, the mainstay chemotherapeutic regimen. Alternatively, doxorubicin has been implemented in addition or in lieu of dactinomycin and studied in extremely high-risk sarcomas (18). Albeit controversial, doxorubicin has been shown in IRSG III to have some benefit when added to the VAC regimen. Also, etoposide/ifosfamide has been shown to be effective for intermediate risk RMS (1). However, with complex chemotherapeutic regimens that also contain etoposide and cisplatin, the efficacy of doxorubicin alone has been difficult to ascertain. For refractory or relapsed RMS, topotecan/vincristine/doxorubicin has demonstrated remarkable response rates, albeit in a small number of patients (1). Chemotherapeutic agents such as alkylating agents (i.e., cyclophosphamide) can also have dose-dependent adverse effects on the bladder such as hemorrhagic cystitis, with gross hematuria, fibrosis, and bladder contracture, not to mention the increased risk of secondary bladder cancers. This condition is typically treated with mercaptoethane sulfonate (mesna), a compound that binds the cyclophosphamide metabolite, acrolein (3). The majority of patients have acute toxicity from the chemotherapy: Ninety percent developed myelosuppression, 55% developed significant infections, and renal toxicity was seen in 2% (8). Most relapses occur within 3 years of initial diagnosis (19). Late recurrences can occur in patients who are treated with chemotherapy alone. Of 883 patients, 10 developed a secondary cancer. Patients with preexisting renal abnormalities were at a higher risk of death (5% versus 1%). Relapse in group 3 patients (incomplete resection) was associated with a 22% chance of 3-year survival, compared to 41% in group 1 or 2 patients (localized disease or total gross resection) (8). Twenty-nine percent required sex hormone replacement, and 11% were shorter than expected (17) (Fig. 91.5).

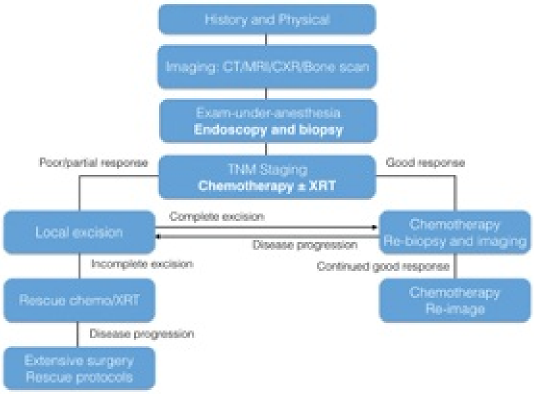

FIGURE 91.5 RMS treatment algorithm. *CT*, computerized tomography; *CXR*, chest X-ray; *MRI*, magnetic resonance imaging; *TNM*, tumor–node–metastasis; *XRT*, external beam radiation therapy.

Bladder and Prostate Rhabdomyosarcoma

Initial treatment of bladder and prostate RMS includes management of urinary obstruction with urethral catheterization for bladder outlet obstruction and ureteral stent placement if ureteral obstruction is present. Suprapubic drainage is not recommended secondary to the potential for tract seeding (3). Percutaneous nephrostomy tube placement may be indicated in cases where the trigone is distorted by a large mass and retrograde access cannot be gained. The treatment of bladder and prostate RMS is multimodal, with the goal of preserving bladder function by limiting complete resection. Unfortunately, in the majority of cases, partial resection is not a viable option given disease extent. Many centers recommend neoadjuvant chemoradiation, followed by partial surgical resection (i.e., bladder sparing) depending on response (2). With larger tumors having more extensive involvement, surgical reconstruction may be necessary including ureteral reimplantation and bladder augmentation in conjunction with partial cystectomy (3). A pretreatment re-excision may be necessary in patients who have been diagnosed endoscopically but have gross resectable residual tumor, microscopic positive margins, or unclear margin status. A second-look operation is indicated to confirm clinical and pathologic response to therapy and, if needed, to remove residual tumor in patients that achieve clinical complete or partial response.

The approach to partial or total cystectomy is similar to that for muscle-invasive transitional cell carcinoma. The initial step after opening the abdomen is to examine the retroperitoneum. Although a full retroperitoneal lymphadenectomy is not indicated because there is no therapeutic benefit, any suspicious lymph nodes along the vessels between the obturator fossa and the renal veins are removed. The next step is to properly stage the tumor by obtaining multiple frozen-section biopsies of the bladder around the area of the tumor. If these are negative and the tumor is amenable to partial cystectomy with a 2- to 3-cm margin, then the bladder does not need to be entirely removed. RMS is a nonencapsulated, infiltrative tumor, so attaining adequate margins is necessary.

If the tumor extends down the urethra, then the symphysis should be split to gain better access. After completing the distal dissection of the urethra, the symphysis is closed with long-term absorbable sutures. With this improved exposure, it is also possible to perform a nerve-sparing dissection. The placement of brachytherapy catheters for afterloading (to treat microscopic positive margins if needed) should be considered. Currently, pelvic exenteration is reserved for patients who have failed both chemotherapy and radiotherapy and who have tumors that invade both the bladder and the rectum.

The final surgical decision is whether to proceed with concurrent continent urinary reconstruction. It is not necessary to perform the reconstruction at the same time unless the patient is both motivated and able to perform clean intermittent catheterization to drain a urinary reservoir. For younger patients who are not ready to manage a urinary reservoir, a vesicostomy or low end cutaneous ureterostomies are viable options.

Radiation therapy is also a viable treatment option and is an integral part of the bladder-sparing approach with distinct risks of adverse outcomes including bladder dysfunction, which has been demonstrated urodynamically with reduced bladder capacity and abnormal voiding patterns (2) (Figs. 91.6 and 91.7).

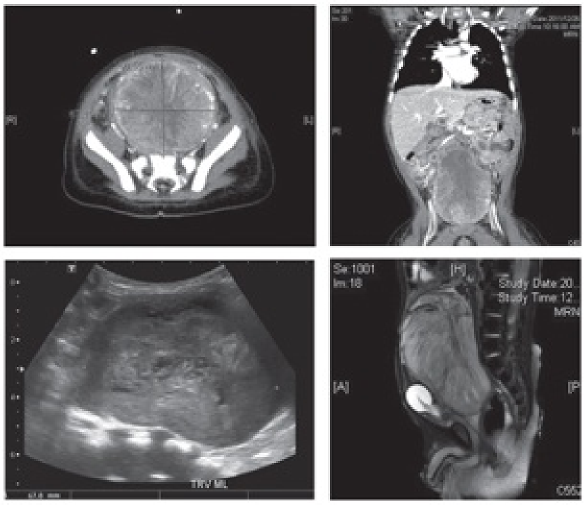

FIGURE 91.6 Radiographic images of an infant boy with pelvic RMS, axial CT (**top left**), coronal CT (**top right**), pelvic ultrasound (**bottom left**), and MRI (**bottom right**) demonstrating large pelvic mass.

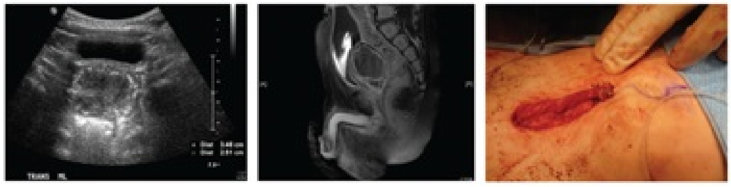

FIGURE 91.7 Postchemotherapy radiographic images of an infant boy with pelvic RMS, pelvic ultrasound (**left**) and sagittal MRI (**middle**) showing a residual pelvic mass, with the patient undergoing subsequent cystoprostatectomy and cutaneous ureterostomies (**right**).

Paratesticular Rhabdomyosarcoma

Treatment for paratesticular RMS includes radical inguinal orchiectomy. Frozen section of the proximal cord should be negative. A scrotal approach should be avoided because although chemotherapy often cures residual disease, some cases have required hemiscrotectomy due to tumor infiltration. An ipsilateral retroperitoneal lymph node dissection (RPLND) is recommended as part of routine staging before chemotherapy by the Children’s Oncology Group for all boys with stage I disease older than age 10 years, regardless of the findings on abdominal CT. The technique is identical to RPLND for retroperitoneal masses in patients with testis cancer. Usually, 60% of these tumors are localized and completely excised. Patients with positive lymph nodes are recommended to undergo intensified chemotherapy and pelvic and para-aortic retroperitoneal radiation with doses of 30 to 50 Gy (2,18). Chemotherapy has been shown to adequately clear microscopic disease (30% to 40% incidence). Survival rates have been estimated to be 90% with current multimodal therapy (2) (Fig. 91.8)

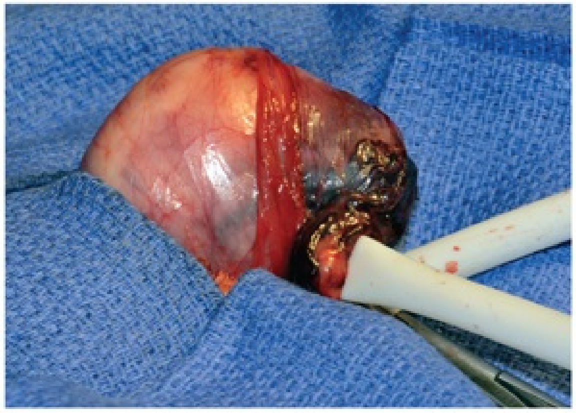

FIGURE 91.8 Paratesticular RMS, gross specimen. (Image courtesy of Dr. Kristina Suson, Children's Hospital of Michigan.)

Vaginal and Uterine Rhabdomyosarcoma

Primary chemotherapy followed by radiotherapy for relapse or nonresponders seems to be effective for these patients (20).

For surgical resection, the patient is placed in the lithotomy position, and the pelvis and vagina are prepared. For the initial resection, vaginoscopy is helpful in defining the limits of the tumor. Stay sutures and a small weighted vaginal speculum are helpful for exposure, as is a headlight for vision. Sharp excision of the tumor is carried out, staying away from the external sphincter, urethra, and bladder neck. The vaginal mucosa is closed with interrupted absorbable sutures. Hysterectomy is rarely carried out because uterine tumors are rare and tend to present in older girls (>10 years old) (Figs. 91.9 and 91.10).

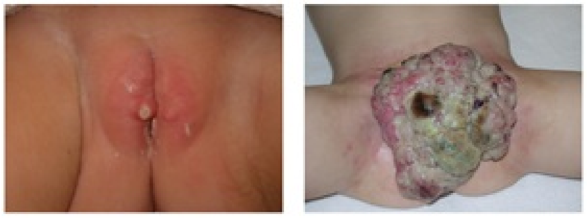

FIGURE 91.9 A 2-year-old girl with vulvar mass (left). Recurrence after wide excision despite multimodal therapy (right). Died of local disease without metastases.

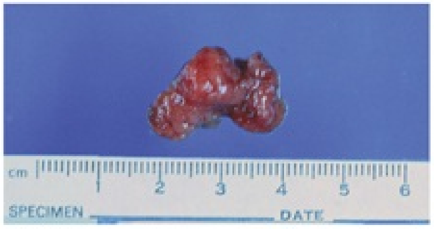

FIGURE 91.10 Gross specimen of a vaginal mass in a 4-year-old girl with painless bleeding found to be a vaginal papilloma.

Adolescent Rhabdomyosarcoma

When comparing adult and pediatric sarcomas, there are a number of differences regarding histopathology with adult tumors being leiomyosarcoma and lipomyosarcoma as compared to pediatric RMS. Adult sarcomas are typically managed upfront with radical surgery with a limited role of chemotherapy, whereas pediatric RMS is managed by a multimodal approach with an emphasis on chemoradiation to reduce the morbidity of radical surgery. RMS in children and adolescents is also more sensitive to chemoradiation therapy than the adult counterpart (21). Adolescent RMS is unique compared to “pediatric RMS” because males older than 10 years of age with paratesticular RMS should be managed with ipsilateral RPLND and those with metastatic disease are considered high-risk.

The second peak of the bimodal distribution for RMS includes the adolescent population, which comprises only 2% of new cancer diagnoses in this population (21). Paratesticular RMS is the most common genitourinary location and the third most common location for RMS in this population. Adolescent RMS is considered to be higher risk and portends a significantly worse outcome with higher recurrence and retreatment rates (21). This may be multifactorial including a greater percentage of more aggressive histologic type (alveolar RMS) as well as an increase in adverse events resulting in dose modification and resultant less efficacious therapy.

Unfortunately, with aggressive multimodal treatment, transient or permanent infertility is unavoidable. The discussion of potential alteration in fertility potential should be discussed before initiation of treatment to assess the role of preemptive fertility preservation. The mechanism for doing so involves direct preservation of germ cell lines via sperm banking or oocyte preservation. For this reason, it is prudent to include fertility specialists in the management team before initiation of cancer therapy. The gonadotoxic treatments that have the most significant effect on fertility include whole abdominal or pelvic radiation (>6 or 10 Gy, respectively, in female and >1.2 Gy to testes in males) and chemotherapeutic alkylating agents (21). Preventative options for females include oophoropexy (surgical relocation of ovaries to site outside of radiation field) and gonadotropin-releasing hormone agonists (protection from chemotherapy). Another option is embryo cryopreservation, but this may delay treatment. In males, preservation options include sperm banking with typical ejaculation, vibratory stimulation, electroejaculation, or surgical sperm collection before the start of therapy.

Pelvic radiation is part of the multimodal approach to childhood and adolescent RMS but has significant potential side effects associated with it including infertility secondary to direct gonadotoxic effects as well as uterine vascular insufficiency in girls, leading to adverse pregnancy outcomes. The radiation dose can be large ranging between 36 and 50 Gy, depending on the stage, grade, and degree of surgical control and can have a six- to eightfold risk of secondary malignancy (21). With patients treated with alkylating agents in addition to radiation, this risk is even greater with the most common secondary malignancy being skin cancer. Certainly, other potential secondary malignancies include bone, uterine, ovarian, and bladder cancer. This obviates the role of counseling patients in leading healthy lifestyles with avoidance of alcohol, smoking, and other drugs.

Chemotherapeutic agents also carry the potential for short- and long-term side effects depending on the agent used. Vincristine has been associated with peripheral neuropathy, with a higher incidence observed in adolescent patients and correlated with cumulative dosing (21). Platinum-based chemotherapy, including cisplatin is associated with nephrotoxicity, with both glomerular and tubular damage, and with a greater detrimental effect observed in the adolescent population (21). It is recommended to counsel these patients to avoid exacerbating factors such as nonsteroidal anti-inflammatory drugs, smoking, alcohol, or dehydration.

Emotional support is critical during this time period, particularly in the adolescents, an age group that is already transitioning into adulthood with all of the associated adjustments and challenges. Certain challenges must be addressed including self-image secondary to alopecia, changes in weight, mood, etc. Other issues include the psychosocial stress on interpersonal relationships and the psychological and socioeconomic implications on education, career plans, and employment. The tactic for the best outcomes involves adequate preparedness for the demands of treatment with adequate counseling via a multidisciplinary approach and providing good social support to increase compliance to treatment while simultaneously maintaining quality of life.

RISK STRATIFICATION

Intergroup Rhabdomyosarcoma Study Group Treatment Groups

Previous IRSG protocols employed a staging system (groups I to IV), reflective of disease extent and extent of initial surgical resection (3). The current protocols risk stratify the patients into low-, intermediate-, and high-risk groups. Risk stratification and outcome is a complex process that is dependent on multiple variables including extent of excision, the presence of metastatic disease, origin site, age, and the histologic and genetic characteristics.

The *low*-risk group includes patients with localized embryonal RMS at favorable sites (paratesticular and vaginal, including botryoid RMS) and completely resected or microscopic residual disease in patients with RMS at unfavorable sites. The patients may be upstaged to an intermediate-risk group if there is confirmation of alveolar or undifferentiated RMS. Therapy begins with chemotherapy (VAC) for four cycles and a subset of patients go onto four cycles of actinomycin D and vincristine, whereas the other subset is continued on actinomycin D and vincristine for an additional 13 weeks (3).

The *intermediate*-risk group includes patients with embryonal RMS at unfavorable sites (bladder/prostate) and those with gross residual disease, patients that are younger than 10 years of age, and patients with nonmetastatic alveolar RMS or undifferentiated RMS. Given the higher risk associated with this group, the potential for bladder-sparing procedures is diminished to 25% to 45% (3).

The *high*-risk group is composed primarily of patients with alveolar RMS and undifferentiated RMS as well as patients who are older than 10 years of age with metastatic embryonal RMS. The treatment algorithm for this group includes delayed surgical excision after stabilization of metastatic disease with systemic therapy at 3 to 6 months after initial diagnosis. Radical excision is only indicated if no residual metastatic disease is present. Chemotherapy in the high-risk group has not had an impact on prognosis, but agents such as ifosfamide and etoposide have been incorporated along with radiation therapy upfront to assess response in previously untreated patients (3) (Tables 91.3 and 91.4).

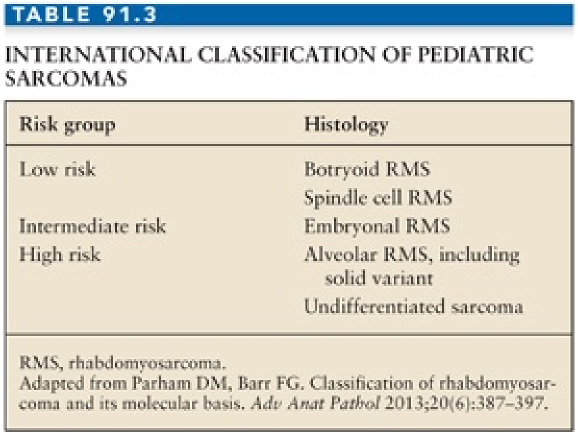

TABLE 91.3

INTERNATIONAL CLASSIFICATION OF PEDIATRIC SARCOMAS

Risk group	Histology
Low risk	Botryoid RMS
	Spindle cell RMS
Intermediate risk	Embryonal RMS
High risk	Alveolar RMS, including solid variant
	Undifferentiated sarcoma

RMS, rhabdomyosarcoma.

TABLE 91.4

RISK STRATIFICATION BASED ON SITE OF PRIMARY DISEASE

Risk group	Anatomical site
Low risk	Vaginal, paratesticular, and embryonal RMS with gross total resection, no metastases
Intermediate risk	Bladder/prostate RMS, nonmetastatic embryonal, alveolar or undifferentiated tumors with gross residual disease, metastatic embryonal tumors >10 years of age
High risk	Metastatic embryonal tumors >10 years of age, metastatic alveolar or undifferentiated tumors

RMS, rhabdomyosarcoma.

OUTCOMES

The long-term prognosis of RMS has improved in recent years through the implementation of multimodal therapy and the risk-based treatment protocols by the IRSG (1). The 5-year survival is now more than 70% up from 25% in the 1960s. Current long-term survival probabilities were found to be highest for younger children, patients with localized disease, and embryonal histology, whereas poor prognosis has been associated with diagnosis during infancy and adolescence, metastatic disease at time of presentation, and alveolar histology. For patients who survived 5 years or greater, the conditional 10-year survival rate is as high as 85% (22). Patients with advanced disease (group III/IV) and large primary tumor at diagnosis are at the highest risk of late events (disease recurrence, second malignant neoplasm, or death from other causes) after having being alive and event-free at 5 years (23).

Metastatic RMS is a unique subset of patients treated with multimodal therapy with the potential for high-dose end-intensification therapy with stem cell support at select centers. In a large retrospective review, the 3-year overall survival rate and failure-free survival rate were 35% and 29%, respectively. Patients who had embryonal histology, metastases confined to the lung, and age younger than 10 years fared better with a 3-year overall survival of 100% (24).

Due to the implementation of multimodal treatment, there are established side effects from each of the treatment modalities. Long-term nephrotoxicity from chemotherapeutic agents is difficult to assess, but at 10 years follow-up in patients who have undergone ifosfamide therapy, 89.5% have normal renal function and 78.5% have normal glomerular filtration rate. Other potential side effects include hypomagnesemia and hypophosphatemia, which are rare, along with glycosuria and proteinuria, which are relatively more common. Older age at diagnosis and length of treatment interval were correlated with abnormal glomerular filtration rate (25). Older age also correlated with increased peripheral nervous system toxicity, yet less hematologic toxicity (neutropenia, thrombocytopenia, anemia, and infection) and less 5-year event-free survival rate compared to younger patients receiving the same amount of chemotherapy (vincristine, actinomycin-D, and cyclophosphamide [VAC]; vincristine, actinomycin-D, and ifosfamide [VAI]; vincristine, ifosfamide, and etoposide [VIE]) (26).

Radiation therapy can have direct effects on the bladder, including inflammatory infiltrates causing cystitis, fibrosis, cellular atypical, hematuria, fistula formation, necrosis, and even bladder rupture. There have been reports of repeat spontaneous bladder rupture years after radiation therapy following therapy for RMS (27). Complications such as bladder rupture should prompt urologic assessment, including urodynamics after both bladder-sparing procedures and radiation treatment for

RMS. Preservation of erectile function in children and adolescents has been shown to be feasible despite multimodal treatment including radical surgery with urinary diversion, chemotherapy, and radiotherapy (28) (Fig. 91.11).

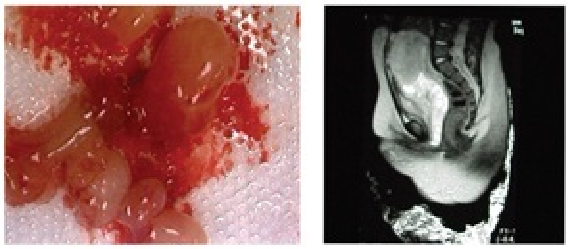

FIGURE 91.11 A 1-year-old girl with asymptomatic gross diaper spotting (**left**) with normal examination and MRI (**right**) revealing bladder lesions. Endoscopic biopsy revealed RMS, treated with chemotherapy but repeat examination under anesthesia showed persistent active disease. The patient ultimately had a subtotal vaginectomy with sigmoid neovagina and no radiation. She is alive and with no evidence of disease after 20 years.

Bladder and Prostate Rhabdomyosarcoma

The main advances in the management of bladder and prostate RMS include improvements in chemoradiation therapy and the resultant rise of bladder-sparing surgery with the goal of preserving function while maintaining cancer control. The third IRSG included intensified chemotherapy and 6 weeks of radiotherapy, increasing the functional bladder salvage rate from 25% to 60%. In the fourth IRSG, VAC was shown to be as effective as two other three-drug regimens (8). On a second-look procedure, half of patients were managed with biopsy, 30% had partial cystectomy, 13% had cystoprostatectomy, and the remainder underwent either cystectomy or prostatectomy alone (29). For persistent disease, the patients were irradiated. At 24 weeks, a third operative evaluation was performed with consideration for exenteration. The patients with embryonal pathology had an 83% 3-year failure-free survival, compared to 40% in those with alveolar pathology. All patients with metastatic (group 4) prostate disease died. Renal function, as assessed by serum blood urea nitrogen and creatinine, was normal in 95%, although 29% of patients had abnormal renal scans (30). Bladder function (as assessed by questionnaire) was normal in only 40% of patients (29).

With the increasing trend in bladder-sparing operations, the pertinent question is how functional are these bladders and does bladder preservation affect event-free and overall survival (3). The fourth IRSG group on bladder preservation demonstrated that under half of the patients had normal bladder function as determined by history, but over 70% of patients achieved event-free survival, with over 80% of patients achieving overall survival (29). The less aggressive multimodal approach of bladder-sparing operations in conjunction with chemoradiation therapy has shown promising results on posttreatment bladder function, with one study demonstrating that almost half of the patients were asymptomatic with normal urodynamics, whereas the remaining patients had either minor yet tolerable urologic complaints or complaints with urodynamic findings of reduced bladder capacity. Only one patient in this series required cystectomy with urinary diversion secondary to refractory urologic complaints (31).

In a larger international series, 48% of patients underwent biopsy alone, 30% had partial cystectomy, and 21% had complete cystectomy. Of the male patients, only 24% underwent prostatectomy. Bladder function was normal in 69% of patients treated with biopsy alone and 73% of patients who underwent partial cystectomy. Neither of these series utilized urodynamic studies to fully evaluate bladder function. Renal function was abnormal in 40% of patients, and bowel function was abnormal in 13% (32).

Certainly bladder-sparing procedures when appropriate can minimize alterations to lifestyle; however, many of these patients ultimately require cystectomy or more aggressive surgical treatment secondary to significant alterations in normal bladder function due to small-capacity, noncompliant bladders resulting in refractory urinary frequency or incontinence. Fortunately, there are many reconstructive options including bladder augmentation and continent urinary diversion given the fact that long-term survival from this condition is more commonplace (33). Orthotopic urinary diversion has been shown to be technically feasible with long-term outcomes that offer good quality of life with preserved daytime and nighttime continence and ability to void spontaneously (34). A limitation in urinary reconstruction using bowel segments is prior exposure to radiation therapy, which may limit the viability of this tissue for use in urinary reconstruction (33).

Bladder and prostate RMS managed with neoadjuvant chemotherapy, an organ-sparing approach initially, radical approach for positive margin status, and radiotherapy for residual disease after radical approach still has a very high potential for cure with preservation of continence and erectile and renal function (35). Urinary tract reconstruction may be safely performed initially with radiation limited to patients with residual and metastatic disease to reduce radiation-induced morbidity (35) (Fig. 91.12).

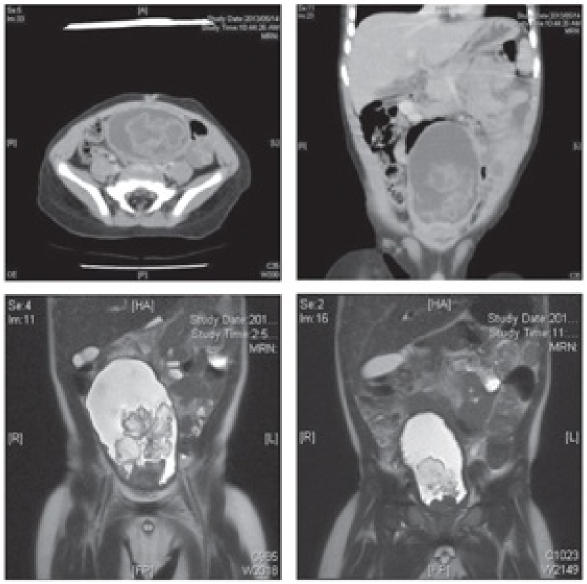

FIGURE 91.12 Prostate and bladder RMS shown with axial CT (top left), coronal CT (top right), and coronal MRI (bottom left) demonstrating bladder mass and post-chemotherapy imaging with coronal MRI (bottom right) demonstrating mass shrinkage.

Paratesticular Rhabdomyosarcoma

A significant factor that influences prognosis in paratesticular RMS is age. The biologic activity of the tumor is different between the neonate and the teenager (90% versus 63% failure-free survival at 3 years). In previous studies, all patients underwent RPLND (8). However, Olive et al. (36) showed in 1984 that of 19 patients with clinical stage I disease, 17 were cured with adjuvant chemotherapy alone. This showed that chemotherapy could eradicate microscopic retroperitoneal disease, making RPLND unnecessary. In the fourth IRSG, RPLND was not recommended, leading to a significant understaging of disease and a decrease in failure-free survival rates, primarily in patients >10 years old because patients with negative CT scans did not receive radiation. Thirty percent of those patients who were clinically stage I and over 10 years of age required retreatment. In contrast, because the outcome for stage I disease in those under 10 years of age was so good in IRSG IV, those patients who are <10 years old and have stage I disease and negative abdominopelvic CT are treated with VA (vincristine/dactinomycin) only in IRSG V, whereas all patients with stage I disease who are 10 years or older undergo RPLND regardless of CT findings. Group 2 tumors (positive lymph nodes on pathology) are treated with radiotherapy and VAC. The 3-year failure-free survival rate was 81% for group 1 tumors overall, but those patients >10 years old had only a 63% survival rate.

Vaginal and Uterine Rhabdomyosarcoma

Surgery and chemotherapy cure most cases of vaginal RMS. In the overall IRSG I to IV experience, 42% of patients were treated with surgery and chemotherapy, 19% required additional radiotherapy, 21% were treated with biopsy and chemotherapy alone, and 12% were managed with biopsy, chemotherapy, and radiotherapy (37). In IRSG IV, only 19% of patients required wide excision of the tumor. Primary treatment with VAC chemotherapy is usually successful, and a biopsy 8 to 12 weeks after chemotherapy is recommended. Pelvic lymph node dissection is not necessary. Radiotherapy should be used only for persistent disease or relapse (38). Rhabdomyoblasts on biopsy are evidence of chemotherapy response, and therefore further chemotherapy, instead of resection, is the proper treatment (39).

The majority of girls diagnosed with genital tract RMS have localized disease with embryonal RMS located in the vagina in the girls younger than 9 years of age, closely followed by the uterus/cervix in the girls older than 9 years of age. Superior survival is seen in those with embryonal histology and early stage presentation (40).

Dilemma of Mature Rhabdomyoblasts

The increasing trend of organ-sparing surgery has resulted in functional preservation while concurrently warranting close surveillance, sampling of the residual tissue, and further resection of involved sites, if needed. The assessment of the sampled specimens can reveal dramatic changes in the histopathologic appearance with the potential for maturation of the tumor cells, forming “mature” rhabdomyoblasts. This finding presents a diagnostic and prognostic conundrum (39). The mature rhabdomyoblasts are terminally differentiated muscle cells and have been shown to indicate apparent cure or a better prognosis, thereby not necessitating further treatment, including radical surgery. Mature rhabdomyoblasts have been shown not be malignant but rather a sign of response to treatment demonstrating that the malignant cells have disappeared (41). Histologically, these mature cells exhibit a large, smooth nucleus, no significant pleomorphism, no mitotic activity, and the absence of cell clusters suggestive of growth from a common precursor (3). Despite the evidence that supports the benign nature of these cells, it is prudent to continue close surveillance of these patients with follow-up imaging and endoscopy.

CONCLUSIONS

The management of childhood RMS remains one of the most controversial topics in pediatric urologic oncology. An improved understanding of the biologic disease process of RMS has allowed for the development of multimodal therapy, thereby minimizing the adverse effects of overly aggressive surgical resection and chemoradiation treatment, allowing for optimal cancer control with minimization of organ dysfunction. Although all agree that a combination of surgery, chemotherapy, and radiotherapy is best, the optimal timing and extent of the three treatment modalities remain unclear. The future of childhood RMS treatment involves a balance between maximizing oncologic control, life expectancy, and quality of life via a multimodal approach while minimizing morbidity via tissue-sparing and minimally invasive procedures. CHAPTER 92 VESICOURETERAL REFLUX

MARK R. ZAONTZ AND CHRISTOPHER J. LONG

Until the 1980s, the treatment for reflux was dominated by ureteral reimplantation, with cure rates approaching 98%. However, multicenter studies have since shown that not all reflux is created equally. Lower grades (I to II) of reflux have high spontaneous resolution rates, and these patients could be followed at least initially with observation or medical management with continuous low-dose prophylactic antibiotics and yearly reassessment. Higher grades of reflux (III to V) are associated with a higher incidence of renal scarring and lower rates of spontaneous resolution and warrant closer follow-up. These findings have led to a field change in management of vesicoureteral reflux (VUR).

Surgical correction of reflux has been shown to decrease the incidence of urinary tract infection (UTI) but may not prevent progression of reflux nephropathy when present. Reflux in the presence of sterile urine in general does not cause renal damage, although reflux in the presence of UTI and/or lower urinary tract obstruction can lead to renal scarring.

Boys, in general, present with higher reflux grades than girls of the same age and are more likely to develop a UTI, but boys also have a higher spontaneous resolution rate compared to girls. Studies showing that circumcised boys with low grades of reflux rarely get UTIs have led to a nonoperative algorithm in this group of patients. Circumcision can be offered to boys with reflux as a protective measure.

Reflux is commonly linked with voiding dysfunction in children. Screening assessment for any signs of abnormal voiding patterns (wetness, urgency, constipation, penile pain, dysuria, holding maneuvers) should be performed in all potty-trained children diagnosed with reflux. Recent evidence has shown high spontaneous cure rates for refluxing children when bladder bowel dysfunction is treated with urodynamics and biofeedback techniques. Conversely, children with significant voiding dysfunction have higher failure rates than those with normal bladder function, particularly when endoscopic bulking agents are used (1). While most cases of reflux are congenital in nature and considered primary reflux, increased intravesical pressure due to anatomic bladder outlet obstruction (posterior urethral valves) or functional causes such as neuropathic bladder/voiding dysfunction can lead to what is termed *secondary reflux*. Patients suspected of having secondary causes of VUR need further assessment prior to intervention.

Sampson (2) in the early 1900s proposed a flap-valve mechanism for the ureterovesical junction that was corroborated by Gruber (3), who found that those ureters with shorter intravesical segments were more prone to have reflux and therefore have a defective flap-valve mechanism. Stephens and Lenaghan (4) added that the deficiency of the intravesical ureter's longitudinal muscle with or without a deficiency in ureteral tunnel length was also responsible for the reflux phenomenon. From a surgical perspective, we have learned that a 5:1 ratio of ureteral tunnel length to ureteral lumen diameter is necessary to prevent reflux. Care must be taken to mobilize the ureter such that the repair is not under tension, a straight trajectory through the bladder wall is maintained, that the ureter is sufficiently spatulated to prevent meatal stenosis, and that the blood supply is preserved throughout the dissection. Certainly meticulous technique is required to minimize trauma to the tissue. These guiding principles are fundamental to successful surgical correction of VUR.

DIAGNOSIS

Today, thanks in great part to widespread use of antenatal screening, reflux is often diagnosed prior to the development of a urinary infection. As a result, pyelonephritis and subsequent renal scarring may be avoided by promptly beginning antibiotic prophylaxis after delivery. Prenatal ultrasound (US) findings suspicious for VUR include bilateral hydronephrosis, bladder thickening, and/or ureterectasis, all of which should prompt postnatal voiding cystourethrogram (VCUG) study to rule out reflux. The remainder of patients will be discovered after workup for UTI. Presenting symptoms in neonates can be nebulous and may include malaise, fever, vomiting, diarrhea, or failure to thrive. Toddlers and young children may have more typical symptoms, such as fever, frequency, urgency, dysuria, foul-smelling urine, incontinence, or abdominal and/or back discomfort. Once reflux is diagnosed, it is graded according to the International Study Classification (Fig. 92.1) (5). This system is based on the radiographic appearance of the ureter and collecting system during a VCUG. Follow-up studies to assess for resolution or progression are in general done using either VCUG or nuclear cystography at yearly intervals for low-grade reflux or longer intervals for higher grade reflux.

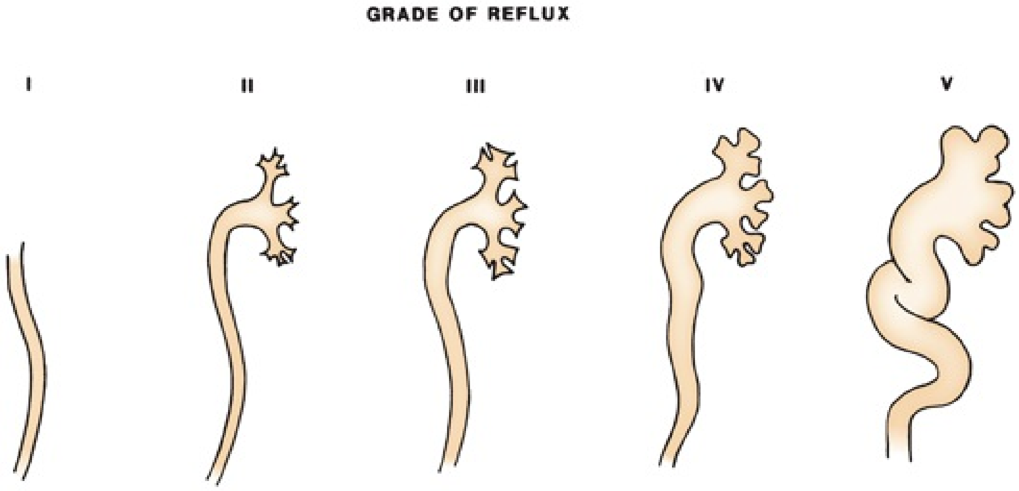

FIGURE 92.1 International classification of VUR. Grade I, into the nondilated ureter; grade II, into the pelvis and calices without dilation; grade III, mild to moderate dilation of the ureter, renal pelvis, and calices with minimal blunting of the fornices; grade IV, moderate ureteral tortuosity and dilation of the pelvis and calices; and grade V, gross dilation of the ureter, pelvis, and calices and loss of papillary impressions and ureteral tortuosity.

In 2011, the American Academy of Pediatrics (AAP) updated its guidelines for UTI workup in children ages 2 to 24 months (6). These guidelines do not apply to newborns and children outside these age ranges. It is critical that a urine culture and urinalysis be obtained in all cases of suspected UTI or workup for fever of unknown origin. A urinalysis alone is unacceptable as it only alludes to the presence of UTI and at best is only 80% accurate in diagnosis. On urinalysis, pyuria suggests an acute infection (along with positive leukocyte esterase and nitrite), whereas a positive culture is now defined as >50,000 colony-forming units per mL. According to the AAP guidelines, US of the kidneys and bladder is indicated after the first UTI. VCUG is obtained for bilateral hydronephrosis, bladder thickening, renal scarring, or evidence of obstruction. Otherwise, it is reserved for patients that develop a second febrile UTI. VCUG study at initial UTI remains a controversial topic as the American Urological Association clinical guidelines leave this as an alternative for the clinician.

A major contention with the AAP guidelines is reserving VCUG study until there is either an abnormal US or the development of a second UTI. The sensitivity of US for detecting renal scarring in the literature ranges from 22% to 65%, which certainly questions US as the screening tool of choice (7). Although this approach decreases the number of children undergoing invasive testing, it potentially delays intervention and definitive therapy in those who would benefit from it (8). AAP guidelines currently do not include recommendations for ^{99m}Tc-labeled dimercaptosuccinic acid (DMSA) scan even though it remains the best available study to assess focal pyelonephritis and renal scarring.

The “top-down approach” is an alternative to the given algorithm and limits VCUG study to patients with evidence of renal damage (pyelonephritis, renal dysplasia, renal scarring). Patient evaluation after first febrile UTI consists of US and a DMSA scan to determine if the kidney has been engaged in the infection. If the scan is negative, then a VCUG can be obviated. Proponents for this approach cite a 50% decrease in invasive testing for what will likely be clinically insignificant reflux. Although this is an attractive option, a second febrile UTI would still warrant evaluation with a VCUG.

Cystoscopy has little value in predicting the presence or cessation of reflux based on ureteral orifice configuration or location. Factors such as tunnel length or the presence of incomplete versus complete duplication anomalies will guide the surgeon to choose an appropriate technique, open or endoscopic. PIC cystogram (positioning the instilled contrast at the ureteral orifice) is rarely indicated but may be useful in patients with recurrent febrile UTI in the absence of VUR on VCUG (9).

Screening for reflux in asymptomatic siblings should be limited to renal bladder US, reserving VCUG for children with an abnormal US (10). The majority of asymptomatic reflux discovered in siblings spontaneously resolves.

INDICATIONS FOR SURGERY

Indications for surgical correction of VUR include the following:

- Older patient with clinically significant reflux
- Breakthrough UTI
- Persistent high grade of reflux (III to V)
- Presence of renal scarring or decreased function
- Noncompliance with prophylaxis
- Family concerns for repeated invasive testing and long-term prophylaxis

Findings from the International Reflux Study in Children lend support toward surgical intervention in grade III and IV reflux, with the majority of these patients failing to resolve their reflux (11). Other studies have supported these findings, with rates of resolution of reflux ranging from 10% to 33% in patients with grade IV reflux (12,13). Surgery is in general recommended for grade V reflux because of the low likelihood of spontaneous resolution. Recurrent breakthrough urinary infection while on adequate antibiotic prophylaxis is the sine qua non for surgical intervention because otherwise these children are at high risk for recurrent pyelonephritis and renal damage.

ALTERNATIVE THERAPY

There are several factors that must be taken into consideration for appropriate management of VUR and should be individualized to the patient: reflux grade, degree of renal scarring, volume at onset of reflux, patient age, presence or absence of bladder outlet obstruction, compliance of the patient/family on prophylactic antibiotics, ability to remain infection-free while on prophylaxis, and presence/absence of associated bladder and bowel dysfunction. Reflux may spontaneously resolve, the majority of which occurs by 5 to 7 years of age. There is an inverse relationship between reflux grade and likelihood of spontaneous resolution; the lower the grade of reflux and younger age of diagnosis, the higher the likelihood for spontaneous resolution. Boys are more likely to resolve than girls, and unilateral reflux is statistically more likely to resolve than bilateral reflux. Medical management consists of daily low-dose antibiotic prophylaxis, usually a sulfa-based compound or nitrofurantoin at bedtime. In addition to antibiotics, bladder training with biofeedback in cases of dysfunctional voiding is instituted. This is designed to improve bladder emptying at regular intervals, obviate bladder-sphincter dyssynergia, and maintain a minimal postvoid residual. This may require a variety of teaching aids and the use of pharmacotherapy such as anticholinergics and/or alpha antagonists. Equally important is to improve bowel function in the presence of constipation.

SURGICAL TECHNIQUE

Once the decision is made for surgical intervention, there are a myriad of operative procedures available depending on one’s preference and comfort level. The existing techniques are divided into endoscopic injection: the open approach via extravesical, intravesical, or a combination of the two; and the minimally invasive correction.

Endoscopic Surgery

Teflon was the first bulking agent used for endoscopic correction of reflux. Although the results were encouraging, later studies showed that there was migration of the Teflon particles to the lung, lymph nodes, and brain as well as the finding of granuloma formation; this resulted in the search for more biocompatible bulking agents (14). These have included both autologous agents (fat, blood, human collagen, bladder muscle cells, and ChondroGEL) and nonautologous agents (silicone, BioGlass, polyvinyl alcohol, and dextranomer microspheres). Deflux (dextranomer microspheres) has emerged as the agent of choice for bulking agents and at present is the sole agent approved by the U.S. Food and Drug Administration. Endoscopic surgery technique for reflux will be discussed in another chapter.

Extravesical Approach

Lich (15) and Gregoir (16) in the 1960s separately developed the extravesical approach to correct reflux. Further modifications of this approach have yielded success equal to that of the intravesical techniques (17). The benefits of this procedure are several: (a) The surgery is performed entirely outside of the bladder mucosa and as such avoids gross hematuria and irritable postoperative voiding problems such as urgency and bladder spasms, (b) catheter drainage of the bladder is brief, (c) wound drains are avoided, and (d) ureteral stents are eliminated. A further advantage of this technique is that hospital stay is brief, averaging 1.5 days in our hands, thus decreasing overall hospital costs.

The patient is placed in the supine position, and the bladder is catheterized on the field and filled to about one-third to one-half of its estimated capacity with sterile saline. This facilitates dissection of the detrusor muscle from the mucosa. The bladder may be further filled or emptied throughout the procedure. The surgical procedure begins similarly to the intravesical approach with a Pfannenstiel incision. A Dennis–Browne retractor is then placed over moistened gauze pads, and the bladder is carefully mobilized and rotated anteromedially, exposing the perivesical space. Care should be taken to avoid entering the peritoneum during this maneuver. Placing an appropriate-sized Deaver retractor to help keep the rotated bladder in place will greatly facilitate locating the obliterated hypogastric vessel. This vessel is tied off with 3-0 polyglycolic acid suture, and the most lateral tie is tagged to help expose the ureter, which lies just beneath this vessel. In cases of bilateral detrusorrhaphy, the obliterated hypogastric vessel need not be tied off but simply recognized for ease of finding the underlying ureter. The detrusor innervation courses posteromedial to the ureter and care must be taken to limit dissection in this part of the bladder. This minimal dissection technique as described, as well as limiting the dissection of the extravesical submucosal tunnel, may help prevent significant denervation and avoid postoperative urinary retention. The ureter is carefully mobilized and encircled with a vessel loop (Fig. 92.2). The ureter is freed up to its entry point into the bladder. During this maneuver, the Deaver retractors may need to be reset to keep the ureter in the middle of the operative field. A tennis racket incision is made around the ureteral detrusor hiatus and deepened until the ureter is only attached to the mucosa. The detrusorotomy is then extended to create a 3- to 5-cm trough. It is helpful to place stay sutures of 3-0 polyglycolic acid on the detrusor edges to facilitate dissection of the detrusor muscle off the mucosa. All vessels encountered during this dissection are tied off with 4-0 or 3-0 polyglycolic acid suture, and great care is exercised to avoid making a rent in the bladder (Fig. 92.3). If this occurs, immediately close the defect with the 6-0 chromic catgut. The dissection should be generous enough to lay the ureter in the newly created trough and permit the detrusor muscle to be closed over the ureter without too much tension. To complete the detrusorotomy, dissection is extended toward the bladder neck beyond the distalmost detrusor incision to allow placement of the advancement sutures. The first limb of the two sutures is through the detrusor (outside-in), entering at the distal limit of the trigonal musculature and exiting in the plane between the mucosa and detrusor. The second limb of the suture is placed through the ureteral muscle, and the final limb of the suture is back through the detrusor (inside-out). Tying the pair of "vest- type" sutures advances the ureter on the trigone, creating a longer submucosal tunnel, and anchors the ureteral orifice distally, preventing proximal migration of the ureter (Fig. 92.4). The remaining detrusor defect is closed over the ureter in two layers; the first is a running layer and the second is an interrupted Lembert suture, both using 4-0 polyglycolic acid suture. Care must be exercised to avoid making the ureteral hiatus too snug. The exit point for the ureter should be able to admit a hemostat between the detrusor and the ureter easily (Fig. 92.5). No perivesical drains or ureteral stents are used, and the Foley catheter is removed the following morning.

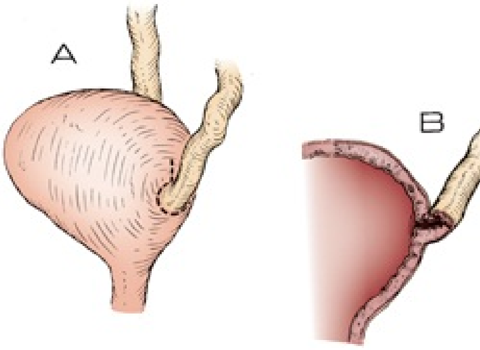

FIGURE 92.2 **A:** After ureteral mobilization, detrusor is incised (*broken lines*) at level of ureteral hiatus. **B:** Sagittal section demonstrates ureteral hiatus.

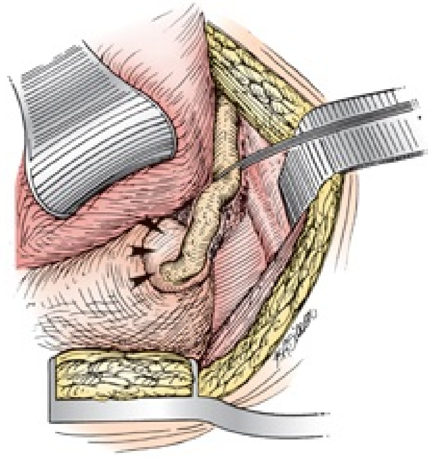

FIGURE 92.3 Ureter contiguous with detrusor mucosa (*arrowheads*).

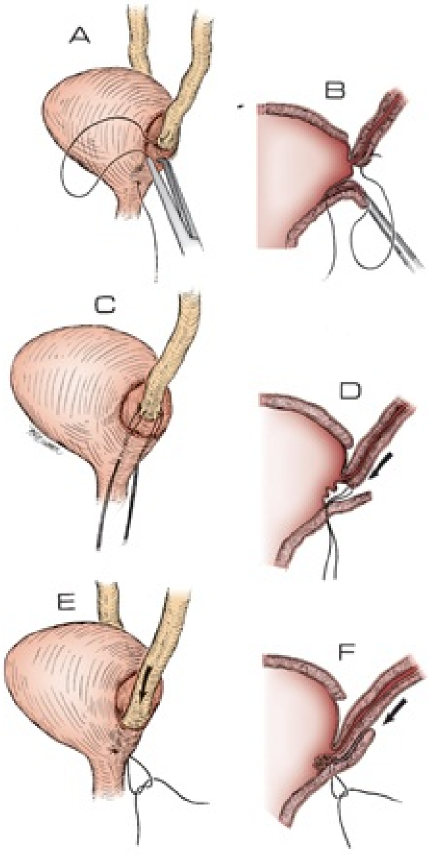

FIGURE 92.4 **A:** Bladder mucosa is elevated off bladder wall muscle and vest-type sutures are placed. **B:** Sagittal section shows suture passing between undermined mucosa and detrusor. **C:** Alignment of vest sutures after placement. **D:** Sagittal section demonstrates appropriate positioning of sutures. **E:** Tying vest sutures advances and anchors ureter onto trigone. **F:** Sagittal section of ureteromeatal advancement (arrow reflects advancement of distal ureter within the detrusor tunnel).

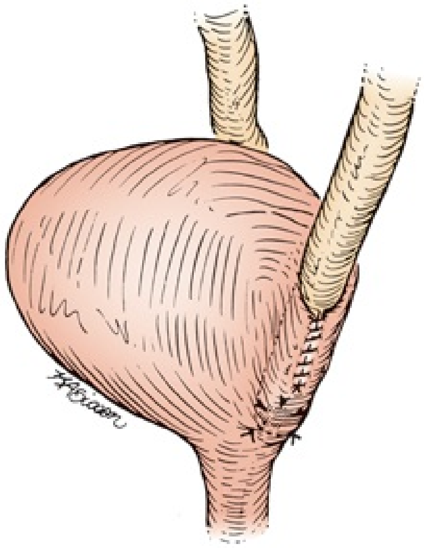

FIGURE 92.5 Closure of detrusor flaps over ureter allows for long submucosal tunnel and completes detrusorrhaphy.

Complete and incomplete ureteral duplication may also be approached extravesically. In this case, cystoscopy at the time of surgery is recommended to visualize the ureteral orifice location with respect to location and proximity to each other as well as distance to the bladder neck. A ureteral orifice that inserts too closely to the bladder neck will impede the surgeon’s ability to perform an advancement, in which case another technique is more appropriate.

Finally, as we continue to push the envelope with minimally invasive procedures, the extravesical technique can be approached in select patients via a small transverse inguinal incision to achieve access to the ureter. In these cases, it is advantageous to perform a cystoscopy to pass a temporary ureteral stent up the refluxing ureter to aid in initial identification. The procedure is otherwise essentially the same as already described, although some institutions are obviating the advancement portion of the procedure.

Intravesical Approach

One of the earlier and still highly popular and successful techniques to correct reflux is the Politano–Leadbetter approach (18). This procedure is performed entirely intravesically and avoids mobilization of the bladder as seen in the extravesical approach. Once the bladder is exposed via the technique previously described for the extravesical approach, it is opened in the midline between 3-0 chromic catgut stay sutures. The bladder is packed with moist 4 inches × 8 inches gauze pads to allow cephalad retraction of the bladder, which exposes the ureteral orifices. This is further facilitated with the placement of a Dennis–Browne retractor with the curved blades within the bladder over moist sponges. The ureteral orifice is identified and intubated with a 5Fr feeding tube and secured with 4-0 or 5-0 silk sutures to allow tenting of the ureter when gently pulling on the feeding tube. As with all intravesical repairs, the ureter is mobilized in similar fashion (Fig. 92.6). An incision is made to score the mucosa around the orifice. This can be done with a scalpel, tenotomy scissor, or, as we prefer, the cutting current of the Bovie with a Colorado tip, which provides a precise dissection. Carefully, using long tenotomy scissors, vascular forceps, Kittner dissector, a right-angle clamp, and judicious use of the cautery unit, the muscular attachments to the ureter are taken down through the wall of the bladder. As the dissection proceeds proximally, we have employed the use of a no. 3 Freer elevator along the posterior surface of the ureter, which further aids in mobilization. It is critically important to stay outside of the adventitia of the ureter to avoid devascularization during this dissection. The peritoneum is encountered and gently swept back off the ureter to avoid injuring the bowel during the relocation of the ureter. A hernia retractor or a very thin Deaver helps to better expose the peritoneum and extravesical attachments to the ureter. In the male patient, care must be taken to avoid injury to the vas deferens.

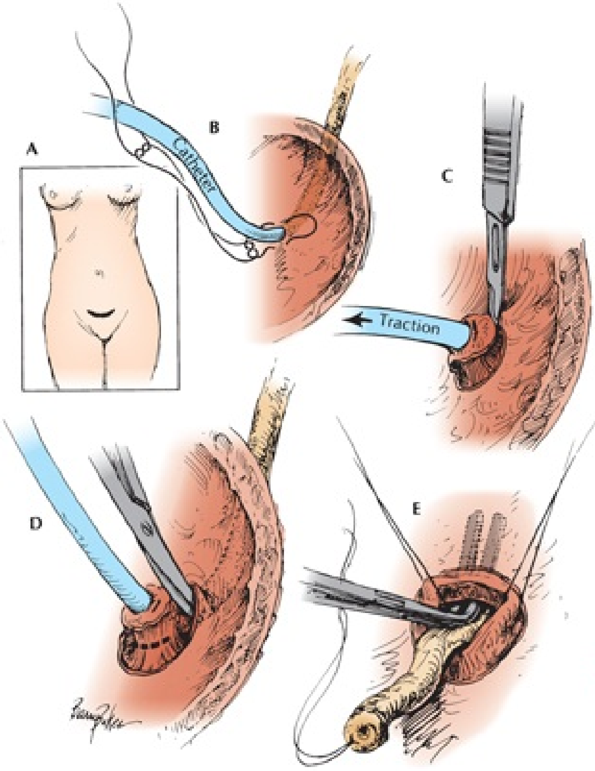

FIGURE 92.6 Intravesical mobilization of ureter. A: Low transverse incision. B: A 3.5Fr or 5.0Fr polyethylene tube and traction suture. C: Incision around meatus with mucosal cuff using long-handled knife. D: Cutting and blunt dissection of muscle of superficial trigone. E: Extravesical mobilization with right-angle clamp and Kittner dissector.

After completion of ureteral mobilization, the surgeon may choose one of several procedures to complete the ureteral reimplantation. The Politano–Leadbetter repair employs a suprahiatal approach (Figs. 92.7 and 92.8). A submucosal tunnel is created from the old hiatus superiorly, long enough to achieve a 5:1 ratio of submucosal tunnel to ureteral diameter. We like to use 135-degree blunt-tipped Metzenbaum scissors to facilitate this maneuver and avoid tearing the bladder mucosa. Once the desired tunnel length is achieved, the new hiatus is developed by making a small incision directly on top of a right-angle clamp. Using a stay suture or the feeding tube, the mobilized ureter is passed from the old hiatus to the new hiatus, care being taken to avoid twisting, kinking, or angulating the ureter as well as avoiding the peritoneum. The mucosa of the old hiatus is repaired with 4-0 chromic catgut. The new meatus is trimmed and spatulated if necessary. The first stitch is critical, anchoring the distal and posterior lip of the ureter with a deep suture of 4-0 or 5-0 chromic catgut to the mucosa and muscular layers of the bladder. The remaining anastomosis is performed with the same suture for a mucosal-to-mucosal approximation, resulting in an everted, patent meatus. Leaving a ureteral stent is at the surgeon's discretion. In general, this is based on the urine output from the reimplanted ureteral orifice; if there is copious drainage, then do not leave a stent, but in the setting of decreased drainage or significant edema at the orifice, a stent is left through a separate stab wound to bring it through the skin. A stent may also be placed if ureteral tapering is required at the time of the reimplant. Cystorrhaphy is done in three layers using running 4-0 chromic catgut for the mucosa, muscularis, and seromuscular layers. This has allowed us to avoid leaving any perivesical drains when the ureters are not stented. A Foley catheter remains in the bladder for 1 or 2 postoperative days.

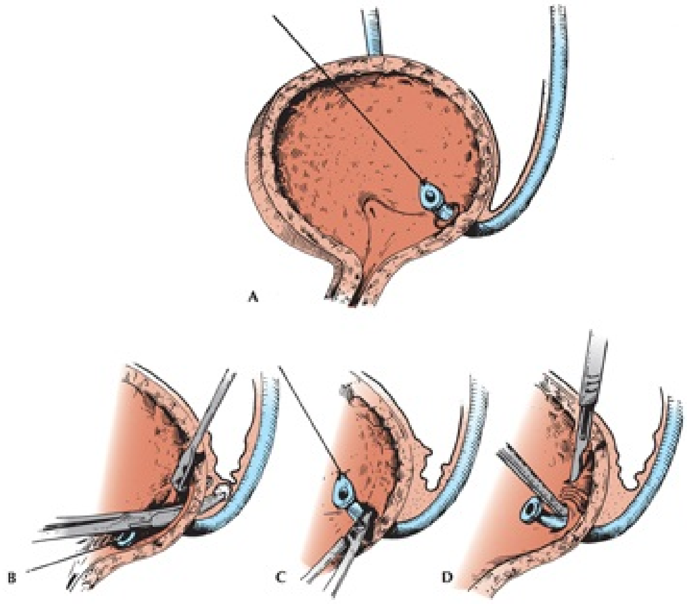

FIGURE 92.7 Politano–Leadbetter repair. A: Mobilization of intravesical ureter. B: Dissection of peritoneum with Kittner dissector. C: Development of submucosal tunnel. D: Creation of the new hiatus.

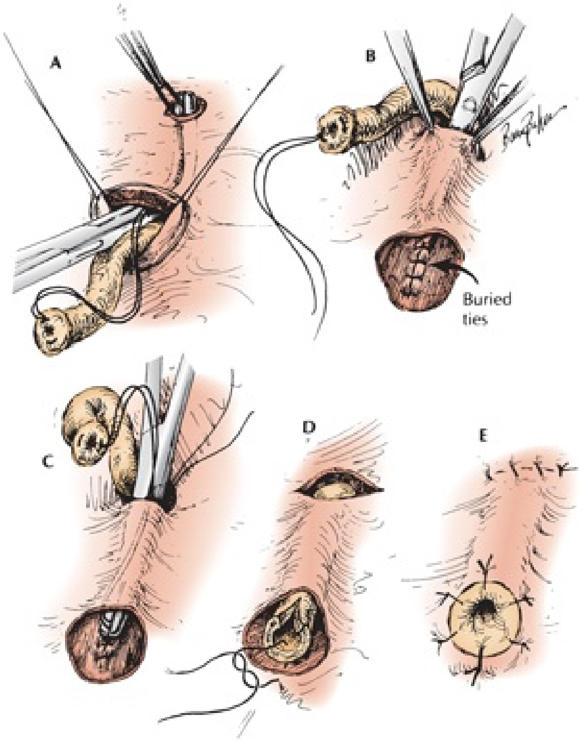

FIGURE 92.8 Politano–Leadbetter repair and details of ureteral reimplant. A: The ureter is brought through the new hiatus, and the old hiatus is closed with interrupted absorbable suture. B: The ureter is brought through the new tunnel (C), spatulated if necessary (D), and sewn in place with interrupted absorbable suture (E).

The Glenn–Anderson procedure (Fig. 92.9) (19), in comparison to the Politano–Leadbetter, is an infrahiatal repair that incorporates a submucosal tunnel advancement toward the bladder neck (Fig. 92.10). It is particularly advantageous when there is sufficient distance between the native ureteral orifice and the bladder neck that an appropriate tunnel length can be obtained. Adequate mobilization of the ureter is paramount to achieve satisfactory success rates. If the tunnel length appears too short on initial inspection, moving the hiatus more superiorly will allow for satisfactory tunnel creation. Advantages of the Glenn–Anderson technique are that the entire procedure is done under direct vision and it creates a relatively straight tunnel with an easily catheterized ureter (as opposed to the course of the Cohen or Politano–Leadbetter reimplant).

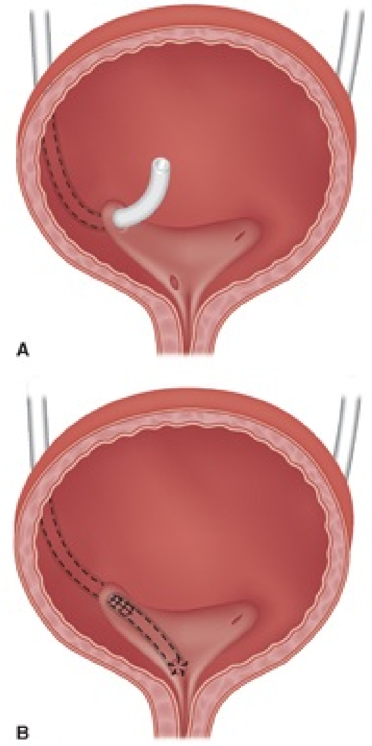

FIGURE 92.9 Glenn-Anderson Repair. Ureter is mobilized from the original meatus through the wall of the bladder (A). Tunnel is advanced caudad in the trajectory of the ureter towards the bladder neck (B). Neo-orifice is sewn in place with interrupted sutures.

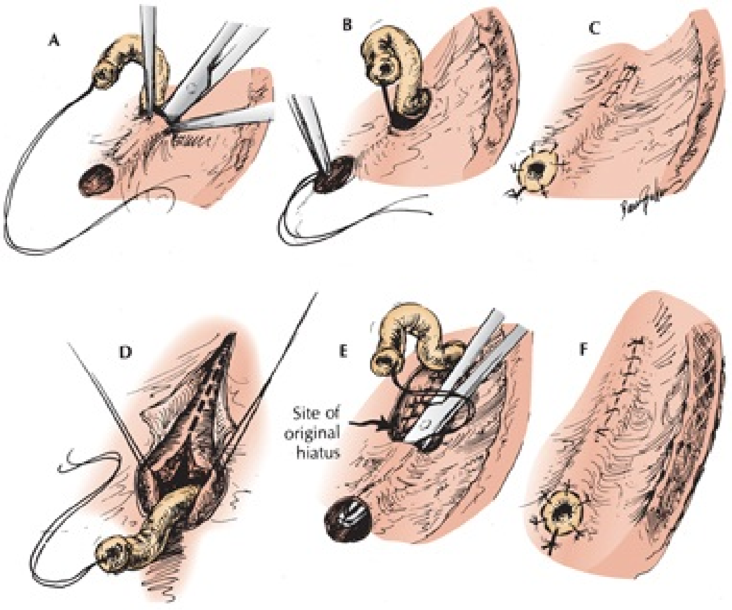

FIGURE 92.10 Glenn–Anderson repair: details of ureteral reimplantation. A: Tunnel made toward bladder neck. The ureter is brought through the tunnel (B) and sewn in place (C). An alternative, similar to the Mathison technique, allows enlargement of hiatus (D) and results in longer repair (E and F).

The cross-trigonal approach (20) is similar to the Glenn–Anderson procedure with the exception that the ureter is transposed across the trigone (Fig. 92.11). This is particularly useful in small-capacity and neurogenic bladders where an appropriately long tunnel is critical to success. The ureteral tunnel created is an extension of the natural course of the ureter; thus, it carries a low risk of ureteral kinking and obstruction. If bilateral reimplant is necessary, it is important to create separate tunnel paths for each ureter. Always remember to close the hiatus with absorbable 4-0 chromic catgut. Leave enough room for a hemostat or right-angle clamp to be interposed between the ureter and the approximated detrusor muscle to avoid obstruction at the hiatus. A potential disadvantage of the Cohen technique is the difficulty of ureteral access postoperatively. These patients may need percutaneous access for any future procedures.

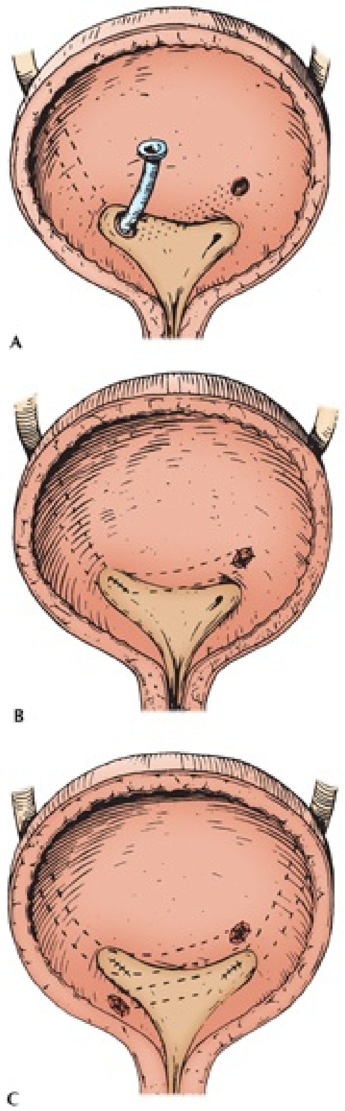

FIGURE 92.11 Cohen technique of ureteral reimplantation. Cross-trigonal tunnel, with the stippled area (A) sewn in place with interrupted sutures (B). C: Bilateral reimplants easily accomplished.

Ureteral Duplication

Determining whether the ureteral duplication is complete or incomplete guides operative considerations. In the absence of a ureterocele, a complete duplication can be approached extravesically or intravesically. The key to intravesical surgery is to mobilize the duplicated ureters as one unit because their blood supply at the bladder level is intertwined within a common sheath (Fig. 92.12). This will avoid devascularization and stricture of the ureter. The technique chosen for reimplant can be achieved with any of the intravesical repairs mentioned. In cases of a complete duplication, an ipsilateral ureteroureterostomy of the refluxing to the nonrefluxing ureter is an attractive alternative. In situations where there is an associated ectopic ureter with a salvageable renal moiety, separate ureteral tunnels should be created or ipsilateral ureteroureterostomy should be performed.

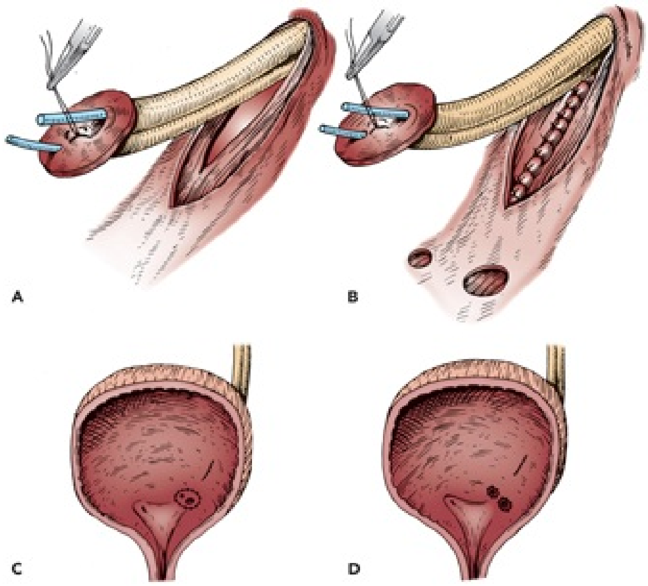

FIGURE 92.12 Reimplantation of both duplex ureters. Reimplantation can be performed with any of the previously described repairs. Care must be taken to mobilize the ureters as a single unit to preserve blood supply (A). Detrusor tunnel should be closed (B) and neoorifice can be performed en-bloc (C) or separately (D), the later of which is particularly suited for an ectopic ureter.

One tip that is useful to aid in freeing up the ureter and also with submucosal dissection for all of the intravesical techniques is the use of 1% lidocaine (Xylocaine) with a 1:100,000 epinephrine solution. This is injected periureterally at the orifice and along the proposed subepithelial tunnel using a 26-gauge needle. This minimizes bleeding and facilitates ureteral dissection in a readily defined plane.

Intra–extravesical Approach

The Paquin technique (Fig. 92.13) (21) is a commonly used repair and has the advantage over the Politano–Leadbetter approach of doing the entire procedure under direct vision, thus avoiding the potential risk of peritoneal injury. The initial approach to the ureter is extravesical, similar to that previously described. When the ureter is mobilized to the level of the detrusor hiatus, a right-angle clamp is placed on the distal ureter, and the distal stump is oversewn after the ureter has been divided using polyglycolic acid suture. Alternatively, the bladder may be opened in the midline and the ureteral orifice circumscribed and mobilized from within the bladder. The ureter should be intubated with a 5Fr or 8Fr feeding tube and secured with a suture prior to mobilization, as described earlier. The ureter is then passed extravesically, taking care to avoid the peritoneum, which should be swept off the posterior lateral bladder wall. If ureteral tailoring is warranted, it is performed at this point. If a longer tunnel is needed and ureteral length is suspect, consider a psoas hitch at this time as well (Fig. 92.14). Place two fingers inside the bladder, bringing it up to the psoas muscle tendon, where it should sit under no tension. Place interrupted figure-of-eight sutures of heavy chromic or polyglycolic acid from the tendon of the psoas to the bladder wall just lateral to where the new ureteral hiatus will be situated. Avoid the genitofemoral nerve superficially and the femoral nerve deep within the psoas during this maneuver. Likewise, the vas deferens in boys and the fallopian tubes in girls must be protected.

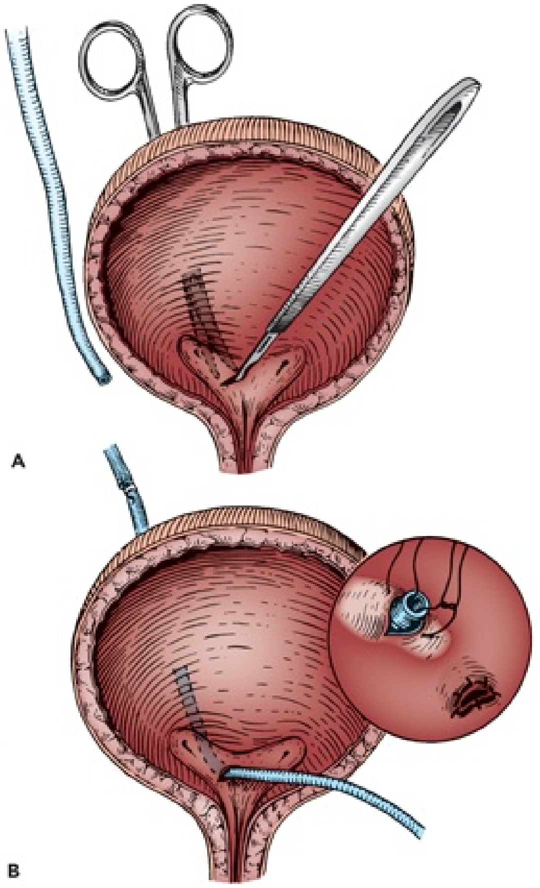

FIGURE 92.13 Paquin Repair. The ureter is mobilized completely, both an intra- and extravesical fashion. A submucosal tunnel is then developed towards the neo-meatus (**A**). The ureter is then advanced through the tunnel and secured within the bladder with interrupted sutures (**B**).

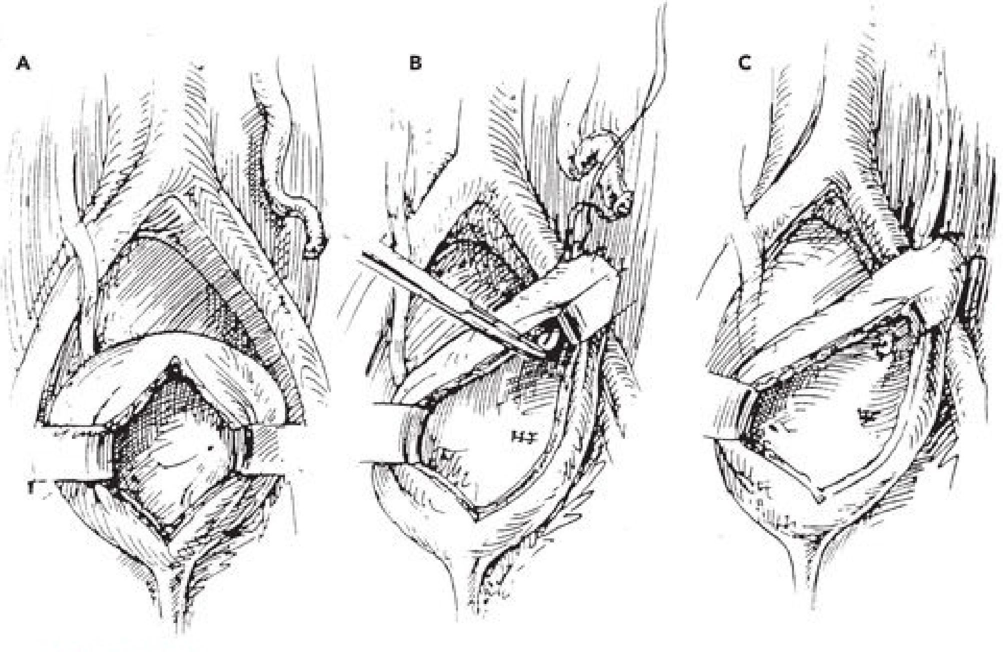

FIGURE 92.14 Bladder mobilized and sutured to psoas over iliac vessels by psoas hitch. **A:** Blunt dissection and exposure of psoas tendon and iliac vessels. **B:** Psoas hitch with interrupted absorbable sutures. **C:** Completed reimplant. Long submucosal tunnel to prevent reflux is shown. (Adapted with permission from Ehrlich RM, Melman A, Skinner DG. The use of the vesicopsoas hitch in urologic surgery. *J Urol* 1978;119:324. Copyright 1978 Elsevier.)

A submucosal tunnel is created as described for the Politano–Leadbetter repair. The ureter is brought through the new hiatus, under the subepithelial tunnel, and secured in its new location. Care is taken to avoid twisting or kinking the ureter as it is brought through the bladder wall. As with all of the intravesical techniques, after the final ureteral anastomosis is complete, a 5Fr feeding tube should easily pass up through the reimplanted ureter to the kidney.

Minimally Invasive Repair

The modern era of minimally invasive surgery has brought forth many new and innovative techniques. These new procedures take advantage of technologic advances and have been designed to decrease patient morbidity while shortening convalescence. The laparoscopic ureteral reimplant has yielded to the robotic-assisted laparoscopic approach, which will be the focus of this discussion. Designed to emulate the Lich–Gregoir repair, this particular repair can be performed transperitoneally or transvesically, the former which is more commonly used and will be discussed in detail. Positioning is either supine or dorsal lithotomy, dependent on patient size. Taller children require the lithotomy position to allow robot docking from the foot of the bed (Fig. 92.15). All pressure points are padded with gel pads, and tape is placed across the chest and midthigh to prevent patient migration during the procedure. Cystoscopy is not required in our opinion, although a Foley catheter is inserted on the sterile field prior to establishing pneumoperitoneum for bladder cycling during the dissection. Pneumoperitoneum in the pediatric population should be obtained via an open technique. A semicircular incision is hidden within the umbilicus, and an 8.5-mm Hassan trocar is inserted as a camera port. Parallel 2-0 polyglycolic sutures can be placed as holding sutures through the fascia to aid with camera port insertion. Direct inspection with the camera should be done to rule out any visceral or vascular injury. Of note, the robotic camera should never be “wiped” on the bowel due to the intensity of the light because this could result in bowel injury. Two additional 5-mm robotic trocars (8-mm trocars can be used in teenagers or larger children) are placed under direction vision on either side of the umbilicus along the midclavicular line (Fig. 92.16A and B). There should be at least 6 cm of separation between ports to allow for full range of movement for the robot. The patient is then placed in steep Trendelenburg to mobilize the abdominal contents cephalad. The initial approach differs based on patient gender because care must be taken to preserve the vas deferens and uterine structures during mobilization (Fig. 92.17A and B). The ureters can typically be visualized through the thin peritoneum, which is incised over the iliac vessels to expose the ureter. The ureter is exposed by gently grasping the adventitia with a Maryland instrument and then tenting it anteriorly with the hook to bluntly dissect the ureter for 5 or 6 cm proximal to the ureterovesical junction (Fig. 92.18A). This dissection will ultimately allow the ureter to lie in the trough without tension. A 0 Prolene suture is placed through the suprapubic region as a hitch stich on the bladder. The needle is straightened and inserted under vision and then passed through the bladder both medial and anterior to the apex of the trajectory of the detrusor trough. Tension is placed on the stitch to pull the bladder anteriorly toward the abdominal wall. This alignment facilitates detrusor dissection. The Maryland is then used to measure the width of the ureter and the length of the detrusorotomy to achieve the desired ratio. Next, the detrusor layer is incised with hook electrocautery and the Maryland dissector, taking caution to avoid violation of the mucosal layer (Fig. 92.18B). Dissection continues for the entire length of the tunnel until the mucosa bulges throughout the incision (Fig. 92.18C). The ureter is placed in the trough, and the detrusor edges are approximated over the ureter with advancement stitches at the apex of the trough (Fig. 92.19A–D). The remaining detrusor defect is closed over the ureter with absorbable suture (5-0 polydioxanone or poliglecaprone) in an interrupted fashion. We recommend closing the fascia at all port sites due to hernia risk. A Foley catheter is left overnight as in the open approach and typically no additional drains are required.

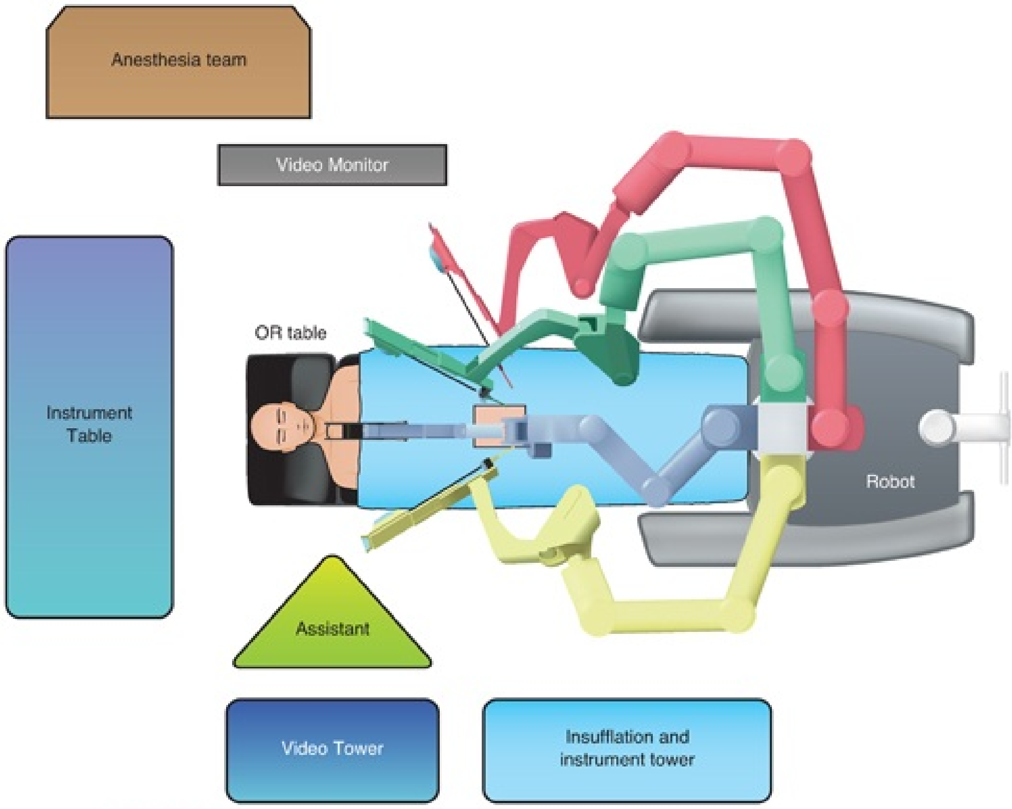

FIGURE 92.15 Layout for robotic procedure. The patient is intubated and the bed is rotated 90 degrees to dock the robot from the foot of the bed. Only one bedside assistant is necessary because no assistant ports are used.

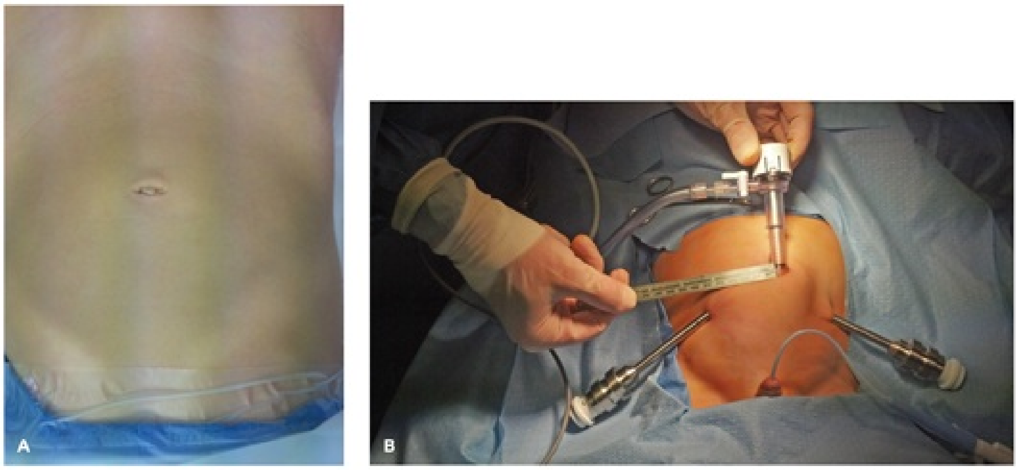

FIGURE 92.16 Port insertion. **A:** An 8.5-mm camera port is inserted within the lower umbilicus (*1*). Two additional robotic ports are placed on either side of the midline within the midclavicular line (*2* and *3*). **B:** Ports should be separated by at least 6 cm and should be approximately 1 cm caudad to the umbilicus. Ports should be adjusted for pubis–umbilicus distance to ensure that there is a safe working distance for the robotic instruments.

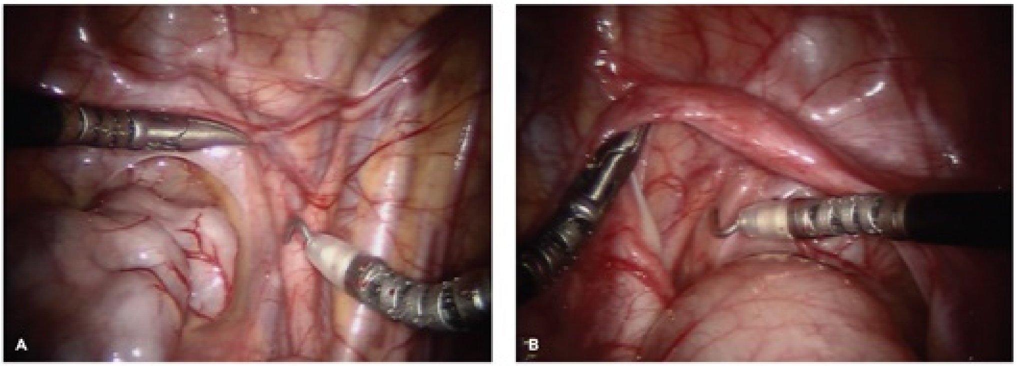

FIGURE 92.17 Exposing the ureter. Peritoneum is incised posterior to the bladder to expose the ureter in its descent to the bladder. The approach differs for males versus females. Care must be taken to avoid damage to the vas deferens in males (**A**), whereas in females, the uterus, uterine artery, and round ligament must be identified during dissection (**B**).

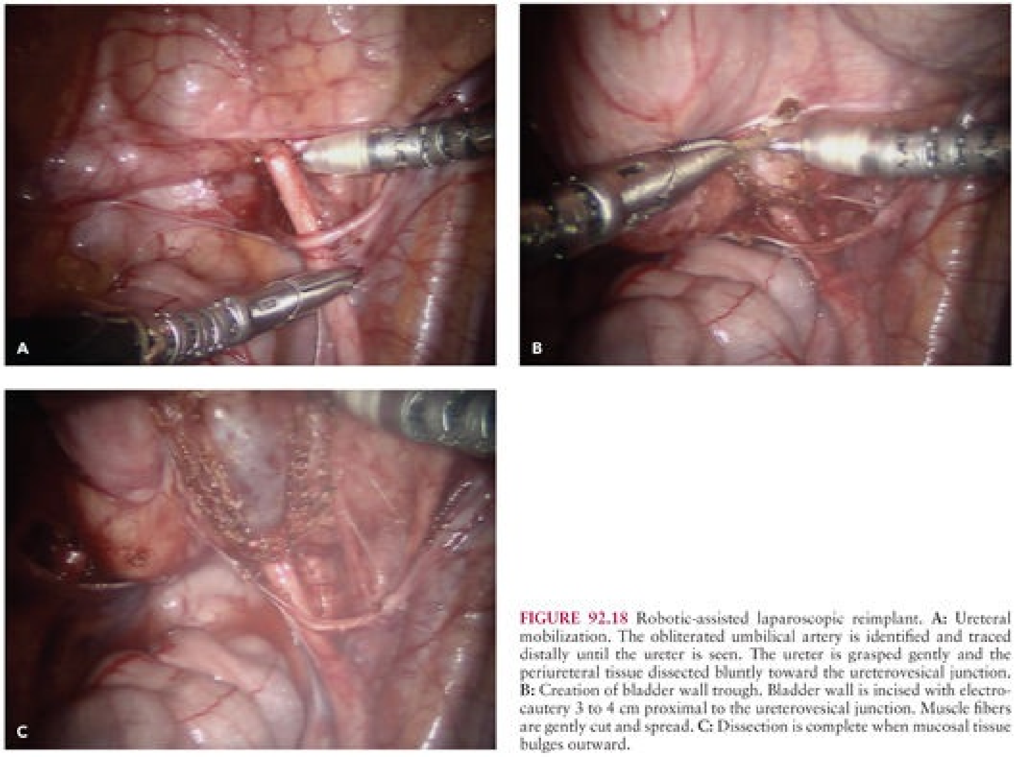

FIGURE 92.18 Robotic-assisted laparoscopic reimplant. A: Ureteral mobilization. The obliterated umbilical artery is identified and traced distally until the ureter is seen. The ureter is grasped gently and the periureteral tissue dissected bluntly toward the ureterovesical junction. B: Creation of bladder wall trough. Bladder wall is incised with electrocautery 3 to 4 cm proximal to the ureterovesical junction. Muscle fibers are gently cut and spread. C: Dissection is complete when mucosal tissue bulges outward.

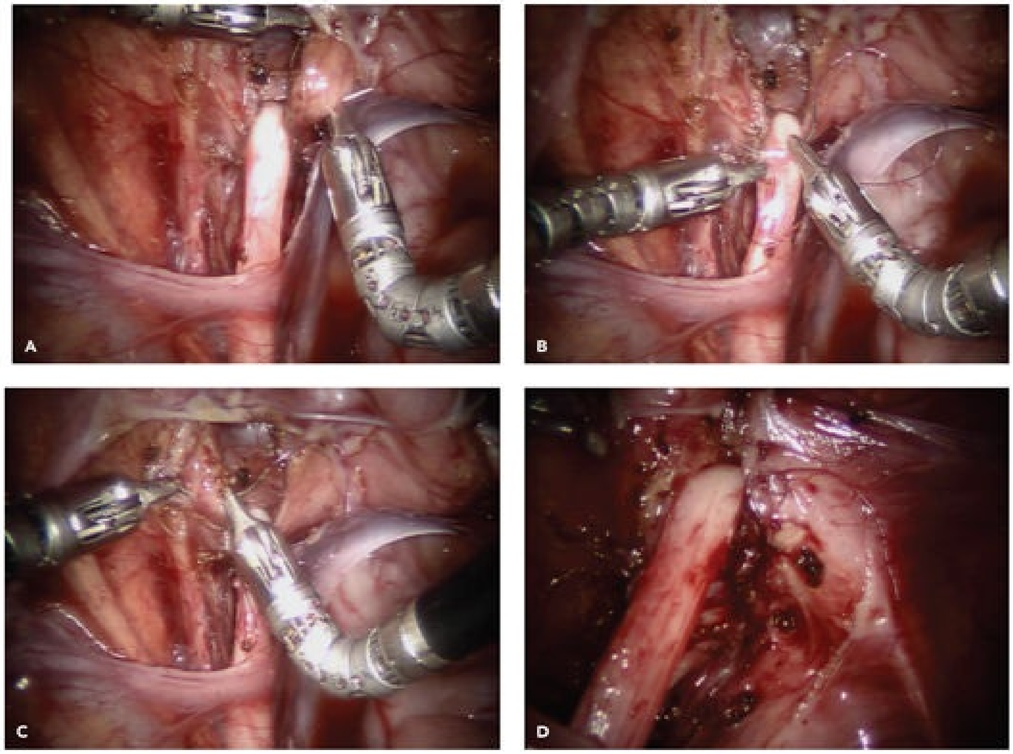

FIGURE 92.19 Detrusorrhaphy is completed with interrupted 5-0 poliglecaprone. A: After placing the ureter in the trough, suturing begins from right to left (out to in) through the detrusor just above the mucosa. The stitch is then passed under the ureter, and the adventitia at the 6 o'clock position is incorporated in the closure (B). C: The detrusor from the contralateral side is then sutured (in to out), and the suture is passed under the ureter to the initial side. D: Completed repair, in this case, a bilateral reimplant. The detrusorrhaphy brings the ureter forward in the repair, limiting visualization of the suture line.

There are few reports in the literature that directly compare the open and robotic reimplant. Those that do have found the robotic approach to result in similar surgical outcomes, albeit with success rates slightly below those for open reimplant. The robotic approach has been found to shorten hospital length of stay and result in decreased narcotic requirement (22,23).

POSTOPERATIVE CARE

The patient stays on prophylactic antibiotics until postoperative US has been performed, usually 4 to 12 weeks postoperatively. In patients with lower grade reflux, no recurrent UTIs, no voiding dysfunction, and a normal US, reflux resolution with confirmatory VCUG study can be avoided. Any patients not meeting these criteria, those with abnormal US, or those with high-grade reflux should undergo a follow-up VCUG or nuclear cystogram at 3 months to assess the surgical result. If reflux is no longer present, we routinely repeat a renal US 1 year later to make sure that anatomically all is well. Should known renal scarring be present, then yearly urinalysis, blood pressure measurements, and periodic US are recommended.

OUTCOMES

Complications

Fortunately, the success rates for open surgery to correct reflux approach 98% for nondilated ureters in patients with normal bladder function. In cases with dilated ureters, significant voiding dysfunction, neuropathic bladder, and secondary reflux such as in prune belly syndrome and posterior urethral valves, the success rates diminish somewhat. Previously unrecognized bladder and bowel dysfunction is the most common cause of postoperative failure and needs to be vigorously addressed preoperatively. The most common complication is persisting reflux on the operative side or contralateral reflux of a previously nonrefluxing ureter. It has been postulated that this is due to a "pop-off" mechanism for ipsilateral reflux and seen mostly in cases of repair of severe reflux or as simply reflux that was missed on initial examination. In most cases, observation with prophylactic antibiotics is the treatment of choice because the vast majority of these patients will have spontaneous resolution of reflux within 1 year. Recurrent reflux that is high-grade suggests technical failure, such as not creating a long enough tunnel or insufficient ureteral mobilization, which frequently requires reoperation.

Ureteral obstruction is fortunately a rare complication of reflux surgery and typically is transient in nature, resulting from postoperative bladder spasms, edema, or intraluminal blood clots. Hence, it is not unusual to see some mild renal or ureteral dilatation in the first few weeks after surgery on sonography. Should problems persist, ureteral stenting or percutaneous nephrostomy will help temporize the situation until resolution occurs spontaneously or surgical reimplantation is performed. Prior to stenting, a Lasix renogram can be obtained to confirm obstruction. Alternatively, a retrograde pyelogram at the time of stenting can be used to evaluate for a stenotic ureterovesical junction or delayed antegrade flow. Our preference is for double-J stent insert to avoid a "dry" anastomosis. Higher grade obstructions usually present with a variety of symptoms such as flank pain, fever, nausea, vomiting, and ileus. These are due to angulation, obstruction at the hiatus, extravasation (of a tapered ureter), or ureteral ischemia with resultant stricturing. Urinary diversion or stenting is paramount in these situations and redo reimplantation required. If the remaining ureter is too short to reimplant in the standard fashion, consider a psoas hitch or a transureteral ureterostomy.

Bladder diverticula are usually the result of a defect in the closure of the muscular hiatus at the original procedure. If the diverticula is wide-mouthed and drains well in the absence of obstruction or reflux, then observation is all that is needed. In the presence of ureteral pathology or poor drainage of the diverticula, surgical correction is necessary.

Robotic reimplant offers the same spectrum of complications as the open approach with the one difference being that the procedure is transperitoneal. Any postoperative leak will result in a significant ileus, which can typically be relieved with continuous bladder drainage. This approach also shares the theoretic risk of bowel and vascular injury, although these are quite rare.

CONCLUSIONS

Surgical management of VUR is highly successful if performed for the right indications and if one adheres to the proper principles of good surgical technique. There are a myriad of corrective techniques available, each with their respective advantages and disadvantages. It is up to the individual surgeon to decide what works best in his or her hands after analyzing the available information on the respective patient.

CHAPTER 93 ENDOSCOPIC TREATMENT OF VESICOURETERAL REFLUX

ANGELA M. ARLEN AND ANDREW J. KIRSCH

Vesicoureteral reflux (VUR) is the retrograde flow of urine from the bladder to the upper urinary tract and is one of the most common urologic diagnoses affecting children, with an estimated prevalence of 0.4% to 1.8% in the general pediatric population and 30% in those with a history of febrile urinary tract infection (UTI) (1,2). VUR is a risk factor for pyelonephritis, which can lead to renal scarring and subsequent complications such as hypertension, proteinuria, and even chronic kidney disease (3). VUR is one of several modifiable risk factors in the development of UTI. The goal of VUR treatment is to prevent pyelonephritis and preserve renal function. Management options include observation with or without continuous antibiotic prophylaxis and surgical correction via endoscopic, open, or laparoscopic/robotic approaches. Surgical intervention may be necessary in children with persistent reflux, renal scarring, or recurrent febrile UTIs. An individualized risk-based approach that takes into consideration a multitude of demographic, radiographic, and clinical factors should guide management (4).

Endoscopic treatment of VUR is an outpatient procedure associated with decreased morbidity compared to ureteral reimplantation. Endoscopic injection for VUR was introduced in 1981 as an investigational method with the first clinical experience published in 1984 (5,6). Over the past three decades, both injection techniques and bulking agents have significantly improved, which has resulted in higher treatment success rates (7,8). The success rate of outpatient endoscopic treatment of VUR approaches that of open ureteral reimplantation and offers considerable advantages to patients including limited morbidity, fewer complications, and reduced cost. Endoscopic injection has become an increasingly common method of correcting VUR because of its minimal invasiveness and high success rates (9).

DIAGNOSIS

Contrast voiding cystourethrogram (VCUG) has long been a mainstay of VUR diagnosis. Advantages include the ability to grade the severity of reflux based on a standardized international scale, visualization of bladder anatomy, and assessment of the urethra during voiding (10). VUR can also be diagnosed via radionuclide cystography (RNC), which has comparable sensitivity to VCUG (11). VUR grading system conveys clinical significance not only for spontaneous resolution but also for treatment method and outcome (4,12). VCUGs performed with a single cycle of filling and voiding show false negatives up to 15% to 20%; for improved sensitivity, cyclic VCUGs consisting of three voiding cycles are recommended (13,14).

Approximately 30% to 40% of children with febrile UTIs are subsequently diagnosed with VUR. Children who experience recurrent febrile UTIs without evidence of VUR by VCUG may suffer from occult VUR. It is conceivable that despite negative conventional VCUG, occult VUR is clinically significant. One method to diagnose occult VUR is the positional instillation of contrast cystography (PICC). The tip of the cystoscope is positioned at the ureteral orifice and contrast instilled at full flow with a pressure of 80 cm of water. A patient is designated PICC-positive if contrast is seen in the ureter (15). An alternative approach for the diagnosis of occult VUR is hydrodistention of the distal ureter, thus avoiding the use of contrast and ionizing radiation. The degree of hydrodistention has been shown to correlate with the presence of occult reflux. VUR may be incidentally discovered by a VCUG obtained for reasons other than febrile UTIs, such as posterior urethral valves, patent urachus, or suspected bladder rupture. The obligation to diagnose VUR in asymptomatic patients (no history of febrile UTIs, prenatally diagnosed hydronephrosis, sibling screening) has been questioned because the natural history of asymptomatic VUR may be benign and treatment unnecessary.

The “top-down approach” in the management of UTI attempts to distinguish clinically significant from insignificant VUR by evaluating kidneys for pyelonephritis and/or scarring with dimercaptosuccinic acid (DMSA) scans performed within weeks of the onset of acute pyelonephritis. A positive DMSA scan is an indication for VCUG, and consequently, 50% of “unnecessary” VCUGs can be avoided. The 2010 American Urological Association (AUA) Summary Guidelines recommend DMSA imaging in children with primary VUR in whom ultrasound is abnormal or there is greater concern for scarring due to breakthrough UTI, high-grade VUR, or elevated creatinine (16).

INDICATIONS FOR SURGERY

Spontaneous resolution of primary reflux is common secondary to remodeling of the ureterovesical junction (UVJ), elongation of the intravesical ureter, and stabilization of bladder voiding dynamics. Reflux resolution depends on multiple factors including initial grade of reflux, gender, age, voiding dysfunction, presence of renal scarring, and timing of VUR on VCUG (4,12). Management should therefore be individualized and based on patient age, health, VUR grade, clinical course, presence of renal scarring, and parental preference. Surgical intervention may be necessary in children with persistent reflux, renal scarring, or recurrent febrile UTIs.

While open ureteral reimplantation may be a good treatment option after failed injection therapy, endoscopic treatment has also been successfully employed after failed ureteral reimplantation (Table 93.1). Current evidence suggests that either antireflux surgery or continuous antibiotic prophylaxis reduces the incidence of new renal scarring when compared to observation alone (17); however, no study has demonstrated a reduction in the incidence of end-stage renal disease. Valuable goals of VUR treatment are to prevent UTIs, particularly pyelonephritis, to avoid long-term antibiotic prophylaxis, and to reduce the need for distressing VCUGs and radiation exposure. Proponents of the endoscopic approach argue that decreasing the incidence of febrile UTIs is the main goal of therapy. Recurrence, while possible, may occur in the absence of symptoms and be viewed as subclinical, similar to an individual with VUR diagnosed after a sibling screen or for fetal hydronephrosis. Proponents of the open surgical approach comment that ureteral reimplantation provides a permanent cure and is worth the increased morbidity to achieve this goal. In terms of reducing the risk of UTI, endoscopic treatment may achieve this goal as well as or better than open surgery (8,16,18).

Success after one or several treatments in some studies.
Dx/HA, dextranomer/hyaluronic acid; PDMS, polydimethylsiloxane.

Indications for surgical correction of VUR via open, robot-assisted laparoscopic, or endoscopic approach include moderate- to high-grade reflux (grades III to V), low probability of spontaneous resolution, renal scarring, recurrent pyelonephritis, breakthrough febrile UTI while on continuous antibiotic prophylaxis, and parental preference (19,20). While endoscopic injection has focused on the treatment of primary VUR, it was initially largely avoided for cases of complex VUR (i.e., VUR associated with functional or anatomic abnormalities such as neurogenic bladder or megaureters). In general, endoscopic treatment is emerging at many centers as the first-line surgical treatment modality of choice for VUR, whereas ureteral reimplantation remains reserved for cases of failed injection therapy, significant anatomic abnormalities (i.e., large paraureteral diverticula, ectopic ureters, megaureters), and surgeon or parental preference.

ALTERNATIVE THERAPY

Optimal management remains controversial, and options include observation with or without continuous antibiotic prophylaxis and surgical repair. Families should be thoroughly counseled regarding the various VUR management options and all children should undergo screening for and treatment of bowel/bladder dysfunction. The 2010 AUA guidelines recommend management of any suspected bladder/bowel dysfunction, preferably prior to any surgical intervention (19). Traditionally, most patients diagnosed with VUR were started on antibiotic prophylaxis irrespective of grade. Antibiotic prophylaxis may be continued for several years until VUR resolution or significant grade reduction or if it is deemed clinically insignificant. VUR status has been documented to improve with continuous antibiotic prophylaxis and surveillance (21). The presumed benefits of antibiotic prophylaxis, prevention of pyelonephritis, and avoidance of surgery have been challenged by recent studies demonstrating increased bacterial resistance and failure to protect against UTIs. The *R*andomized *I*ntervention for the management of *V*esico*U*reteral *R*eflux (RIVUR) study is supported by the National Institutes of Health and was designed to address some of the questions that have been raised in the management of VUR including to determine whether antibiotic prophylaxis is beneficial for the prevention of UTIs in children with VUR.

Ureteral reimplantation has a high success rate and prevents VUR by increasing intravesical ureteral length which facilitates compression of the ureter against the backing of detrusor muscle during bladder filling and emptying. Various open reimplantation techniques have been described including both intravesical and extravesical approaches, with success rates typically reported at >95%. Laparoscopic ureteral reimplantation was initially reported in the 1990s. More recently, robotic-assisted approaches have been described, negating some of the longer operative times and technical difficulty associated with pure laparoscopy.

SURGICAL TECHNIQUE

Endoscopic repairs correct VUR by injection of a bulking substance that allows elevation and coaptation of the ureteral orifice and detrusor tunnel (22). Endoscopic correction of VUR using a bulking agent was pioneered by Matouschek (5) in 1981 as an alternative to continuous antibiotic prophylaxis or ureteral reimplantation. O'Donnell and Puri (6) further advanced this concept by performing subureteric injections using Teflon paste coining the term *STING* (subureteric Teflon injection). Modifications of the injection procedure have occurred so that now total ureteral tunnel coaptation is achieved using the hydrodistention implantation technique (double hydrodistention implantation technique [HIT]) (7,23) which involves two intramural injections (proximal and distal). The ideal injectable material should be durable, effective, safe, and should not extrude or migrate. Currently, the only U.S. Food and Drug Administration (FDA)–approved bulking agent is dextranomer hyaluronic acid copolymer (Dx/HA, Deflux). Polyacrylate polyalcohol copolymer (Vantris) has had promising short-term results outside of the United States; however, long-term clinical data is lacking.

Patient Positioning

The patient is placed in the dorsal lithotomy position after induction of general anesthesia. The ability to freely rotate the cystoscope in order to adequately visualize and inject laterally displaced orifices, is important. An offset lens should be used to permit direct passage of the needle in line with ureter without damaging the needle. The bladder should be filled to less than half capacity during injection in order to prevent high tension within the detrusor muscle.

STING (Subureteric Teflon Injection) Technique

When performing the traditional STING procedure, a needle is introduced under the bladder mucosa 2 to 3 mm below the refluxing orifice at the 6 o'clock position and the injection is continued until there is a prominent bulge with the orifice assuming a crescent-like shape (6,22). The injected material augments the tissue below the ureteral orifice, providing a solid support under the refluxing ureteral orifice. This increases the submucosal ureteral length and creates a fixation point whereby the valve mechanism is enhanced preventing retrograde reflux of urine. One concern regarding the STING method is that caudal migration of material, particularly of low injected volume, while resulting in a coapted ureteral orifice initially may result in a failure longer term.

Double Hydrodistention Implantation Technique Method

The endoscopic method currently achieving the highest success rates is the double HIT (Fig. 93.1). Hydrodistention (HD) is performed with the tip of the cystoscope placed at the ureteral orifice; a pressure stream is achieved by placing the irrigation bag approximately 1 meter above the pubic symphysis on full flow. HD is graded according to the distensibility of the orifice (Table 93.2) and allows visualization of the intraluminal injection site as well as assessment of injection progress. Ureteral HD causes the orifice to open before treatment but following proper implantation, the ureter should remain closed with an H0 grade. HD grading correlates with VUR grade, with higher HD grades requiring more injected volume (23). Although HD grade plays a significant role in determining injection volume, surgeon experience, tissue planes, and redo operations also contribute to the volume necessary to achieve an H0 ureter.

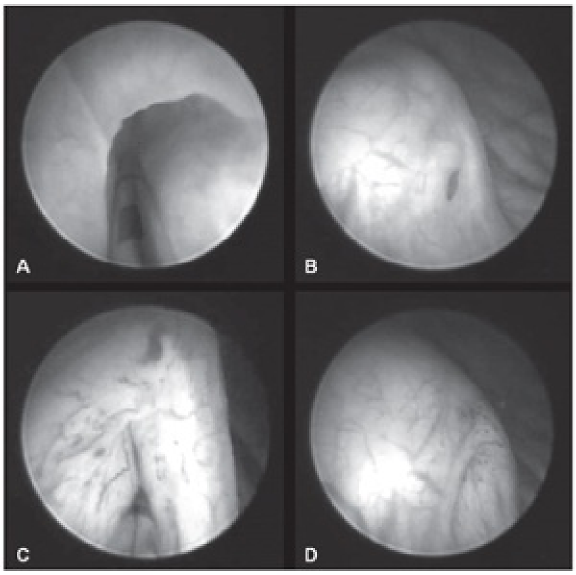

FIGURE 93.1 Endoscopic treatment of vesicoureteral reflux (double HIT technique). A: Proximal intraureteric injection. B: Coapted intramural ureter. C: Distal intraureteric injection. D: Coapted ureteral orifice.

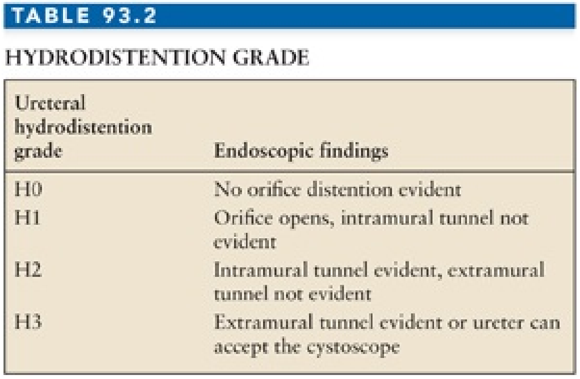

TABLE 93.2

HYDRODISTENTION GRADE

Ureteral hydrodistention grade	Endoscopic findings
H0	No orifice distention evident
H1	Orifice opens, intramural tunnel not evident
H2	Intramural tunnel evident, extramural tunnel not evident
H3	Extramural tunnel evident or ureter can accept the cystoscope

When employing the double HIT methodology, the needle is placed into the ureteral orifice and inserted in the midureteral tunnel at the 6 o’clock position after performing ureteral HD. This differs from the STING technique, where the needle is inserted 2 to 3 mm *below* the refluxing orifice. Bulking agent is injected until a sufficient bulge is produced, which coapts the detrusor tunnel. A second injection at the distal most aspect of the intraureteral tunnel results in coaptation of the orifice. Rarely, if the two intraureteric submucosal injections (double HIT method) fail to coapt the ureter, a classic STING (subureteric Teflon injection) is needed to achieve coaptation (Fig. 93.2). HD is performed following each injection to monitor progress. A retractable injection needle guide (Injekt Needle, Cook Urological) is available that includes a 4-cm filiform needle guide that allows for improved control of injection site and depth (Fig. 93.3).

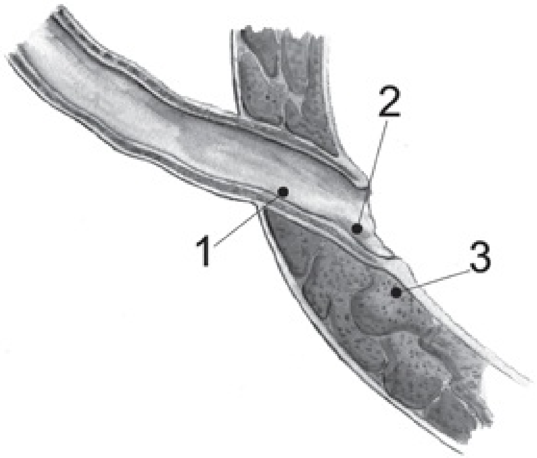

FIGURE 93.2 Needle placement algorithm for the endoscopic treatment of vesicoureteral reflux. The double hydrodistention implantation technique uses sites *1* and *2*; site *3* (subureteric injection of Teflon) is rarely used.

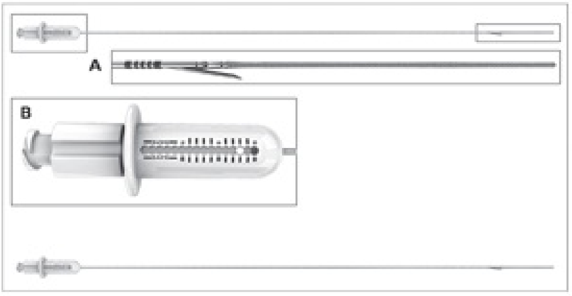

FIGURE 93.3 Retractable injection needle guide (Injekt, Cook Urological, Spencer, Indiana). **A:** Flexible wire is placed into the ureter and the needle is advanced submucosally. **B:** Depth gauge allows needle advancement in 1-mm increments.

In general, all procedures are performed on an outpatient basis and all patients receive preoperative antibiotic prophylaxis, which is continued until clinical follow-up. Patients should be kept on prophylactic antibiotics until appropriate postoperative studies have been obtained, particularly if there is a history of recurrent UTIs preoperatively. Renal ultrasound should be obtained 4 to 6 weeks postoperatively to assess for asymptomatic hydronephrosis. A concomitant bladder sonogram will assess the integrity of the implants. The most recent AUA reflux guidelines (19) also recommend a postoperative VCUG, but there is wide variability in the performance of postoperative imaging dependent on the individual patient and the surgeon's clinical experience and success rate (24).

OUTCOMES

The clinical success of any type of antireflux surgery can be measured both radiographically (absence or downgrading of VUR) and clinically (absence or decrease in frequency of febrile UTIs). In the medical literature, there is considerable variability as to how success is measured; therefore, true surgical outcomes can be difficult to ascertain (24). The outcomes of endoscopic treatment for VUR have been evaluated in several large series (see Table 93.1). Most studies included both primary and complicated cases of VUR; however, interpretation and comparison of these studies are confounded by varying inclusion criteria, different length of follow-up, definition of success, and single versus multiple injections. Nevertheless, the average resolution of VUR following a single endoscopic injection is 83% based on aggregate data, although success rates have ranged from 70% to 95% (20).

Although the STING technique yields lower success rates with higher grades of VUR, the double

HIT method in experienced hands achieves similar outcomes across all VUR grades up to grade V (8). Endoscopic treatment of complicated VUR has been evaluated in smaller series and success rates vary significantly depending on the associated pathology (see Table 93.1). In general, cure rates for complex cases of VUR are lower than for primary VUR. Treatment of VUR associated with neurogenic bladder or voiding dysfunction has been shown to yield acceptable outcomes. Endoscopic injection has also been successfully employed in patients who failed either ureteral reimplantation or initial injection. Injection after failed reimplantation or second injection will be curative in most instances, whereas a third injection has been shown to be far less successful (25). Refluxing ureters of transplanted kidneys in symptomatic patients may be treated endoscopically. Although this approach is curative in only half the cases, it represents an attractive alternative to open surgery in the setting of immune compromise and reduced wound-healing properties. VUR associated with anatomic abnormalities (i.e., duplex ureters, paraureteral diverticula, and ureteroceles), previously thought to be contraindications for endoscopic treatment, have recently shown to be amenable to injection treatment (see Table 93.1).

In addition to proper patient selection, there are a number of technical principles that can help to ensure a successful outcome. Proper injection technique, selection of correct injection site(s), adequate injected volume, and recognizing the end points of the injection are all important components of the injection procedure necessary to follow in order to avert failure. Volume of injection varies depending on the injection method(s). The HD grade of the ureter should directly correlate with the volume used when the double HIT method is employed. After injection, the bladder should be emptied and HD performed to confirm the absence of ureteral distensibility (i.e., H0 ureter). Failures may result from Deflux displacement (implant migration), disruption (mucosal breach), or dissolution (decrease in implant volume).

COMPLICATIONS

In comparison to ureteral reimplantation, endoscopic VUR treatment offers major advantages to patients and parents. The procedure generally lasts <15 minutes and is performed on an outpatient basis. Although cure rates approach those of open ureteral reimplantation, significant complications are rare. Endoscopic treatment entails greater patient convenience, lower morbidity (i.e., pain, abdominal scar), and reduced cost (26).

Complications can be categorized into those that occur in the immediate postoperative period and those that manifest later, even as long as several years from the time of surgical intervention. Early complications typically occur within the first few days following injection and are often transient. Less than 4% of children undergoing endoscopic VUR therapy complain of flank pain or nausea postoperatively and nearly all resolve with analgesics. Ureteral obstruction following endoscopic injection occurs in approximately 0.6% of patients and is frequently associated with voiding dysfunction or with larger ureters when a large volume of bulking agent is injected (19,22). Complete obstruction that requires either placement of ureteral stents or nephrostomy tubes to allow upper tract drainage is rare.

It is not uncommon for patients to develop a febrile UTI after endoscopic injection. This can usually be avoided by checking the urine preoperatively and beginning appropriate antibiotics if indicated. In patients with a symptomatic UTI, surgery should be postponed.

Postoperative reflux may be the result of uncorrected, ipsilateral, or new-onset contralateral reflux. Treatment failure following endoscopic therapy ranges from 7% to 50% and is dependent on the technique, VUR grade, and surgeon experience. Success rates for the double HIT technique approach those following ureteral reimplantation in experienced hands (8). Voiding dysfunction or dysfunctional elimination accounts for the majority of treatment failures. Patients with a previous history of voiding dysfunction must be encouraged to continue their voiding program postoperatively.

Although perhaps not a true surgical complication, the development of contralateral VUR after unilateral endoscopic injection may require continued medical or surgical treatment. This finding has been explained based on either occult reflux or even the possibility that high-grade VUR may be a pop-off mechanism for high bladder pressure, which when corrected may destabilize the contralateral ureter. New contralateral reflux may be prevented by injection of ureters with abnormal HD, that is, grades H2 to H3 (27).

CHAPTER 94 URETEROCELES

RICHARD N. YU, CHESTER J. KOH, AND DAVID A. DIAMOND

Ureteroceles are congenital cystic dilations of the intravesical submucosal ureter. They are more commonly found in female children and are almost exclusively diagnosed in Caucasians. Approximately 10% of these children have bilateral ureteroceles. Ureteroceles may be orthotopic (contained entirely within the bladder) or ectopic (partially situated at the bladder neck or urethra). An orthotopic ureterocele is typically associated with a single collecting system, whereas an ectopic ureterocele is usually associated with the upper pole moiety of a kidney with complete ureteral duplication.

DIAGNOSIS

Increasingly, ureteroceles are diagnosed by prenatal ultrasonography (Fig. 94.1A and C), which can demonstrate both the intravesical cystic dilation as well as the corresponding hydronephrosis. These patients should undergo a comprehensive postnatal urologic evaluation and be placed on prophylactic antibiotics, which may help to prevent future urinary tract infections (UTIs) (1).

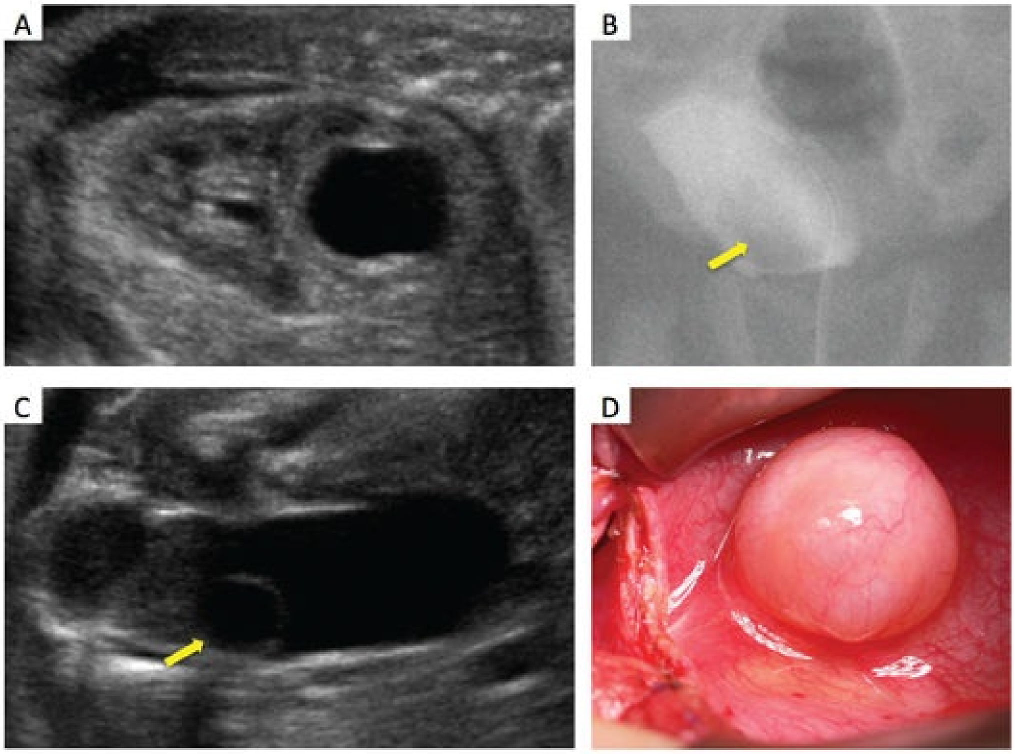

FIGURE 94.1 Ureterocele images. **A:** Fetal ultrasonography demonstrating upper pole hydronephrosis associated with an ectopic ureterocele. The image is oriented with the fetal spine at the top of the image and the head toward the right of the image. **B:** Voiding cystourethrogram with contrast outlining the ureterocele (*yellow arrow*) in a partially filled bladder. **C:** Fetal ultrasonography of the bladder showing a thin-walled ureterocele (*yellow arrow*) within the bladder lumen. **D:** Intraoperative view of a right ectopic ureterocele.

However, for many children, the diagnosis of ureterocele is only made after a UTI or urosepsis. Ureteroceles can also present as a palpable abdominal mass usually representing a hydronephrotic kidney or as a vaginal mass, which represents prolapse of an ectopic ureterocele. Large ureteroceles may even lead to obstruction of the bladder neck or of the contralateral ureteral orifice, which may result in bilateral hydronephrosis.

In general, ultrasonography is the first radiologic study obtained in diagnosing ureteroceles. In addition to the intravesical cystic dilation, ureteroceles are usually seen with duplex collecting systems, with the ureterocele being associated with hydronephrosis of the upper pole moiety.

A voiding cystourethrogram (VCUG) is essential in the evaluation of the patient with a ureterocele because of the high incidence of concomitant ipsilateral and contralateral vesicoureteral reflux. In addition to the reflux, VCUG can demonstrate the size and location of the ureterocele (Fig. 94.1B).

Currently, the dimercaptosuccinic acid (DMSA) renal scan provides the most precise estimate of the differential renal function between each kidney as well as of the associated upper pole contribution to the overall renal function. DMSA scans may even detect lower moiety abnormalities that may not have been demonstrated by ultrasonography (2).

Intravenous urography (IVU) is less commonly used in the modern evaluation of ureteroceles. However, in cases of unusual urinary tract anatomy, IVU, or increasingly magnetic resonance urography (MRU), may be helpful in the delineation of previously undefined anatomy. Severe hydroureteronephrosis associated with a ureterocele may lead to lateral deviation of the upper pole away from the spine.

INDICATIONS FOR SURGERY

The goals of surgical treatment should be the preservation of renal function, elimination of obstruction and reflux, prevention or elimination of infection, and maintenance of urinary continence while minimizing surgical morbidity (3). The main factors to consider in developing an individual treatment plan should be patient age, patient's clinical presentation, ureterocele size and anatomy, presence of reflux and UTI, and function of the involved renal segment.

ALTERNATIVE THERAPY

The anatomy and clinical presentations of children with ureteroceles vary widely. Therefore, each child should have an individualized treatment plan, as no single method of surgical repair is appropriate for all cases. Table 94.1 lists some therapeutic options for patients with ureteroceles.

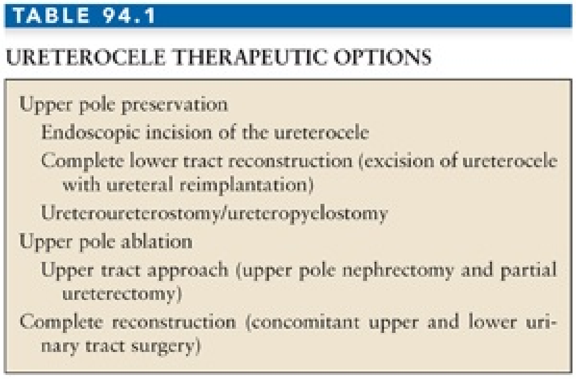

TABLE 94.1

URETEROCELE THERAPEUTIC OPTIONS

- Upper pole preservation
  - Endoscopic incision of the ureterocele
  - Complete lower tract reconstruction (excision of ureterocele with ureteral reimplantation)
  - Ureteroureterostomy/ureteropyelostomy
- Upper pole ablation
  - Upper tract approach (upper pole nephrectomy and partial ureterectomy)
- Complete reconstruction (concomitant upper and lower urinary tract surgery)

SURGICAL TECHNIQUE

Techniques that preserve functional upper pole moieties are listed in the following sections. However, in many instances, the upper pole has little to no contribution to the overall renal function and upper pole ablative techniques, also described in the following sections, may be indicated.

Upper Pole Preservation

Endoscopic Incision of the Ureterocele

The goal of endoscopic incision of ureteroceles is to decompress the ureterocele in a minimally invasive manner while minimizing the risk of postincision vesicoureteral reflux and the need for further urinary tract reconstruction (4). This technique can be used in infants, if infant-sized endoscopic equipment is available, and should be used to drain obstructive urinary systems in any ureterocele patient with urosepsis. Blyth and coauthors (5) recommended the use of a 3Fr Bugbee wire electrode (using the cutting current) to incise the roof of the ureterocele through its full thickness near its base and proximal to the bladder neck. A new unobstructed intravesical ureteral orifice will be created, and the roof of the collapsed ureterocele can act as a flap-valve mechanism to prevent reflux. Although the Bugbee electrode has been a widely used instrument for ureterocele puncture, it has limitations, primarily that following initial decompression enlargement of the puncture site is difficult. Therefore, we prefer to use the pediatric resectoscope and the right-angle hook electrode with the cutting current, which allows one to make a clean transverse incision and enlarge it by placing the hook into the original incision and withdrawing under vision (Fig. 94.2). Magnification with the use of video projection helps improve the accuracy of the incision. Making the incision as distal and as close to the bladder neck as possible should reduce the risk of postoperative reflux into the corresponding ureter. The adequacy of the incision can be confirmed by the presence of a jet of urine from the ureterocele or by visualization of the urothelium inside the ureterocele. The major advantage of the endoscopic incision is that it can be done on an outpatient basis without the need for hospitalization. Other energy sources, such as a laser, have also been described as an alternative method of endoscopic incision (6).

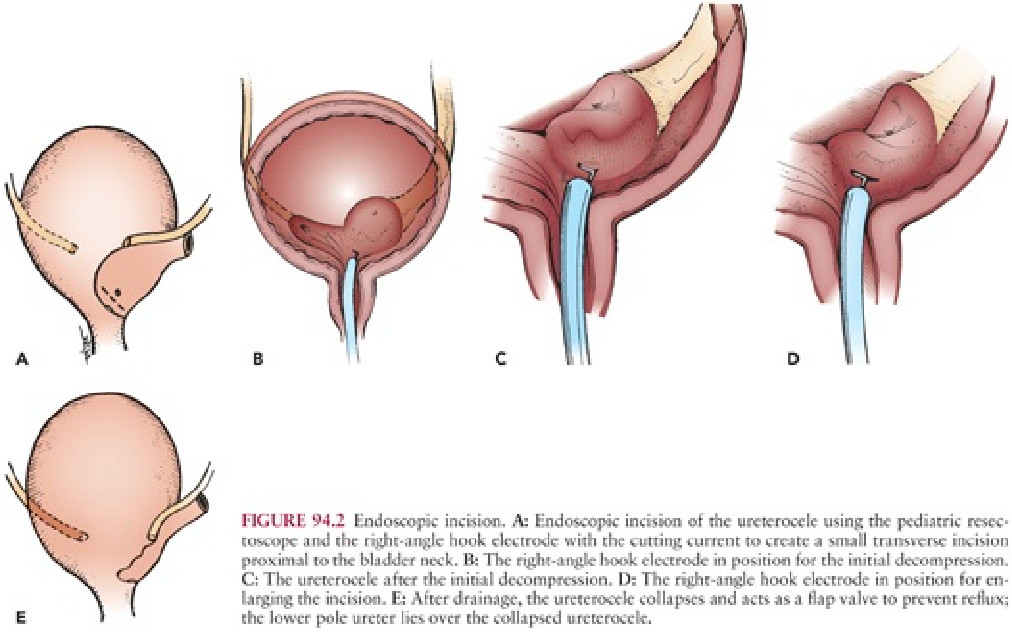

FIGURE 94.2 Endoscopic incision. **A:** Endoscopic incision of the ureterocele using the pediatric resectoscope and the right-angle hook electrode with the cutting current to create a small transverse incision proximal to the bladder neck. **B:** The right-angle hook electrode in position for the initial decompression. **C:** The ureterocele after the initial decompression. **D:** The right-angle hook electrode in position for enlarging the incision. **E:** After drainage, the ureterocele collapses and acts as a flap valve to prevent reflux; the lower pole ureter lies over the collapsed ureterocele.

Complete Lower Tract Reconstruction (Excision of Ureterocele with Ureteral Reimplantation)

For excision of the ureterocele and common sheath reimplantation of upper and lower pole ureters, a Pfannenstiel incision is made and the bladder is opened (Fig. 94.3). The lower pole and contralateral ureters are intubated with 5Fr feeding tubes and multiple circumferential stay sutures are placed. A circumferential incision is made around the perimeter of the ureterocele with electrocautery and the wall of the ureterocele and its associated upper pole ureter are dissected away from the thinned posterior muscular wall of the bladder, incorporating the lower pole ureter in the dissection. All attempts should be made to avoid injury to the sphincteric mechanisms at the bladder neck during the distal dissection of the ureterocele. The upper and lower pole ureters are dissected as a common sheath to avoid injury to the blood supply of both ureters. After excising the distal ureterocele, the dilated upper pole ureter often requires tapering. The thin posterior bladder wall is repaired by imbrication of adjacent muscle with running 3-0 absorbable sutures to provide sufficient muscle backing for the reimplanted ureters. An unoperated portion of the bladder floor is selected and the ureters are reimplanted as a common sheath into a generous ureteral tunnel.

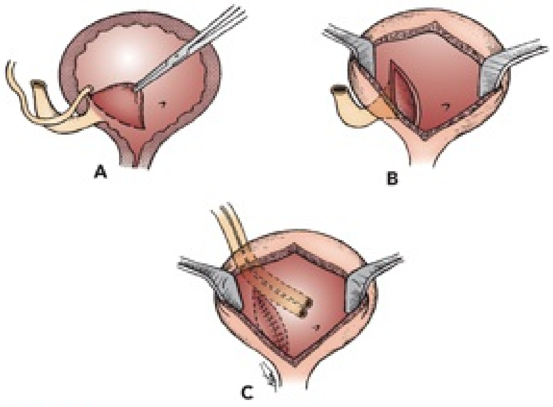

FIGURE 94.3 Complete lower tract reconstruction. **A:** After the bladder is opened, multiple circumferential stay sutures are placed around the ureterocele to assist with the excision. **B:** All ureters should be intubated with 5Fr feeding tubes for identification of the ureters during the dissection. **C:** After excising the ureterocele, the posterior bladder wall is repaired with running 3-0 absorbable sutures and the ureters are reimplanted into a generous tunnel.

Ureteroureterostomy/Ureteropyelostomy

In upper urinary tract anastomotic techniques, the dissection of the upper tracts should be kept to a minimum, and mobilization should be directed toward the upper pole ureter, so that distortion of the adjacent lower pole ureter can be avoided. Because the upper pole ureter is usually larger than the lower pole ureter, generous spatulation of the recipient ureter during ureteroureterostomy may be necessary for an optimal end-to-side anastomosis. Furthermore, a feeding tube should be passed distally into the ureterocele to decompress it. This procedure can be performed using a laparoscopic or robotic approach with improved morbidity in older children and adolescents.

Upper Pole Ablation

Upper Tract Approach (Upper Pole Nephrectomy and Partial Ureterectomy)

In many cases, the upper pole associated with the ureterocele has minimal or no contribution to the overall renal function. The upper tract approach (upper pole nephrectomy and partial ureterectomy) should lead to the relief of obstruction, prevention of recurrent infection, and resolution of the reflux that is present in about half of these patients. This approach should result in the decompression of the ureterocele, hopefully with resolution of the ipsilateral lower pole reflux, because the trigone will be returned to a more normal configuration. This usually eliminates the need for lower tract reconstruction with a potentially difficult bladder neck and urethral dissection (3).

For the upper pole heminephrectomy, we suggest the use of the flank or laparoscopic or robotic approach, which offers superior access to the upper pole vessels. With either approach, care should be taken to avoid excessive traction on the kidney to avoid damage to the viable lower pole. In many cases, the upper pole resembles a dysplastic nubbin, and early division of the upper pole ureter with upward traction on the proximal portion of the transected ureter usually helps in the definition and manipulation of the upper pole (Fig. 94.4). After the upper pole vessels are sequentially ligated, demarcation of the upper pole parenchyma should become apparent. We recommend the use of a no. 15 blade or electrocautery around the upper pole parenchyma, which usually results in a wedge-shaped defect. During the dissection of the upper pole parenchyma, the plane of dissection should remain as close to the upper pole ureter to avoid injury to the vascular supply of the lower pole ureter. After upper pole nephrectomy, the wedge-shaped defect is closed with interrupted 3-0 chromic sutures in a vertical mattress fashion to achieve effective hemostasis. Interposition of perinephric fat or a cellulose-based hemostatic polymer (Surgicel) with a hemostatic matrix may be useful for larger defects.

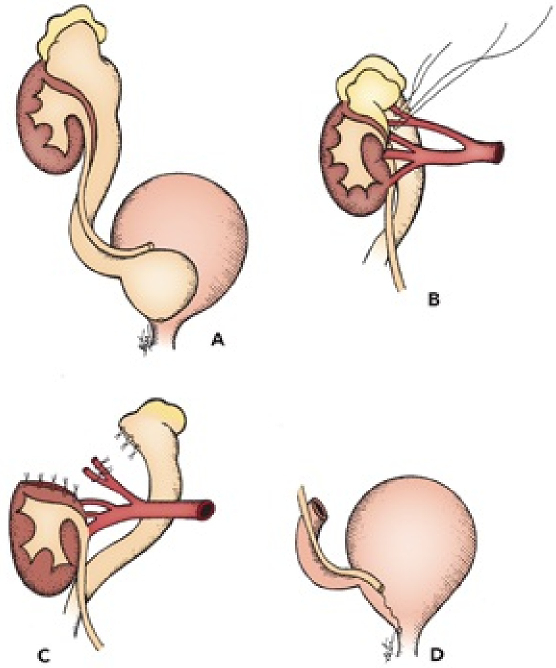

FIGURE 94.4 Upper pole partial nephrectomy and partial ureterectomy. **A:** This procedure is commonly used for a duplex system with a nonfunctioning upper pole and minimal or absent ipsilateral reflux. **B:** The upper pole ureter is transected early after a stay suture has been placed proximally. Upward traction on the proximal portion of the transected ureter assists in the manipulation of the upper pole during the partial nephrectomy. **C:** After removal of the upper pole, the wedge-shaped kidney defect is repaired with 3-0 chromic sutures in a vertical mattress fashion. **D:** This approach should result in the decompression of the ureterocele, with the return of the trigone to a more normal configuration.

Complete Reconstruction

In certain instances, complete reconstruction may be indicated where both an upper tract repair and a lower tract reconstruction are performed via separate incisions in a single stage. These situations include the presence of high-grade reflux into the ipsilateral lower pole ureter or the presence of lower pole reflux associated with a large, everting ureterocele and a nonfunctioning upper pole segment. Depending on the amount of upper tract function, either an upper pole nephrectomy with partial ureterectomy or a ureteropyelostomy (as described earlier) is performed for the upper tract repair. Lower tract reconstruction is also performed, which involves excision of the ureterocele with reimplantation of the ureters as a common sheath, as previously described.

OUTCOMES

Complications

Excision of the ureterocele with ureteral reimplantation achieves the goal of upper tract drainage. However, the disadvantage of this approach is the morbidity associated with bladder surgery, including hematuria, bladder spasms, and catheter drainage. Extensive distal dissection also carries the risk of bladder neck and sphincteric injury, which may jeopardize urinary continence (7).

Results

Endoscopic incision of the ureterocele may be the only surgical procedure required for many patients. For infants, endoscopic incision may be used as a temporizing measure that achieves early decompression. Secondary surgery, if necessary, can be performed electively when the child is older. If the ureterocele is orthotopic, one can expect high rates of decompression and low rates of de novo reflux and the need for secondary procedures (8). On the other hand, ectopic ureteroceles are associated with a high rate of secondary surgery and a significant incidence of postoperative reflux after endoscopic incision. Therefore, patients with ectopic ureteroceles may be best served by more definitive reconstruction, even those younger than 1 year of age (9).

The upper tract approach, which includes upper pole nephrectomy and partial ureterectomy, is usually reserved for the patient with an upper pole that provides little or no contribution to the overall renal function and mild or absent ipsilateral reflux. This approach has the advantage of avoiding the lower tract complications noted earlier.

For patients who are at significant risk for requiring a second procedure with some of the approaches detailed earlier, such as those patients with large, ectopic ureteroceles or high-grade ipsilateral reflux, complete upper and lower tract reconstruction in a single stage has the advantage of expediency (10).

CHAPTER 95 ■ URACHAL ANOMALIES AND RELATED UMBILICAL DISORDERS

LESLIE T. MCQUISTON AND ANTHONY A. CALDAMONE

During bladder development, the urogenital sinus is initially contiguous with the allantois. When the lumen of the allantoic duct becomes obliterated, the urachus remains, connecting the bladder to the umbilicus (Fig. 95.1A and B). It continues to elongate as the fetus grows. The urachus is a muscular tube, with a length ranging from 3 to 10 cm and a diameter of approximately 8 to 10 mm that extends from the dome of the bladder to the umbilicus. It has three distinct tissue layers: (a) an epithelial-lined lumen with cuboidal or transitional epithelium, (b) an intermediate connective tissue layer, and (c) an outer smooth muscle layer. In the adults, the urachus lies between two layers of umbilicovesical fascia along with the umbilical ligaments and the remnants of the obliterated umbilical arteries. This fascial investment tends to contain the spread of urachal disease between the peritoneum and transversalis fascia (Fig. 95.1C).

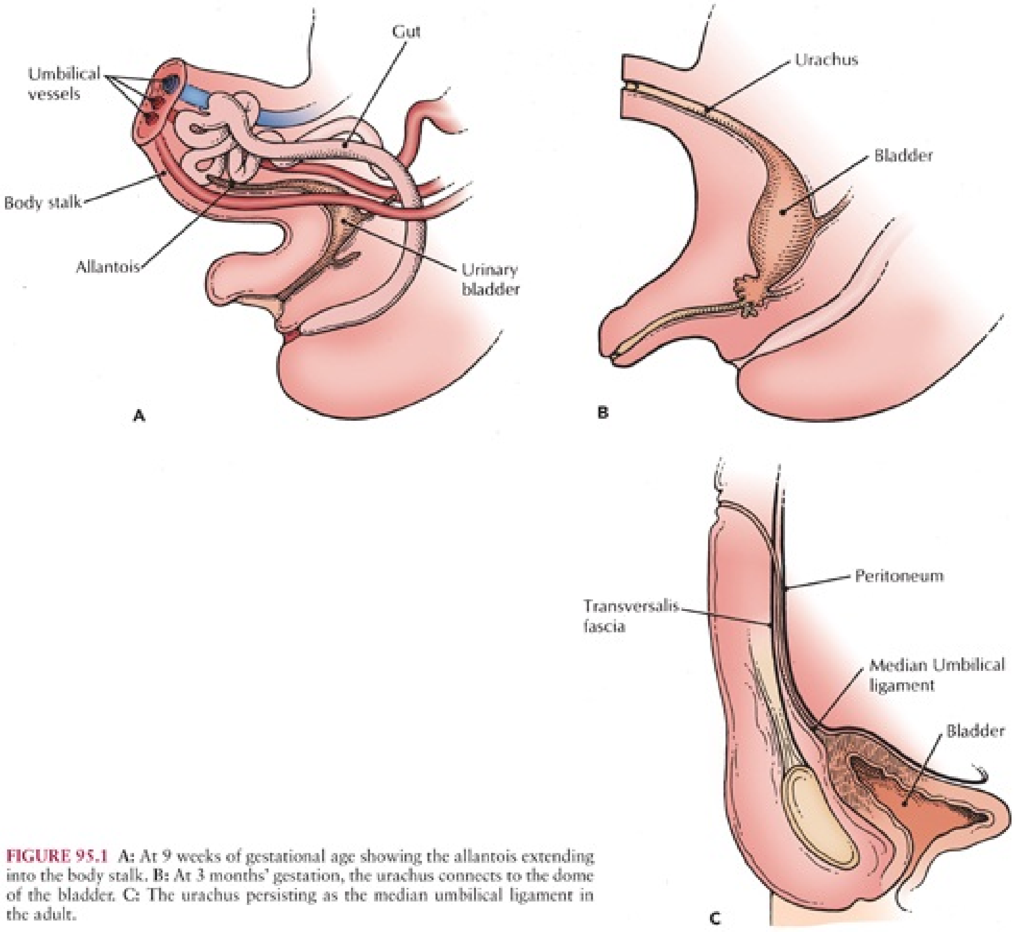

FIGURE 95.1 A: At 9 weeks of gestational age showing the allantois extending into the body stalk. B: At 3 months' gestation, the urachus connects to the dome of the bladder. C: The urachus persisting as the median umbilical ligament in the adult.

The urachus normally closes or involutes at approximately 32 weeks' gestation, and urachal anomalies in general represent an abnormality in the involution process. The anomalies that can result are characterized as patent urachus, urachal cyst, urachal sinus, and urachal diverticulum (Fig. 95.2) (1). Of these anomalies, urachal cysts (45%) and sinuses (37%) are the most commonly identified (2). With the level of detailed imaging available, incidental atretic, cordlike umbilical remnants are also commonly reported.

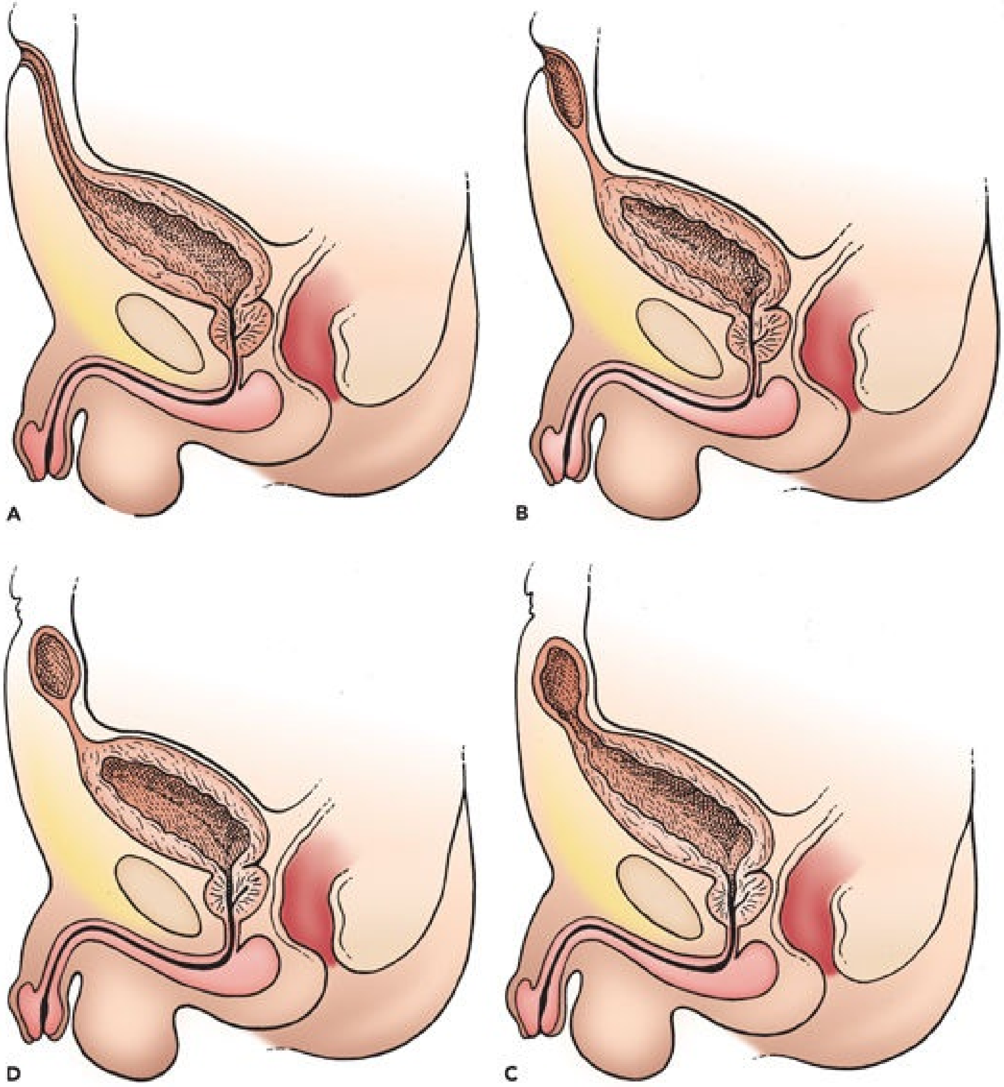

FIGURE 95.2 The four types of abnormalities involving the urachus. **A:** Complete patency to the umbilicus. **B:** A blind-ending urachal sinus open at the umbilicus but not complete to the bladder. **C:** A urachal cyst without communication to either the umbilicus or the bladder. **D:** Simple diverticulum from the dome of the bladder.

DIAGNOSIS

In general, the diagnosis of urachal anomalies requires clinical suspicion and a thorough physical examination. Further evaluation in patients with periumbilical drainage should include a sinogram, and those with a periumbilical mass should undergo ultrasonographic imaging. A voiding cystourethrogram may be required in selected patients (2,3).

Complete failure of the urachal lumen to close results in an open connection between the bladder and the umbilicus. Patients present with umbilical leakage of urine and often a protruding tissue mass (Fig. 95.3). The leakage may be more obvious during times of increased intra-abdominal pressure such as crying, coughing, or straining. The fluid may be analyzed for urea and creatinine to confirm its urinary quality. Two factors thought to contribute to a persistent patent urachus are bladder outlet obstruction and failure of the bladder to descend into the pelvis (4,5). With regard to bladder outlet obstruction, distal urinary obstruction is thought not to be the only causative factor because normally, the urachus closes developmentally before the urethra becomes tubularized (6). In addition, only 14% of patients with patent urachus demonstrate bladder outlet obstruction clinically, and it is uncommon for a patent urachus to be associated with posterior urethral valves. Alternatively, it can be seen with urethral atresia, as in prune belly syndrome. The diagnosis may be confirmed with a sonogram, although a voiding cystourethrogram may be more useful because it may rule out bladder outlet obstruction concurrently. Alternatively, methylene blue or indigo carmine may be instilled in either the bladder or the umbilical opening and detected in the umbilicus or bladder, respectively. The differential diagnosis for patent urachus includes patent omphalomesenteric duct, urachal sinus, omphalitis, granulation of a healing umbilical stump or umbilical granuloma, and infected umbilical vessel. An umbilical granuloma may be associated with a small amount of serous drainage and may appear similar to a patent urachus. It may have a smooth or irregular surface and may appear pedunculated. Normal imaging studies in these patients suggest the diagnosis of umbilical granuloma.

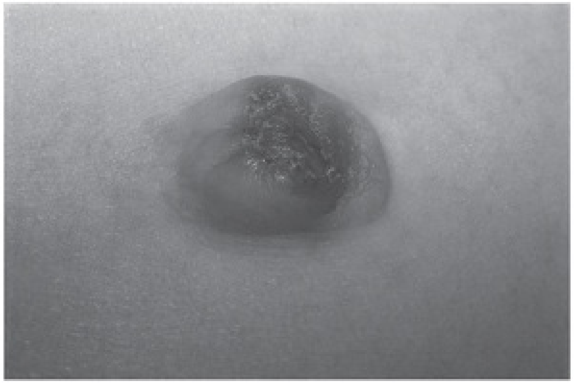

FIGURE 95.3 Patent urachus.

Segmental or incomplete closure of the urachal lumen may result in the formation of a urachal cyst (Fig. 95.4). The cyst usually forms in the proximal or lower third of the urachal remnant near the bladder (7). Usually, the cyst is lined with transitional epithelium and filled with serous fluid, but mucinous contents have been described. In general, urachal cysts are small and asymptomatic. Symptoms such as pain, erythema with localized swelling, and tenderness below the umbilicus may occur with infection and may be accompanied by chills, fever, irritative voiding symptoms, hematuria, and pyuria. Alternatively, symptoms may arise as the result of mass effect due to a large urachal cyst. These patients present with a sensation of abdominal fullness or pain, a mass, or irritative voiding symptoms due to compression of the bladder. Diagnosis is most easily confirmed by ultrasound or computerized tomography (CT).

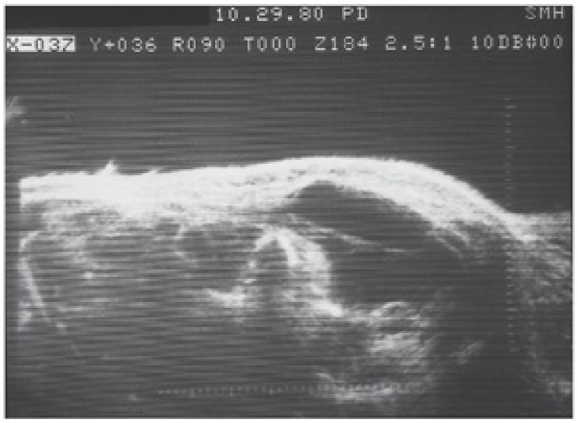

FIGURE 95.4 Abdominal ultrasound that demonstrates an infected urachal cyst.

Incomplete closure of the urachus may also result in a urachal sinus. This may be the result of a urachal cyst that extended either to the bladder or to the skin for drainage. Some urachal sinuses may alternate and at first drain at the umbilicus and then later into the bladder. Presenting symptoms may include periumbilical erythema and tenderness with intermittent drainage, umbilical irritation or granulation tissue, or symptoms of urinary tract infection. Clinical suspicion of a urachal sinus may be confirmed by a sinogram or ultrasound. A cystogram may show an irregular area at the dome of the bladder. Cystoscopy may demonstrate an inflamed area at the dome that may extrude purulent drainage.

A urachal diverticulum results from failure of closure of the urachus adjacent to the bladder, leaving a wide-mouth diverticulum at the dome of the bladder. The urachal diverticulum may or may not be associated with bladder outlet obstruction, as has been often reported in patients with prune belly syndrome. In general, aside from treatment for any coexisting bladder outlet obstruction, the urachal diverticulum requires no specific management, as it usually drains well.

Omphalomesenteric disorders may be confused with urachal anomalies. The omphalomesenteric duct is a fetal structure that connects the yolk sac and the gut. Incomplete closure of this tubular structure may lead to a patent omphalomesenteric duct, an omphalomesenteric sinus, or an omphalomesenteric cyst. A patent duct may be characterized by the drainage of intestinal fluid or fecal material. A sinogram should demonstrate a connection to the gastrointestinal tract.

Malignant lesions of the urachus are rare; however, the cancer risk does increase with advancing adult age (8). The most common sign of urachal cancer is hematuria. Patients may also present with a suprapubic mass, abdominal pain, irritative voiding symptoms, or mucus in the urine. The diagnosis may be made by identification of a filling defect at the dome of the bladder with calcifications on intravenous urogram or cystogram, CT, and cystoscopy with transurethral biopsy. Adenocarcinoma remains the most common malignancy (9); however, sarcoma, transitional cell carcinoma, leiomyoma, and teratoma have been reported as case reports.

INDICATIONS FOR SURGERY

Surgical management has been central to the treatment of urachal anomalies with the exception of infants younger than 6 months of age, in whom the anomalies may resolve spontaneously, and the wide-mouth diverticulum, which in general requires no treatment (10). However, recent studies have shown that even in older children, there is a subset of patients in whom spontaneous resolutions occurs, leaving observation as a viable treatment option (11). In the patient with a persistently patent urachus beyond 6 months of age, surgical excision should be considered because of the risk of recurrent infections; stone formation; and persistent umbilical drainage, excoriation, and pain.

Urachal cysts that are symptomatic due to size or infection also merit surgical treatment. Incidentally discovered small, asymptomatic urachal cysts may be excised at the time of discovery or watched for the development of symptoms or progressive enlargement. With infected cysts, initial antibiotic therapy with possible drainage followed by delayed excision may be required. Similarly, in the case of the urachal sinus, initial treatment should focus on the eradication of any infection before excision is considered. Nonspecific atretic umbilical remnants do not require excision.

With regard to omphalomesenteric ductal anomalies, referral to a pediatric surgeon is recommended for treatment. Small umbilical granulomas may be treated with silver nitrate application, whereas larger or refractory granulomas may require surgical excision. Treatment of urachal malignancy follows the principles of treatment for any malignancy of the bladder and is discussed elsewhere in this book.

SURGICAL TECHNIQUE

For the patent urachus, urachal cyst, alternating urachal sinus, or urachal diverticulum requiring correction, the patient is placed in a supine position. If possible, a small catheter, guide wire, or probe is placed through the patent urachus (Fig. 95.5). If nothing will pass, the tract may be stained with methylene blue for later identification. A Foley catheter should be placed in the bladder and the bladder distended with sterile saline to bring the anterior bladder wall up to the abdominal wall and, in doing so, push the peritoneum cephalad.

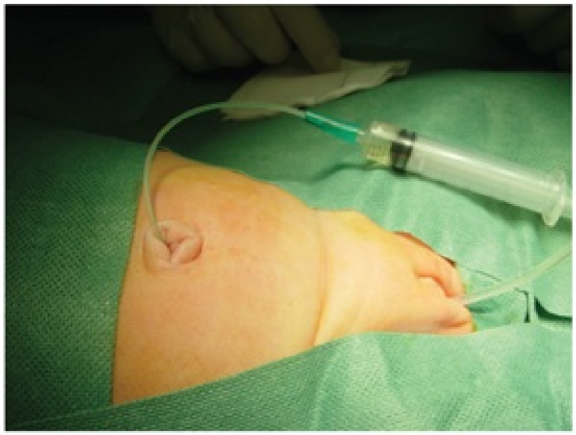

FIGURE 95.5 A catheter in place in a patent urachus.

The urachus may be approached via a vertical midline incision or a transverse infraumbilical incision one-half to two-thirds the distance from the symphysis pubis to the umbilicus (Fig. 95.6). Although the transverse infraumbilical incision will result in excellent exposure, alternatively, a vertical midline incision along the course of the urachus may be more direct and can allow for extension to the umbilicus in a cosmetic fashion, should this be required because of difficulty in procuring the umbilical end of the urachus or for any additional necessary procedures. The rectus fascia is opened and the dome of the bladder is identified. The urachus is identified and isolated. Once the proximal portion of the urachus is delineated, it is resected along with a small cuff of bladder to prevent a residual diverticulum. The bladder is then closed in two layers (Fig. 95.7). Dissection then proceeds toward the umbilicus. The operation is facilitated by identifying the proper plane of dissection between the peritoneum posterior to the urachus and the posterior rectus fascia, which is anterior to the urachus. In this same plane will lie the obliterated umbilical arteries, which may be ligated proximally on the bladder wall or distally at the umbilicus.

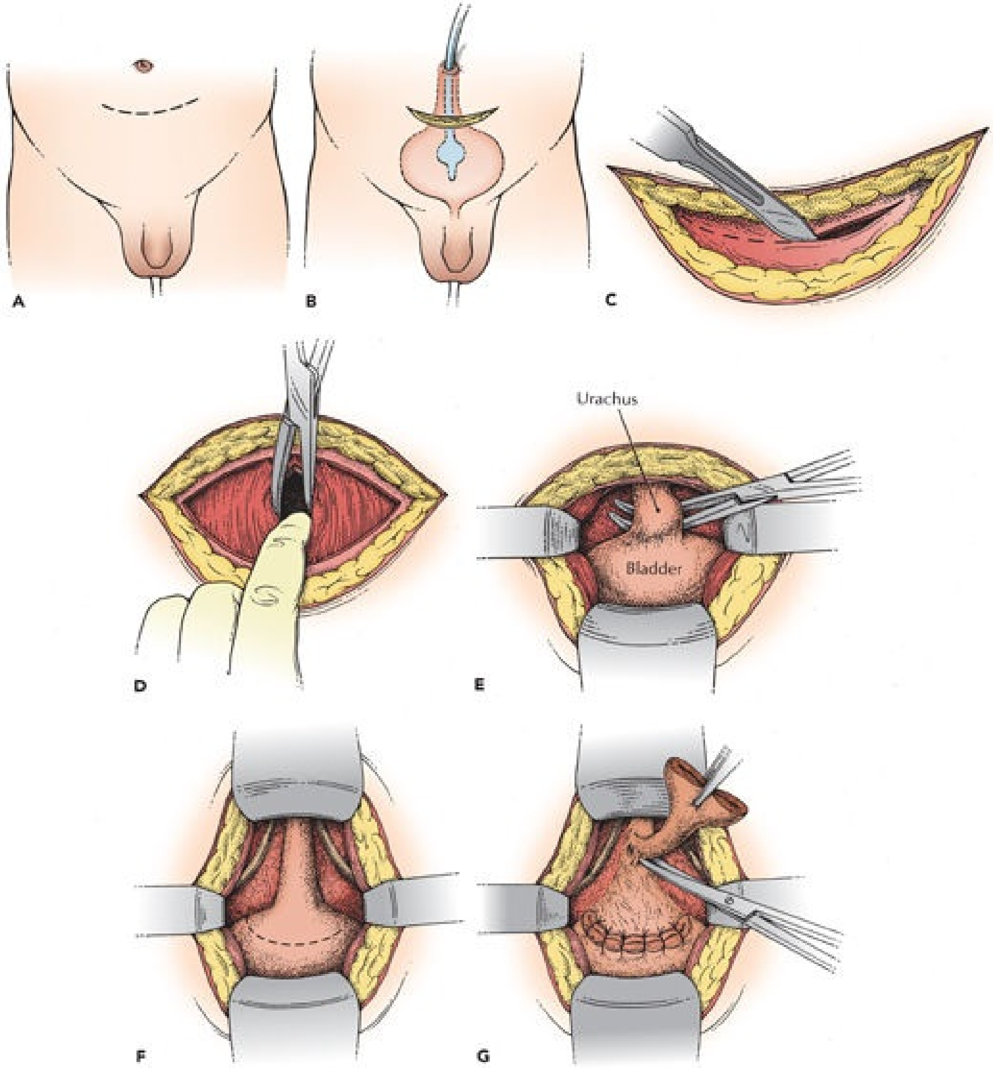

FIGURE 95.6 **A and B:** Typical transverse infraumbilical approach to the urachus. The catheter through the urachus can aid in identification of a patency. **C and D:** The fascia is divided transversely and the rectus muscle is parted in the midline, remaining preperitoneal. **E:** The urachus or urachal remnant can be separated from the peritoneum and identified in its proximal and distal extent. **F and G:** The urachus is resected with a cuff of bladder and the bladder closed in a watertight fashion. The urachus is removed completely out to the umbilicus if necessary.

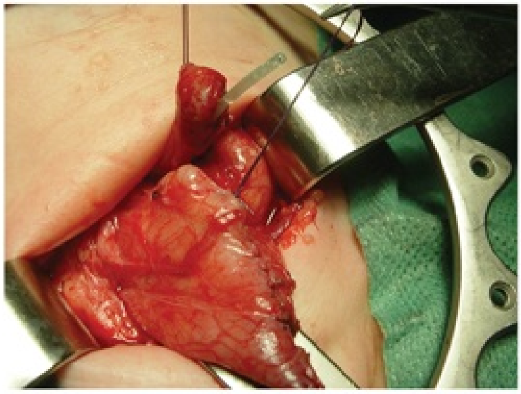

FIGURE 95.7 Intraoperative view after separation of the patent urachus (with catheter) after closure of the bladder.

Infected urachal remnant structures, such as urachal cyst or sinus, may present a more challenging dissection. In fact, it is sometimes advisable to drain a large infected urachal cyst initially percutaneously and allow a period for antibiotic therapy to reduce the local inflammation. Smaller infected urachal cysts or sinuses, however, can be managed safely as a single procedure. With these infected remnants, it may be impossible to dissect the urachus away from contiguous structures. For instance, a larger portion of the bladder may need to be removed with the infected urachal cyst. Similarly, one may find it impossible to separate the infected cyst or sinus from the underlying peritoneum. One should be extremely careful in identifying adherent loops of bowel that may have been involved in the inflammatory process and could easily be injured.

Once the urachus is completely dissected distally, it is excised or ligated at its obliterated point. The goal is to remove all urachal tissue and leave the umbilicus intact. If an umbilical hernia is present, it may be corrected concurrently. A catheter may be left in the bladder and a drain in the prevesical space postoperatively at the surgeon's discretion.

For the urachal sinus draining at the umbilicus, dissection is begun by circumscribing the sinus, again with the goal of preserving as much of the umbilicus as possible. The obliterated umbilical arteries are ligated as they are encountered. The tract is dissected to its termination and excised, and the area is drained because the sinus tract is usually infected.

An alternative to open surgical treatment is laparoscopic treatment. Laparoscopic treatment, including robotic treatment, has been reported in both children and adults with excellent visualization and access to the urachal remnant (Fig. 95.8) (12,13). Port placement may vary by surgeon preference; however, in general, the first port is placed using the open Hasson technique in the midline halfway between the umbilicus and the xiphoid process, and two additional ports are placed under direct vision on each anterior axillary line just above the umbilicus, creating an angle of approximately 45 degrees between the working ports. The procedure then follows the principles as outlined previously for open surgery.

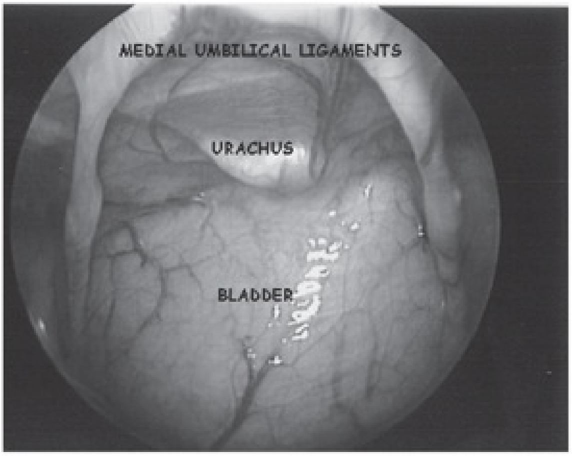

FIGURE 95.8 Typical view of the bladder and urachus during laparoscopy with a 30-degree telescope, showing the urachus, bladder, and medial umbilical ligaments.

OUTCOMES

Complications

Postoperative complications include persistent urinary drainage, which can be managed by prolonged bladder catheter drainage, and infection, which is generally superficial and responds well to antibiotic therapy. With laparoscopic procedures, the reported complications are most often port-related, and therefore, open Hasson technique for initial port placement is recommended.

CHAPTER 96 VESICAL NECK RECONSTRUCTION

JOHN C. POPE IV AND JOHN H. MAKARI

Prior to toilet training, the functions of the lower urinary tract include storage of urine at low pressure and good emptying. The result is protection of the upper tract and avoidance of urinary tract infection. Adequate outflow resistance is not necessary during that time but is eventually critical to achieve urinary continence. Congenital anomalies resulting in inadequate outflow resistance, and thus failure to achieve urinary continence, can in general be divided into two groups based on pathophysiology. In the first group, there is an anatomic or developmental abnormality where the bladder outlet is malformed and incapable of providing adequate resistance. This group would include patients with bladder exstrophy, bilateral single ectopic ureters, persistent cloaca, and rarely an extensive ureterocele. In the second, more common, group involving neurogenic dysfunction, the outlet is normally developed from an anatomic standpoint, but abnormal neurologic control results in inadequate function.

Diagnosis

When urinary continence is not achieved in children, the critical evaluation is video urodynamic study of the bladder and outlet. Parameters that need to be evaluated include sphincteric function, outflow resistance, detrusor function, and bladder compliance.

Monitoring of external urinary sphincter activity is helpful during studies of storage and emptying. Perineal surface electrodes are most widely used to evaluate the activity; however, in children with neurogenic dysfunction who tolerate placement, a concentric needle electrode or dual electrodes placed through a 25-gauge needle increases accuracy.

The functional length and pressure of the external sphincter is important and can be measured with urethral pressure profilometry. This measurement is technically challenging in a small child and there are no standard nomograms for urethral pressure profilometry to use in pediatric patients. Continuous monitoring of the urethral pressure during filling in the area of maximum resistance may demonstrate an etiology for incontinence. Some surgeons also use leak point pressure to evaluate outflow resistance during passive filling and performance of Valsalva maneuvers. Simultaneous fluoroscopic observation is advantageous.

Detrusor function should be evaluated by the cystometrogram, synergistic relaxation of the external sphincter on electromyography, urinary flow rate, and measurement of postvoid residual urine. Bladder compliance should also be evaluated with the detrusor pressure measured as the bladder is filled with warm saline or contrast (37°C) at a rate equal to or less than 10% of estimated or known bladder capacity. Such filling minimizes irritation of the bladder that may artifactually increase bladder pressure. Other artifacts that affect the measurement of compliance, such as urinary infections or low urethral resistance, should be eliminated to obtain the best results.

Before reconstructive surgery on the bladder is considered, the status of the patient's upper urinary tract should also be evaluated. Standard evaluation includes renal ultrasonography and serum electrolytes, including creatinine. If significant hydronephrosis is present, renography should be obtained to rule out obstruction. Vesicoureteral reflux should be sought on voiding cystourethrography, often at the time of video urodynamic evaluation. Any upper tract obstruction or reflux should be corrected at the time of lower urinary tract reconstruction.

Unfortunately, no test ensures that a patient will be able to void spontaneously and empty well after outlet reconstruction with or without bladder augmentation. All patients must be prepared to perform clean intermittent catheterization before considering reconstruction. The native urethra should, therefore, be examined for the ease and discomfort of catheterization.

INDICATIONS FOR SURGERY

If urinary continence is not achieved at an appropriate age in patients with congenital anomalies, and the patient has failed behavioral regimens such as timed voiding, all medical regimens, and other conservative therapies (e.g., intermittent catheterizations), then surgical intervention should be considered. The International Children's Continence Society recommends that surgical treatment should be tailored to the individual patient, with consideration being given to patient age, history, urodynamic findings, and coexisting disabilities (1). It is critical to ensure that the bladder is a compliant storage reservoir prior to any reconstructive procedure on the lower urinary tract. Increasing outflow resistance in the presence of inadequate bladder capacity would put the patient at significant risk for upper tract deterioration and febrile urinary tract infection. Determining the commitment of the patient and family to achieve a good result with reconstructive surgery, including a willingness to perform intermittent catheterization if necessary, is critical.

SURGICAL OPTIONS

In few areas of reconstructive urology, there are as many choices to consider as for bladder neck repair and as little consensus as to which repair is appropriate for a given patient or setting. One reason for the variety of choices is the wide range of patients and problems for which the procedures are used. In some cases, the procedure to increase outflow resistance may logically be chosen based on particular patient considerations, but the experience and confidence of the surgeon with a given technique also may play a significant role in the choice.

Conceptually, techniques to increase outflow resistance may be considered as one of two general types. The first set of repairs is used to improve the function of the native outlet, while the second set is designed to repair the anatomy and functionally alter the outlet. Several procedures that may provide benefit and are occasionally used include urethral suspensions, injection of bulking agents, artificial sphincters, and obliteration of the bladder neck.

One of the first bladder neck repairs to function in such a manner was the urethral suspension described by Marshall–Marchetti–Krantz, which has since been modified by numerous surgeons. While these procedures have been successful in treating stress urinary incontinence among neurologically normal females, they have had minimal effect and are rarely indicated for pediatric patients with congenital anatomic anomalies of the outlet or neurogenic dysfunction.

Recently, transurethral injection of bulking agents has been tried to improve the function of the existing outlet. Initially, the use of polytetrafluoroethylene and later bovine collagen were reported. More recently, the availability of dextranomer/hyaluronic acid copolymer has renewed interest in injection therapy for increasing bladder outlet resistance and for correction of sphincteric incontinence. Injection therapy is relatively simple, avoids any incision, but has met with limited results for significant outlet anomalies (2). Further, the durability of this approach is a concern, as declining rates of dryness and/or improvement are observed even years after treatment (3). Injection therapy may, however, be useful after primary repairs in patients who have some persistent incontinence (3–5).

The most definitive procedure to improve the function of the outlet as it exists is placement of an artificial urinary sphincter. This group of procedures would seem appropriate for patients with a normal or near-normal outlet from an anatomic standpoint and to have little role for patients with significant anatomic anomalies such as bladder exstrophy or bilateral single ectopic ureters. Even with improved durability in newer models, the average life span of an artificial urinary sphincter is 8 years. Therefore, when placed in a pediatric setting, future revision surgery is inevitable (6).

The ultimate procedure to increase outlet resistance is division and closure of the bladder neck. Effective closure requires extensive mobilization of the bladder and bladder neck away from the urethra with interposition of omentum. It must be accompanied by construction of a continent abdominal wall stoma for bladder catheterization and effectively moves the reconstruction into the realm of continent urinary diversion. Division of the bladder neck has in general been reserved for complex patients who have failed multiple prior procedures to effectively increase outflow resistance; however, it may be performed in select patients as primary definitive management. Extremely high success rates have been reported for both primary or secondary management when the above principles are followed (7).

SURGICAL TECHNIQUE

Fascial Sling for Bladder Neck Suspension

In adults, fascial slings may be performed transvaginally, and a small patch of fascia is secured with suspension sutures. In pediatric patients with congenital anomalies, fascial slings have in general been placed from above, often at the time of bladder augmentation. Before placement, the pelvic floor is cleared of overlying fatty tissue and a 2-cm incision made through the endopelvic fascia on either side of the bladder neck and proximal urethra (Fig. 96.1A). This area may be identified by palpation of a transurethral catheter and balloon seated at the bladder neck. Using blunt dissection, a plane is developed between the bladder neck and vagina in girls or rectum in boys (Fig. 96.1B). This plane may at times be more easily developed from the cul-de-sac by dissecting behind the bladder and ureters from above. With a difficult dissection, it may be useful to open the bladder, in particular if bladder augmentation is planned.

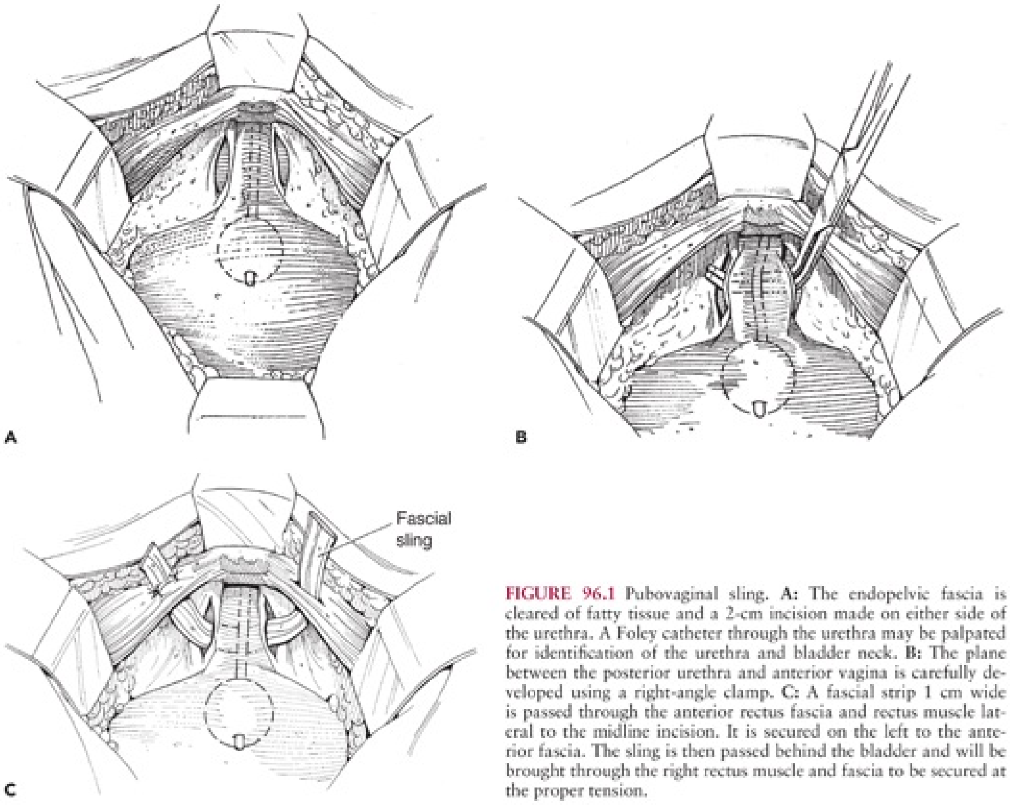

FIGURE 96.1 Pubovaginal sling. **A:** The endopelvic fascia is cleared of fatty tissue and a 2-cm incision made on either side of the urethra. A Foley catheter through the urethra may be palpated for identification of the urethra and bladder neck. **B:** The plane between the posterior urethra and anterior vagina is carefully developed using a right-angle clamp. **C:** A fascial strip 1 cm wide is passed through the anterior rectus fascia and rectus muscle lateral to the midline incision. It is secured on the left to the anterior fascia. The sling is then passed behind the bladder and will be brought through the right rectus muscle and fascia to be secured at the proper tension.

Once the proper plane is developed and the appropriate length of graft determined, a rectus abdominis fascial strip 1 cm in width and appropriate in length is harvested. The fascia may be taken in either a vertical or horizontal fashion depending on the initial incision. Fascia from other sites has been utilized but requires a second incision. Autologous cadaveric tissue or biodegradable scaffolds may also be used.

All of the grafts are in general brought through the rectus muscle and anterior rectus fascia on either side and approximated to the anterior rectus fascia using permanent sutures (Fig. 96.1C). If long enough, the two limbs of the sling may also be approximated to each other superficial to the fascia.

In patients with stress incontinence, the sling is placed tightly enough to maintain the proximal urethra and bladder neck in the appropriate anatomic position. Too snug of placement in such a setting may impede spontaneous voiding. When used for patients with neurogenic dysfunction who will not rely on spontaneous voiding, the sling may be pulled up more tightly to improve compression of the bladder neck and proximal urethra. If intermittent catheterization postoperatively will be performed through the native urethra, intraoperative catheterization should be repeated frequently to make sure the fascial sling is not placed so tight as to impede catheterization.

A commonly employed modification of the traditional suspensory sling, used by many reconstructive surgeons, is the wrap-around sling. In this modification, the sling material (fascial or other) is wrapped around the bladder neck completely prior to securing the free ends in the manner of a suspensory sling. The theoretic advantage of this approach is greater coaptation of the bladder neck tissue than with a traditional sling while preserving the ability to perform intermittent catheterization per urethra (8).

Young–Dees–Leadbetter Bladder Neck Repair

The Young–Dees–Leadbetter bladder neck repair is typically performed in the setting of exstrophy–epispadias complex in the modern staged repair of exstrophy and after epispadias repair. Ideally, it is performed when a patient's bladder capacity under anesthesia by gravity cystography is at least 85 mL and when the patient can participate in a strict postoperative voiding program (9). After bladder exstrophy closure, the procedure is typically performed through a lower midline incision. For patients with epispadias who do not require augmentation, the reconstruction may be done through a Pfannenstiel incision.

The anterior bladder is opened. This incision is carried as far distally into the proximal urethra as possible. Splitting of the intersymphyseal band with subsequent closure may allow closure and tapering of the proximal urethra. Virtually all exstrophy patients require antireflux surgery, and typically, the ureteral hiatus is initially quite low in the bladder. The ureters are mobilized and reimplanted into the bladder 3 to 4 cm more cephalad in location. Typically, the ureters are reimplanted with a cross-trigonal technique, although the tunnels may even be angled upward in a cephalad direction from the new hiatus. A 12- to 15-mm wide strip of mucosa is preserved in the posterior midline of the urethra and bladder trigone for reconstruction of the neourethra. Parallel incisions through mucosa are made on either side of this strip and the triangles of trigone mucosa on either side excised (Fig. 96.2A). Submucosal infiltration of dilute epinephrine in those two areas may aid in excision and decrease bleeding. The midline strip of mucosa and subsequent neourethra are typically made 4 to 6 cm long depending on how much proximal urethra is exposed and reconstructed. The midline strip is tubularized over an 8 Fr catheter using absorbable sutures to approximate the edges. This tubularization may be done with interrupted or running absorbable sutures but should be tension-free (Fig. 96.2B). Small purchases of the adjacent superficial muscle of the trigone may be included with the mucosa for strength. The closure is easier to begin distally and finished cephalad. The lateral flaps of trigone muscle are then wrapped over the neourethra in an overlapping fashion. To do so without tension, the muscle must be incised transversely at the cephalad margin of the mucosal excision. One flap of muscle is wrapped over the neourethra and approximated to the underside of the other muscle flap using interrupted, absorbable mattress sutures. The second flap of muscle is then wrapped over the first and approximated to the outside of the muscle, again with absorbable sutures (Fig. 96.2C). A soft urethral catheter is left in place during healing but should be secured so as to avoid tension on the neourethra. Ureteral stents or catheters are often left in place because of potential edema. The bladder is closed in two layers.

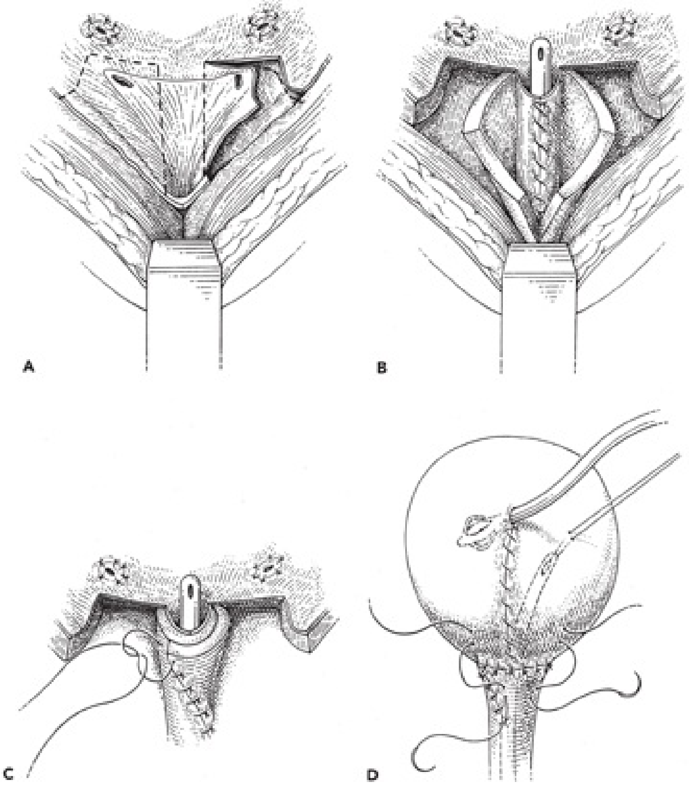

FIGURE 96.2 Young–Dees bladder neck repair. A: The trigone mucosa is incised to leave a posterior, central strip of mucosa 15 mm wide. The triangles of mucosa on either side are excised. The ureters have previously been reimplanted in a more cephalad position. B: The central mucosa strip is tubularized using a running absorbable suture. C: The lateral trigone muscle flaps are closed in an overlapping fashion around the neourethra. D: After completion of the bladder and urethral closure, several pairs of suspension sutures secure the urethra and bladder to the underside of the intersymphyseal band and lower abdominal wall.

If bladder augmentation is required, the bladder should be closed to itself for a short distance from the urethra prior to applying the bowel segment. A clear demarcation between the neourethra and bladder can often be seen after closure. Care should be taken that there is effective closure of the urethra and bladder at this junction. The bladder may tend to kink over the urethra at that level, and the neourethra and new bladder neck should be suspended to the undersurface of the intersymphyseal band and lower abdominal wall using several pairs of sutures as described for the Marshall–Marchetti–Krantz procedure (Fig. 96.2D).

Alternatively, Leadbetter described full-thickness, parallel incisions through the trigone mucosa and muscle on either side of the central strip. These incisions, again, made 12 to 15 mm apart, are started distally at the old bladder neck and continued in a cephalad direction for 4 to 5 cm (Fig. 96.3A). The central strip of mucosa is tubularized with interrupted or running absorbable sutures. The muscle of the central strip is closed as a second layer. If the incision through the muscle is made slightly wider than on the mucosa, the muscle may be approximated in an overlapping manner, but to a lesser degree than that described by Young and Dees. The lateral triangles of full-thickness trigone are left in continuity with the bladder and included in that closure (Fig. 96.3B).

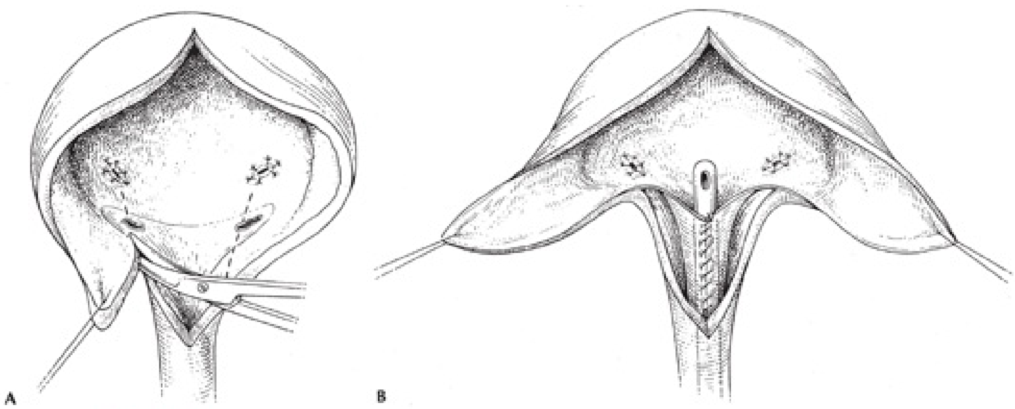

FIGURE 96.3 Leadbetter modification of Young–Dees–Leadbetter bladder neck repair. A: Full-thickness parallel incisions are made through the trigone mucosa and muscle, leaving a central strip 15 mm wide. B: The mucosa of the neourethra is tubularized using a running absorbable suture. The muscle is then closed. The lateral flaps of trigone are left in continuity with the bladder.

Kropp Urethral Lengthening Procedure

The bladder is exposed through a lower midline incision and the bladder neck is identified by palpation of a catheter placed through the urethra. A rectangular, full-thickness strip of anterior bladder is marked and incised. This strip is based at the bladder neck and should be left in continuity with the urethra (10). The incised strip measures 6 cm in length and 2 cm in width (Fig. 96.4A). Stay sutures placed at the cephalad corners of the strip aid in mobilization. The bladder cephalad to the strip is open in the midline. After anterior incision, the catheter is pulled over the pubis to expose the posterior bladder neck. This allows identification of the ureteral orifices, which are catheterized. If reflux is not present and the space between the orifices is adequate for urethral tunneling, ureteral reimplantation may not be necessary. The ureteral stents are often left in place for 4 to 5 days due to edema. Posterior incision of the mucosa at the bladder neck is performed using cutting current with the electrosurgical cautery to completely separate the neourethra from the bladder at the mucosal level. Further dissection through the posterior muscle in the midline is performed to allow smooth tubularization of the neourethra. Posterolateral musculoadventitial tissue at the 5 and 7 o’clock positions is left intact so that the bladder remains anchored in a caudal position. This eventually ensures that the tubularized neourethra reaches well into the bladder lumen to achieve an effective flap valve.

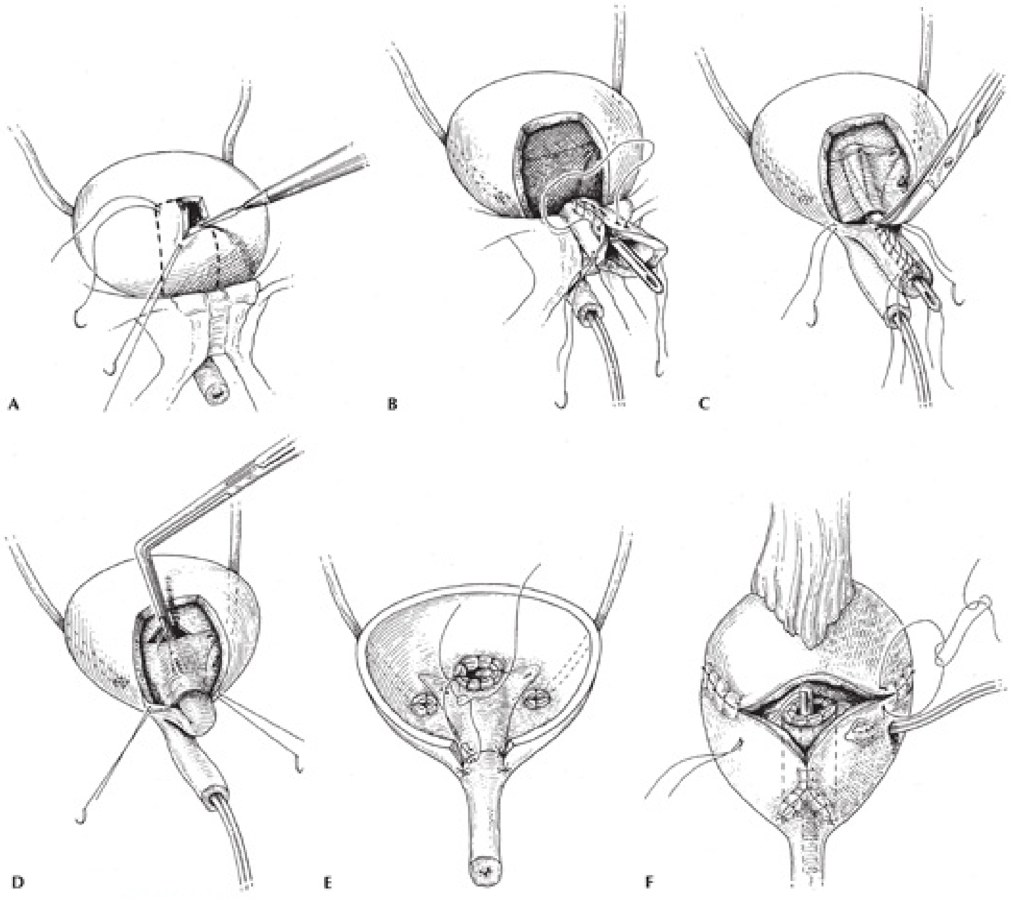

FIGURE 96.4 Kropp procedure for urethral lengthening. A: A 6 cm × 2 cm flap of anterior bladder is mobilized in continuity with the urethra. B: The flap is tubularized. C: The posterior mucosa is incised transversely at the bladder neck and a tunnel created for the neourethra from the old bladder neck to a position above the interureteric ridge. D: The neourethra is brought through the tunnel, taking care that it does not kink. Note that the posterolateral musculoadventitial tissue is intact and keeps the bladder anchored distally. E: The proximal end of the neourethra is trimmed flush with its orifice in the bladder. The end is approximated to the vesical mucosa circumferentially. F: The bladder is carefully closed distally by approximating the bladder muscle and mucosa to the adventitia of the neourethra. The neourethra extends well into the lumen of the bladder to create an effective flap valve. Bladder augmentation is performed when necessary.

The anterior bladder flap in continuity with the urethra is tubularized by approximating the mucosa and then muscle with continuous absorbable sutures (Fig. 96.4B). This closure is again begun distally and continued in a proximal or cephalad direction.

A submucosal tunnel is developed from the posterior bladder neck to a position several centimeters above the interureteric ridge (Fig. 96.4C). The more cephalad portion of this tunnel is easily developed from above and the more distal or caudal portion typically from the bladder neck (Fig. 96.4D). This tunnel must be made wide enough that the neourethra can be brought through in a nice smooth course. Care must be taken that there is no kink whatsoever at the entrance of the neourethra into the bladder at the area of the old bladder neck. Any kinking at that level will result in difficult catheterization.

Alternatively, the mucosa in the posterior midline may be incised for the entire length for the proposed tunnel. The mucosa on either side is then mobilized to create a wide trough into which to place the urethra. The mucosa from either side is then approximated to the adventitia of the neourethra and will eventually grow to cover it completely. The tubularized neourethra should not be redundant in length relative to the submucosal tunnel to minimize the risk of difficult catheterization. If necessary, excess length may be excised. The proximal end of the neourethra is approximated to the bladder mucosa at its orifice with interrupted absorbable suture (Fig. 96.4E). Distally, the lateral and anterior bladder is securely approximated to the adventitia and muscle of the urethra (Fig. 96.4F). This closure should be performed as distally as possible on the urethra to avoid foreshortening of the tunnel within the bladder. Ease of catheterization through the neourethra should be tested at each step of reconstruction and any problems addressed when noted. If augmentation of the bladder is necessary, the incision is extended and the peritoneal cavity entered. A short segment of distal bladder should be closed to itself up from the urethra prior to placing the segment for augmentation. A soft urethral catheter is left in place per urethra during healing. The catheter should be secured so as to avoid any pressure on the reconstructed urethra. The catheter is usually left in place for 4 to 6 weeks during healing, often with a suprapubic cystotomy tube as well. After a static cystogram demonstrates no leakage and good healing, self-catheterization may begin.

Pippi Salle Urethral Lengthening Procedure

In an effort to achieve the effective flap valve created with the Kropp procedure while decreasing the risk for problems with catheterization, Salle et al. (11) described a modification for urethral lengthening. The anterior bladder wall flap is used as an onlay and eventually contributes half of the circumference of the neourethra. Therefore, a full-thickness anterior bladder flap 5 cm × 1 cm is mobilized in continuity with the bladder neck (Fig. 96.5A). One millimeter of mucosa on either side is excised to avoid overlapping suture lines. Two parallel incisions through the mucosa of the trigone are made so as to leave a central strip of mucosa 8 to 10 mm in width and 5 cm in length. The lateral trigone mucosa on either side is mobilized to eventually close over the neourethra. The mucosa of the anterior flap is approximated to the midline strip of trigone mucosa using a running absorbable suture started distally (Fig. 96.5B). The muscle of the anterior flap is approximated to the superficial muscle on either side of the central mucosa (Fig. 96.5C). The trigone muscle on either side of the posterior mucosal strip may be incised superficially to provide an edge to which to sew the muscle of the anterior flap. Closure of the lateral mucosa of the trigone over the reconstructed neourethra creates a flap valve and a neourethra with an intact posterior wall (Fig. 96.5D and E). Distally, the muscle and mucosa of the bladder neck are approximated to the lateral and anterior adventitia and muscle of the neourethra as distally as possible. Proximally, the neourethra should extend well into the lumen of the bladder to create an effective flap-valve mechanism for continence. The neourethra and ureters are often stented temporarily in a manner similar to that described for the Kropp procedure (Fig. 96.5F).

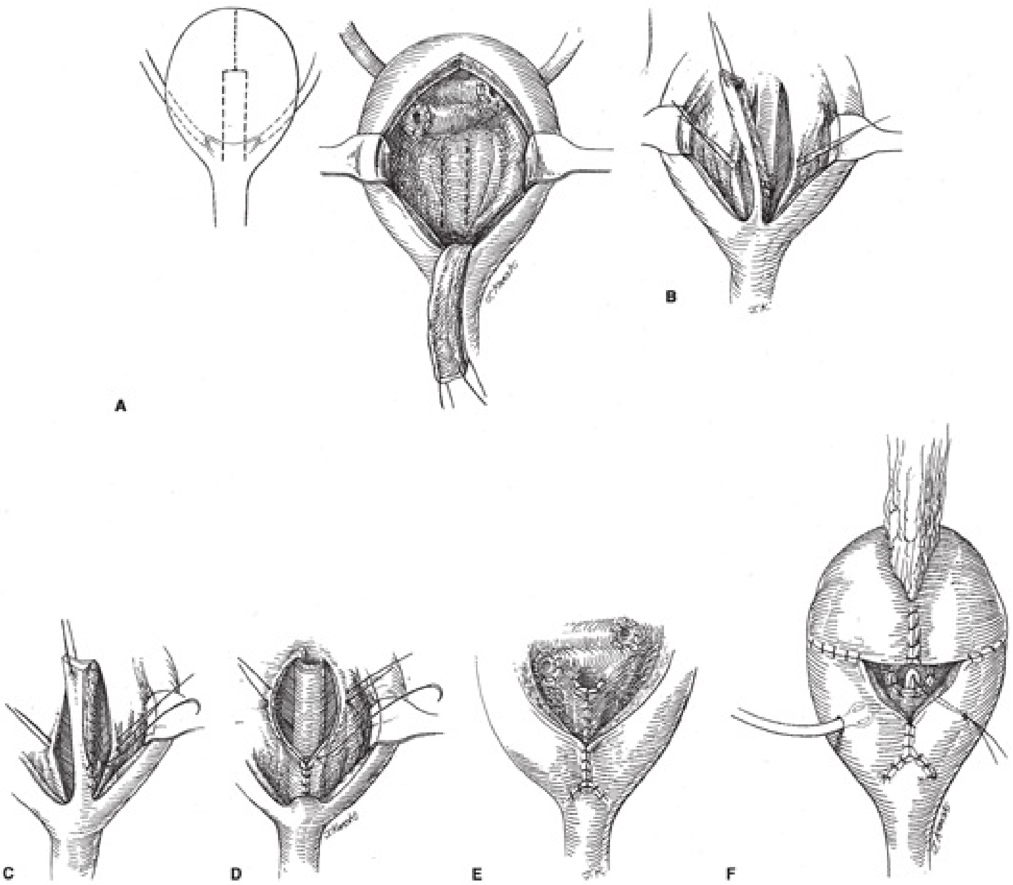

FIGURE 96.5 Pippi Salle procedure for urethral lengthening. **A:** A full-thickness, anterior bladder flap 5 cm × 1 cm is marked and incised. Parallel incisions through the trigone mucosa posteriorly leave a central strip of similar length and width. **B:** The lateral trigone mucosa is mobilized to cover the neourethra. The mucosa of the anterior flap is approximated to the edge of the central mucosal strip using a running absorbable suture. **C:** The muscle of the anterior flap is approximated to the superficial trigone muscle on either side of the mucosal closure. **D:** The lateral mucosa is closed over the neourethra. **E:** The distal bladder is closed to itself and carefully to the urethra. **F:** Bladder augmentation is performed when necessary.

Minimally Invasive Surgical Approaches

The relatively recent integration of robot-assisted laparoscopic surgery (RALS) into pediatric urology practice has facilitated development of minimally invasive complex reconstructive procedures. In this domain, initial reports describe feasibility and safety of RALS Mitrofanoff catheterizable conduit, Leadbetter/Mitchell bladder neck reconstruction, bladder neck sling, and augmentation cystoplasty. Theoretic advantages of RALS include decreased hospitalization, decreased analgesic requirements, improved cosmesis, and improved visualization. Data from large series or with long-term follow-up from RALS for bladder neck procedures is not yet available (12,13).

OUTCOMES

In the pediatric population, fascial slings have been used most extensively in patients with neurogenic sphincter incompetence. Long-term success with slings in that population has varied greatly, from 40% to 100%. Success rates have varied so much that it is not clear that any particular modification of the sling configuration results in any difference in terms of continence. Fascial slings have been used more extensively and with better results in girls with neurogenic dysfunction in whom the continence rate may reach 75% (14). The primary factor predictive of success has been thought to be concomitant enterocystoplasty to ensure a compliant bladder; although recently, the efficacy of sling and catheterizable conduit alone has emerged as an area of investigation (15). Patients undergoing bladder neck sling without enterocystoplasty are more likely to require postoperative anticholinergic therapy to maintain safe reservoir characteristics and are apt to have shorter catheterization intervals to maintain continence than those patients who undergo simultaneous enterocystoplasty (16). Sling placement does not in general interfere with the ability to perform intermittent catheterization, which is usually necessary in the patient population, but many surgeons will perform continent catheterizable conduit procedures (Mitrofanoff, Monti, etc.) simultaneously to facilitate independent catheterization.

The Young–Dees–Leadbetter bladder neck repair has been used most commonly in the classic staged reconstruction for bladder exstrophy. Continence with spontaneous voiding has been achieved in up to 80% of patients with exstrophy and may be even higher for patients with epispadias (17). Other authors have reported a lower continence rate, and even among patients considered dry, clinical and urodynamic problems related to poor emptying may exist (18). When used for patients with neurogenic dysfunction and denervated sphincter muscle, the procedure initially resulted in continence in approximately 25% of patients but can be improved to almost 70% if combined with bladder augmentation (19,20). Due to the high percentage of additional procedures required, the repair has in general fallen out of favor for patients with neurogenic dysfunction. Furthermore, reliable catheterization through the urethra after a Young–Dees–Leadbetter repair may be difficult.

The urethral lengthening procedures have primarily been used in boys with neurogenic bladder dysfunction. Using the technique described by Kropp, continence has been achieved in 75% to 90% of such patients (10,21). Difficulty with catheterization has been reported in 40% of male patients in some series, although that incidence may be lowered when the posterior urethra is not totally transected (21). Because of concerns about the potential problem with catheterization, some surgeons prefer routine construction of a continent catheterizable stoma (22). A significant incidence of new reflux has been apparent in some series using the Kropp technique (22). Using Salle et al.'s modification, less trouble with catheterization in males has been noted, although continence rates have not been quite as high (23,24). Urethrovesical fistula and partial necrosis of the intravesical neourethra have on occasion resulted in incontinence after the repair, and widening the base of the anterior flap at the level of the bladder neck may decrease those problems.

Recent work has begun to address the impact of lower urinary tract reconstruction on health care–related quality of life for patients with neurogenic bladder and exstrophy–epispadias complex. It is not possible to determine the specific effect of vesical neck reconstruction on quality of life from the available literature because vesical neck reconstruction is often performed in conjunction with or in a series of other reconstructive procedures. The limited existing literature, however, has not demonstrated that attainment of urinary continence leads to significant improvement in overall quality of life in either of these patient groups. Further investigation with other metrics or larger sample sizes may demonstrate a positive effect of lower urinary tract reconstruction (25,26).

Complications

Relatively common clinical problems after bladder neck reconstruction include urinary tract infection and bladder stones. Both may occur in exstrophy patients after Young–Dees–Leadbetter bladder neck repair due to poor emptying (18) but are even more common among patients with neurogenic dysfunction requiring intermittent catheterization, in particular if bladder augmentation has been performed. The urethral sling and the artificial urinary sphincter possess unique complications that are related to their periurethral placement or mechanical and synthetic characteristics. Urethral erosion, although low with fascial slings and 5% to 15% of artificial urethral sphincters, is most commonly related to infection. Erosion is a leading cause for permanent failure of the artificial urinary sphincter. Additionally, mechanical problems or tissue atrophy at the cuff lead to artificial urinary sphincter revision rates of approximately one in four in modern series (27). Although highly effective, bladder neck division carries the unique risk of urethral incontinence secondary to vesicourethral fistula. This complication can require multiple interventions to correct and is best prevented by radical mobilization of the bladder neck posteriorly and tissue interposition between the transected bladder neck and proximal urethra. Effective interposition can be achieved with local tissue, omental flaps, rotational muscle flaps, or biosynthetic materials (28).

It is important to perform routine surveillance for hydronephrosis of the upper urinary tract with ultrasonography after any form bladder neck repair. This is particularly true among patients with neurogenic dysfunction if they have not undergone bladder augmentation. Even if the bladder appeared adequate prior to outlet reconstruction, up to one-quarter of patients may develop bladder hostility after an increase in outlet resistance, which may silently threaten the kidneys (29).

CHAPTER 97 SURGERY FOR POSTERIOR URETHRAL VALVES

ROSALIA MISSERI AND KENNETH I. GLASSBERG

A posterior urethral valve (PUV) is the most common cause of congenital bladder outlet obstruction in boys. It is associated with a dilated posterior urethra, poor urinary stream, and incomplete bladder emptying. Bilateral hydroureteronephrosis of varying degrees is almost always present and frequently accompanied by vesicoureteral reflux and/or bladder diverticula.

DIAGNOSIS

With the widespread use of antenatal ultrasound, PUVs are often diagnosed prenatally. The condition is suspected in utero when a male fetus is found to have bilateral hydroureteronephrosis and a thick-walled bladder that does not empty completely on sonography. In addition, there may be a keyhole deformity noted on sonography. This is noted when a dilated bladder and posterior urethra is seen. In severely affected fetuses, oligohydramnios, pulmonary hypoplasia, and Potter syndrome may occur. Newborns may present with abdominal masses representing a distended bladder or hydronephrotic kidney, dry diapers, nonspecific gastrointestinal symptoms, respiratory distress, or urinary ascites. Younger boys usually present with urinary tract infection, respiratory distress, abdominal distention, sepsis, or azotemia, while older boys may present with dysfunctional voiding symptomatology, incontinence, poor urinary stream, urinary tract infections, or hematuria.

If a PUV is suspected in an infant based on antenatal ultrasound evaluation, prophylactic antibiotics should be initiated, and the bladder should be drained with a 5Fr or 8Fr feeding tube securely taped in place with a clear transparent dressing. Positioning is best confirmed with an abdominal radiograph as the tube may coil in the dilated posterior urethra. The feeding tube is left in place until a voiding cystourethrogram (VCUG) is obtained to make the diagnosis. A baseline postnatal ultrasound is routinely obtained to evaluate the renal parenchyma and degree of hydronephrosis. Serum chemistries, blood urea nitrogen and creatinine, should be obtained after 24 hours of life because labs in the first 24 hours reflect the mother's serum values. In patients with severe hydroureteronephrosis and/or azotemia, the catheter should be left in place until the azotemia resolves/stabilizes and hydroureteronephrosis improves.

The VCUG of a boy with a PUV will reveal a posterior urethra that appears dilated, often taking on a "shield shape" or squared-off appearance. The bladder neck is often clearly demarcated and may appear as a thick collar, and the urethra distal to the obstruction will appear less full or more narrow than normal (Fig. 97.1). Vesicoureteral reflux may be present in about 25% to 50% of boys with vesicoureteral reflux and is most often related to bladder outlet obstruction due to PUVs (1–4).

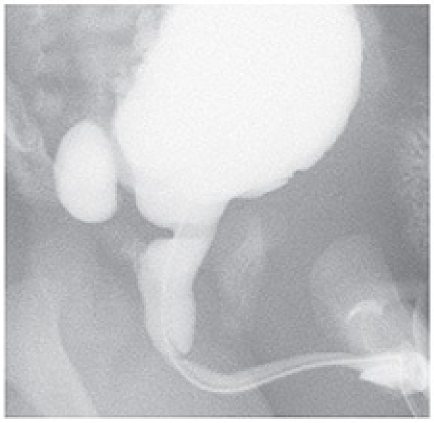

FIGURE 97.1 VCUG of newborn with PUVs. Note the dilated posterior urethra and bladder diverticulum.

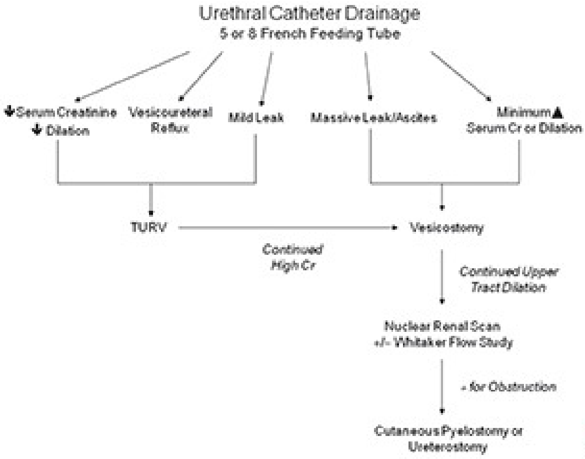
INDICATIONS FOR SURGERY

Although some controversy still exists as to what to do once the bladder has been drained with a catheter, almost all valves are currently treated with transurethral ablation (Fig. 97.2). For severe hydronephrosis, some report better long-term outcomes when these infants are temporarily diverted, while most feel that primary valve ablation is the treatment of choice (5). For those who believe temporary diversion is best, many methods of vesical and supravesical diversion of the obstructed bladder exist.



Urethral Catheter Drainage
5 or 8 French Feeding Tube
↓ Serum Creatinine ↓ Dilation
Vesicoureteral Reflux
Mild Leak
Massive Leak/Ascites
Minimum ▲ Serum Cr or Dilation
TURV
Vesicostomy
Continued High Cr
Continued Upper Tract Dilation
Nuclear Renal Scan +/- Whitaker Flow Study
+ for Obstruction
Cutaneous Pyelostomy or Ureterostomy

ALTERNATIVE THERAPY

There is no effective alternative to surgical therapy. Antenatal attempts at valve ablation, transurethral stenting, and percutaneous vesicoamniotic shunting are offered at few select centers and remain quite controversial.

SURGICAL TECHNIQUE

Transurethral Valve Ablation

Valve ablation is most commonly accomplished transurethrally. The size of the infant's fossa navicularis usually limits the size of cystoscope that may be used. Typically, a 7.5Fr or 8.5Fr scope is used in infants, while a larger scope may be used in older children. The cystoscope should be well lubricated and advanced under direct vision. Gentle dilation of the distal urethra may be required to advance the cystourethroscope. With the bladder full and applying gentle suprapubic pressure, the valve leaflets are more easily seen coming off the verumontanum and extending distally to fuse anteriorly (Fig. 97.3). The goal of valve ablation is to disrupt the leaflet, hence destroying the obstruction.

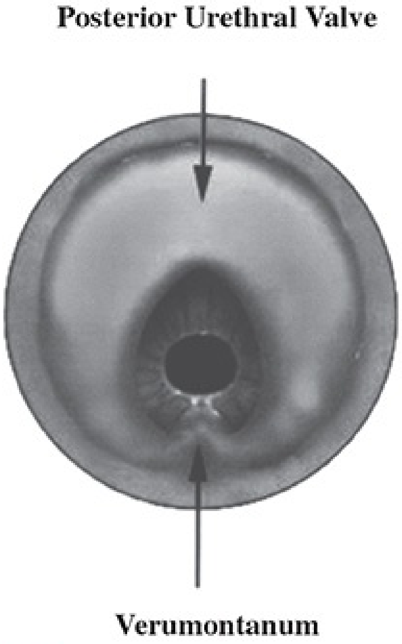

FIGURE 97.3 Cystoscopic appearance of type 1 PUV.

A PUV may be ablated or incised in several ways. The decision to proceed with one technique over another is often based on surgeon preference, availability of equipment, and the size of the child's urethra. The valve may be ablated using a 3Fr Bugbee electrode through a cystoscope. Alternatively, the wire insert of a 3Fr ureteral catheter with the distal end connected to electrocautery may be used. All but the tip of the wire is insulted by the catheter to avoid thermal injury. Once in position, the Bugbee or wire is advanced and pushed into the valve at the 5 and 7 o'clock positions while employing a cutting current of 20 to 25 W. (Note that power settings may vary from machine to machine.) When using cautery, care must be taken to ensure that thermal energy is targeted at the valves alone. The holmium:YAG laser may also be used to incise the valves (6). These techniques may be particularly useful if the infant resectoscope is too large for the child's urethra.

When using a small pediatric resectoscope, the valves are incised with a right-angle hook, loop electrode, or hook-shaped cold knife. When using a loop electrode, a narrow, more oblong loop is preferable to a wider, more circular loop. Some debate exists as to the best location for valve incision. Williams et al. (4) preferred incising at the 12 o'clock position, while Gonzales (7) advocated cutting at the 4, 8, and 12 o'clock positions. However, many prefer incising at the 4 to 5 o'clock and 7 to 8 o'clock positions using a hook-shaped cold knife or with the cutting current set at 20 to 25 W pure cut.

Additional methods of PUV ablation have also been described for use in patients with small-caliber urethras that do not allow passage of even the smallest cystoscope. With the advent of smaller scopes, perineal urethrostomy is now rarely necessary for valve ablation. Zaontz and Firlit (8) have described percutaneous antegrade ablation of PUV as well as antegrade incision of PUV in infants with small-caliber urethras. At our institutions, small or premature infants who are critically ill and cannot be successfully catheterized have had percutaneous suprapubic catheters placed at the bedside.

Once the valves are endoscopically ablated, the bladder should be cystoscoped to evaluate for diverticula, trabeculations, and the appearance of the ureteral orifices. A full stream should be noted at the end of the procedure while applying gentle pressure to the suprapubic area. A small urethral catheter is left in place for 1 to 2 days following the procedure or until an elevated creatinine nadirs. Repeat serum electrolytes and creatinine should be obtained 24 hours after catheter removal while the boy is still hospitalized. A renal ultrasound is useful in the postoperative period to evaluate for improvements in hydronephrosis. Its timing should be dictated by the surgeon's level of concern. A VCUG may be performed after the catheter is removed to assess the success of the procedure. Timing of the VCUG is determined by the surgeon based on his or her confidence in the adequacy of ablation. The urethra, degree of reflux, and bladder appearance should be evaluated on VCUG. A VCUG and urodynamics or preferably videourodynamics should be delayed no longer than 6 to 8 weeks after ablation. If there is suspicion of inadequate ablation or continued obstruction, "second-look" cystoscopy with ablation of residual leaflets should be considered. Some have recommended routine cystoscopy a few weeks after valve ablation because of the high incidence of residual obstruction (9).

Follow-up renal ultrasound and serum creatinine and electrolytes should be performed at the time of the VCUG and urodynamics but may be obtained sooner based on the child's renal function and clinical presentation.

If the child is found to have diminished compliance or detrusor hyperactivity, anticholinergic therapy should be considered. Anticholinergic therapy may also be instituted immediately after valve ablation or prior to closure or reversal of vesical or supravesical diversion. Alpha-blocker therapy may be considered even in the first months of life in the face of high detrusor voiding pressures and in the absence of residual valve obstruction or postvalve ablation stricture (10,11).

Vesicostomy

While most patients with PUV are treated with primary valve ablation, a vesicostomy may be useful in neonates whose urethra will not accommodate a cystoscope or in those whose creatinine rises despite adequate valve resection.

With the patient in the supine position, the lower abdominal skin is prepared and draped in the typical fashion. The procedure is more easily performed with a full bladder. A 2-cm transverse incision is then made midway between the pubic symphysis and umbilicus. The rectus fascia is exposed and a 2 cm × 2 cm cruciate incision is made. Alternately, a triangle or circle of rectus fascia measuring 2 cm may be excised. One must remember that the size of the fascial opening ultimately determines the caliber of the stoma. The rectus muscles are then retracted laterally, exposing the bladder. A 3-0 suture is placed near the dome of the bladder and used for traction. Using the traction suture, the bladder is mobilized superiorly. The peritoneum is gently swept off the superior aspect of the bladder. Additional cephalad sutures may be placed in a stepwise fashion to help bring the dome into the surgical field. Care is taken to avoid the peritoneal contents. With gentle traction, one should be able to visualize the urachus or obliterated hypogastric artery.

The vesicostomy may be created in one of two ways. In the first method, a stay suture is placed proximal to the urachus. The urachus is then transected and excised. In the second method, the portion of the bladder cephalad to the urachal remnant is used as the site for the vesicostomy. The bladder is incised and the fascial edges are sewn to the outer bladder wall using 3-0 or 4-0 polyglactin sutures approximately 0.5 to 1 cm from the opening created in the bladder. The vesicostomy should be calibrated to 24Fr or large enough to allow passage of the surgeon's fifth digit. If the fascial defect is too large, interrupted 3-0 polyglactin sutures may be used to narrow the opening. The edges of the detrusor are then sewn to the skin using 4-0 polyglactin sutures in an interrupted fashion. If the skin incision is wider than the stoma created, the skin is approximated with a suture of choice (Fig. 97.4).

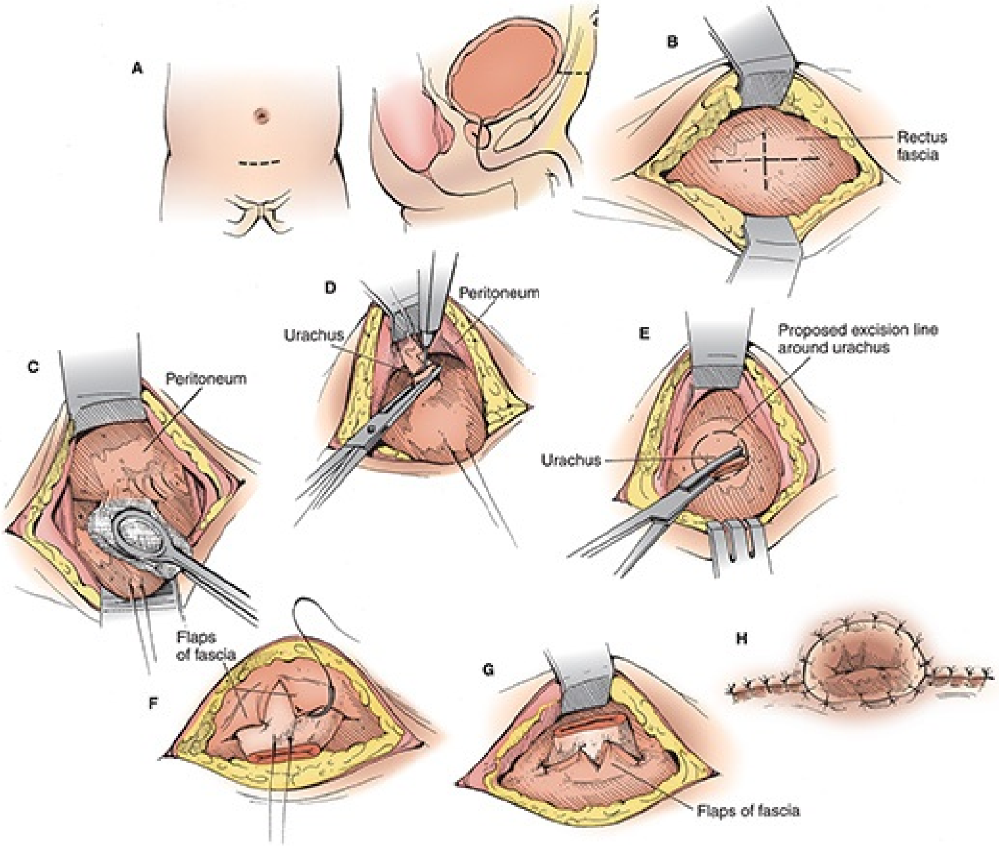

FIGURE 97.4 Blocksom vesicostomy. **A:** A 2-cm transverse incision is made midway between the pubic symphysis and umbilicus. **B:** A 2 cm × 2 cm cruciate fascial incision is made. **C:** Using the traction suture the bladder is mobilized superiorly. The peritoneum is gently swept off the superior aspect of the bladder. **D:** The urachus is incised and the bladder is further mobilized. **E:** The urachus is excised. **F and G:** The outer bladder wall is sewn to the edges of the incised rectus fascia. **H:** The edges of the detrusor are sewn to the skin. (Modified with permission from Belman AB, King LR. Vesicostomy: useful means of reversible urinary diversion in selected infant. *Urology* 1973;1:208–213. Copyright © 1973. Published by Elsevier Inc.)

The decision to close a vesicostomy should be made only once bladder dynamics have been assessed, and renal function and hydronephrosis have stabilized. A plan for permanent therapy should be devised prior to closure. Although some argue that urodynamic studies may be of little use because leakage may occur around the vesicostomy even with a Foley balloon occluding it and high grade reflux may give the impression of normal tracing, a well-performed study that shows adequate capacity with normal storage pressures is reassuring (12).

Ultimately, the timing of closure is dictated by the surgeon's philosophy. Some believe an empty bladder becomes a contracted bladder, while others close vesicostomies just prior to the expected time of potty training. Careful follow-up with renal ultrasounds, serum electrolytes, and creatinine is essential because some children may have poor bladder dynamics after closure of the vesicostomy.

For closure of a vesicostomy, an adequate-size balloon catheter is placed into the stoma of the vesicostomy. With the catheter in the bladder and the balloon inflated, an elliptical skin incision is made around the stoma. The subcutaneous and perivesical tissues are dissected circumferentially around the vesicostomy. Next, 3-0 chromic stay sutures are placed through the bladder wall approximately 1 cm cephalad and 1 cm caudad to the stoma. The skin and protruding portion of the bladder are excised. The previously placed catheter is removed and a urethral catheter is placed for bladder drainage. The bladder defect is then closed in two layers: a running 4-0 chromic suture is used to reapproximate the bladder mucosa, followed by interrupted or running 3-0 polyglactin or chromic sutures as a second layer. The remainder of the wound is closed in a standard fashion.

Supravesical Diversion

Cutaneous Pyelostomy

The decision to proceed with a supravesical diversion remains controversial, and it is rarely used. Some urologists feel that the failure of the creatinine to improve is related to a secondary ureterovesical obstruction and advocate supravesical diversion (7). To safely perform a cutaneous pyelostomy, the renal pelvis should be sufficiently dilated to avoid tension on the renal pelvis as it is pulled toward the abdominal wall. A dilated renal pelvis also ensures that dissection can be carried out away from the ureteropelvic junction (UPJ).

The renal pelvis may be approached in several ways, including a dorsal lumbotomy or a subcostal extraperitoneal approach. A surgeon may use the approach he or she is most comfortable with. Despite the limited exposure that a dorsal lumbotomy incision affords, it is excellent for visualization of the renal pelvis and upper ureter. The procedure avoids a muscle-cutting incision and may produce less postoperative pain.

When using a dorsal lumbotomy approach, the patient is intubated and then placed in the prone position on the operating room table. Cushions should then be placed under the chest and just superior to the anterior superior iliac spines. The landmarks include the 12th rib superiorly, the iliac crest inferiorly, and the lateral border of the sacrospinalis medially. A vertical incision with or without a slight curve at its distal end is made approximately one-third to one-half the distance between the 12th rib and the iliac crest. Alternatively, an oblique incision may be made along the Langer lines (Fig. 97.5). Care should be taken to avoid injuring the subcostal neurovascular bundle. The lumbodorsal fascia is exposed by elevating the skin and subcutaneous tissues for about 3 cm on either side of the incision so that a vertical fascial incision may be comfortably made. The posterior layer of the lumbodorsal fascia is incised vertically 2 cm lateral to the midline. The sacrospinalis muscle is then retracted medially. This exposes the middle layer of the lumbodorsal fascia, which is incised at the lateral border of the quadratus lumborum. Retracting the quadratus lumborum medially, the anterior layer of the lumbodorsal fascia is exposed (Fig. 97.6). This layer and the transversalis fascia are then incised between the subcostal and iliohypogastric nerves. The perinephric fat should then be in view. The kidney should be located in the superomedial part of the wound.

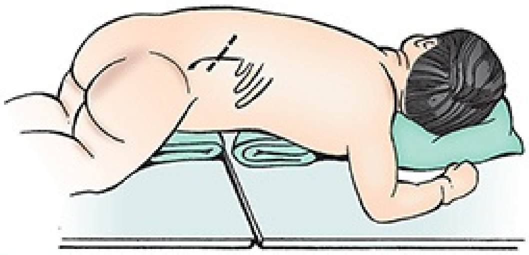

FIGURE 97.5 Positioning for dorsal lumbotomy and possible skin incisions. The *solid line* represents our incision of choice; the *broken line* represents a suitable alternative.

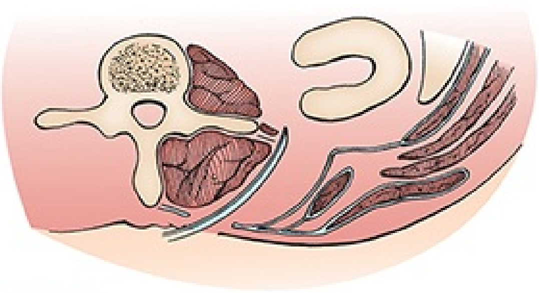

FIGURE 97.6 Fascial incision through lumbodorsal fascia lateral to the sacrospinalis and quadratus lumborum, avoiding the division of muscles as indicated by blue line.

When using a subcostal approach, the child should be placed in a lateral decubitus procedure or in a semi-oblique position with the shoulder turned 30 to 40 degrees. An incision is made off the tip of 11th or 12th rib based on renal anatomy and is extended toward the umbilicus for 2 to 4 cm depending on the child’s size. The subcutaneous tissues are divided with electrocautery, exposing the external oblique muscle laterally and the rectus sheath medially. Once the fibers of the latissimus dorsi muscle are divided in the lateral aspect of the wound, the external oblique muscle and internal oblique muscle layers are split or transected. Care should be taken to avoid injuring the subcostal neurovascular bundle located between the internal oblique and transversalis abdominis muscle layer. The lumbodorsal fascia is entered laterally, and the peritoneum is reflected anteriorly from the undersurface of the transversalis fascia using blunt dissection with a Kittner. The transversus abdominis muscle and the transversalis fascia are split or divided exposing the underlying peritoneum. The retroperitoneal space is entered laterally while retracting the peritoneum and its contents medially. Gerota fascia is entered over the lateral aspect of the kidney.

Once Gerota fascia is entered in the dorsal lumbotomy approach, the dilated renal pelvis is identified and rotated anteromedially. In the subcostal approach, the dilated renal pelvis is identified and rotated posterolaterally. The surgeon must assess if the pelvis can comfortably reach the skin. If not, a very proximal portion of the ureter may be brought out to serve the same purpose. Care should be taken to avoid dissection near the UPJ so as to avoid the possibility of a future UPJ obstruction. Two 3-0 chromic traction sutures are placed on the posterior aspect of the renal pelvis in the dorsal lumbotomy approach and anterior pelvis in the subcostal approach away from the UPJ. Using a scalpel, a 3-cm incision is made. The full thickness of the renal pelvis is sutured to the posterior corner of the skin incision using multiple interrupted 4-0 polyglactin sutures (Fig. 97.7). The pyelostomy should be calibrated to approximately 20Fr to avoid future stenosis or prolapse. Once the planned procedure has been performed, the posterior layer of the lumbodorsal fascia is reapproximated with 3-0 polyglactin sutures and the skin is then closed with either a subcuticular suture or skin staples.

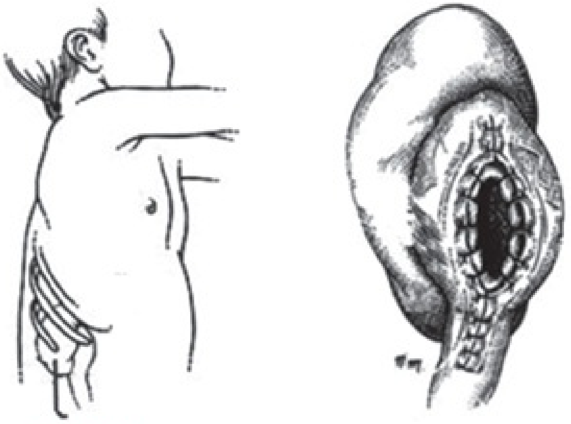

FIGURE 97.7 Cutaneous pyelostomy (sutures at the skin level).

High Cutaneous Loop Ureterostomy

This method is typically employed when the renal pelvis is not large enough for a cutaneous pyelostomy to be performed. The initial steps for a high cutaneous ureterostomy are similar to that for a cutaneous pyelostomy. The ureter is brought to skin level. Two 4-0 polyglactin sutures are placed in the upper ureter approximately 5 mm from each other. Using a scalpel, a 2-cm vertical ureterotomy is created. The abdominal musculature is closed on either side and behind the loop of ureter. Care is taken to avoid strangulating the ureter. The incised ureteral margins are sewn to the skin using interrupted 4-0 polyglactin sutures. The final product is a double-barreled ureteral stoma (Fig. 97.8).

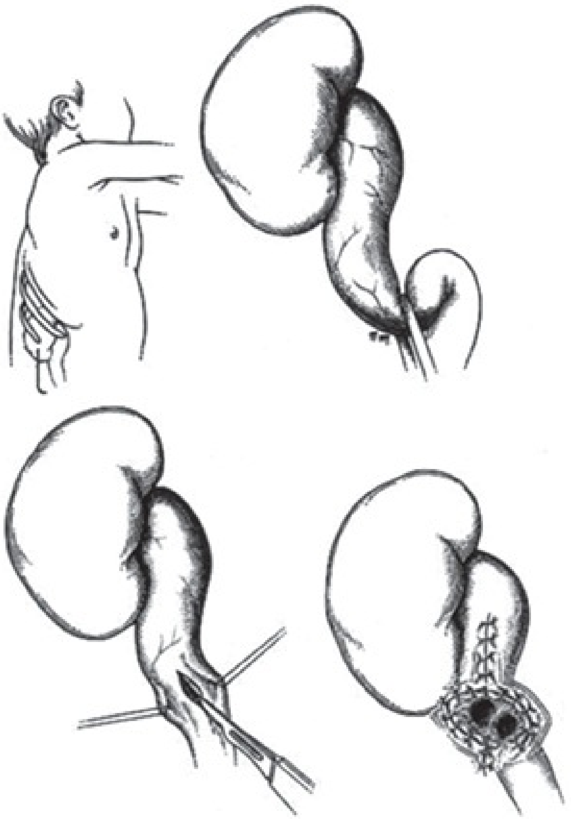

FIGURE 97.8 Loop cutaneous ureterostomy (sutures at the skin level).

Loop ureterostomies maintain continuity of part of the ureter, therefore decreasing the likelihood of disruption of ureteral blood supply and possibly making closure of the ureterostomy simpler.

Pelvioureterostomy-en-Y (Sober Loop Ureterostomy)

The Sober Y ureterostomy allows some urine to drain into the bladder, thus avoiding a completely defunctionalized bladder that may eventually become contracted (13). It is not the procedure of choice in critically ill patients as it is more extensive and time-consuming than other forms of diversion, and it is best used in patients with redundant tortuous ureters. The ureter is mobilized from the level of the kidney to the level of the true pelvis. The ureter is divided at a point where the lower ureteral segment comfortably reaches the renal pelvis. The upper ureter that remains in continuity with the renal pelvis is brought out to the flank caudad to the flank incision. The proximal end of the lower portion of the transected ureter is anastomosed to the renal pelvis. This is done in an end-to-side fashion after creating a pelviotomy at a point that will not cause ureteral kinking. The anastomosis is performed using a 6-0 or 7-0 polyglactin suture in a running fashion (Fig. 97.9). The flank incision is closed in the standard fashion. A small Penrose drain may be temporarily placed. Initially, most urine will drain via the ureterostomy. Over time, increasing amounts of urine will drain into the bladder.

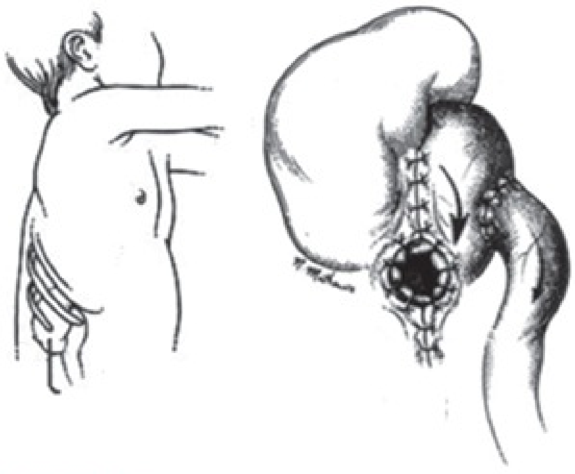

FIGURE 97.9 Pelvioureterostomy-en-Y (Sober ureterostomy).

Percutaneous Nephrostomy Tube

This procedure is typically performed with ultrasound guidance by interventional radiologists. Once access to the dilated renal pelvis is obtained, a pigtail catheter is placed. Ghali and colleagues (14) propose placement of a percutaneous nephrostomy tube prior to formal supravesical diversion because supravesical diversion will rarely prevent progression to renal insufficiency. In addition, tube placement allows for antegrade nephrostogram and pressure flow studies to confirm ureterovesical junction obstruction (14). This minimally invasive technique is also particularly useful in septic or otherwise critically ill children. Despite the ease of the procedure, tubes may become dislodged and formal diversion may be more difficult secondary to inflammatory reaction to the tube placement.

End Cutaneous Ureterostomy

To successfully perform a cutaneous ureterostomy, the ureter must be sufficiently thick-walled and dilated. Preservation of the ureteral blood supply is essential. The ureter should be approached extraperitoneally via either a Pfannenstiel or Gibson incision. The ureter should be carefully dissected from the level of the sacral promontory to the bladder with care to avoid stripping the ureter's adventitia. Once dissected, a thick vessel loop or Penrose drain should be placed around the ureter. One should estimate whether the ligated ureter will comfortably reach the anterior abdominal wall at the right or left lower quadrant. Once satisfied with this, the ureter is clamped and cut. The distal segment is ligated using a 3-0 polyglactin suture. A 3-0 polyglactin stay suture is placed on the cut end with care to avoid the ureter's medial blood supply (Fig. 97.10).

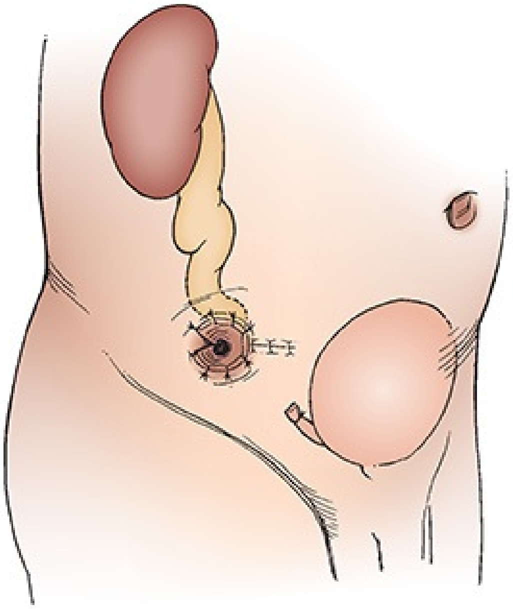

FIGURE 97.10 End ureterostomy (sutures at skin level). (From Indiana University School of Medicine, Office of Visual Media, with permission).

The cutaneous stoma is then created. Stomas should be placed in the right or left lower quadrant for ease of stomal fit in the event an appliance will be used or to ensure it is well covered by a diaper. Once the site of the stoma has been determined, a V-shaped incision is made and taken down through the subcutaneous tissues and rectus sheath. Using the previously placed stay suture, the ureter is gently brought through the incision. If the ureter seems stretched, additional mobilization may be necessary. The ureter is then spatulated medially to avoid its blood supply. The apex of the spatulated ureter is then sewn to the apex of the skin incision using a 4-0 polyglactin suture. The ureter is then sewn to the other angles of the skin incision and additional sutures are placed circumferentially.

Bilateral end ureterostomies may be brought to the midline or either lower quadrant. The medial wall of each ureter is incised approximately 3 cm. The apexes of the incised ureters are sewn to each other using a two-armed 5-0 polyglactin suture. The incised walls of the ureters are then sewn to each other in a running fashion.

Closure of Supravesical Diversions

To close a cutaneous pyelostomy, an elliptical skin incision is made around the stoma. The portion of pelvis that has been exteriorized is trimmed so that healthy renal pelvic edges may be approximated. Using a 6-0 polyglactin suture in a running fashion, the renal pelvis is closed in a transverse fashion. The UPJ should be inspected to ensure that no kinking has occurred secondary to pyelostomy closure.

To close a loop ureterostomy, an elliptical skin incision is made in the skin surrounding the stoma. The proximal and distal ureteral segments are adequately mobilized. The fibrotic exposed portions of the ureter are excised while trying to maintain the continuity of the ureter's back wall and blood supply. The remaining ureteral margins are then spatulated and closed in a transverse fashion using a 6-0 polyglactin suture (Fig. 97.11). Again, one must ensure that no angulation or narrowing of the ureter has occurred. A temporary indwelling ureteral stent may be placed to bridge the anastomosis.

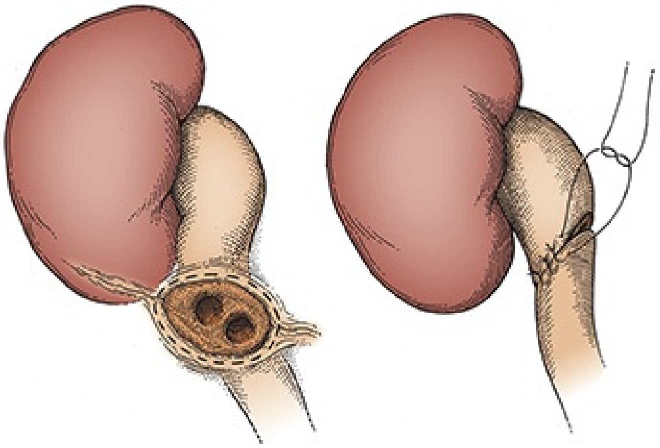

FIGURE 97.11 Takedown of loop cutaneous ureterostomy.

A Sober ureterostomy may be reversed by excising the stoma at the skin level along with the limb of ureter used to create the cutaneous ureterostomy. The dissection is taken down to the level of the renal pelvis. The defect in the renal pelvis is closed using a 6-0 polyglactin suture in a running watertight fashion.

Cutaneous end ureterostomies are taken down and a ureteral reimplant is performed. Ureteral tapering is often required. If ureteral length is deficient, a psoas hitch, Boari flap, or transureteroureterostomy may become necessary.

OUTCOMES

Complications

Transurethral resection of PUVs may result in urethral stricture or sphincteric incontinence. The report incidence of stricture varies from 2% to 50%, with some authors finding an increased incidence with the use of cautery (15–17). The use of appropriately sized resectoscopes, limited cautery, and good visualization with care to identify the external sphincter during resection are essential to avoid these complications. As with any urologic procedure, there is also a risk of urinary tract infection. A preoperative urine culture should be obtained and treated appropriately prior to any intervention.

Cutaneous vesicostomies may be complicated by early or late prolapse of the dome or posterior bladder wall in up to 17% of patients (18). To prevent prolapse, the most cephalad portion of the bladder or the urachus should be used as the site for the vesicostomy. By employing this portion of the bladder, the peritonealized part of the dome becomes immobilized, decreasing the risk of prolapse. The stomal opening itself should be no larger than 2 cm. The final stoma should calibrate to 24Fr. Excessive mucosal eversion should not be mistaken for prolapse. Despite its appearance, no intervention is necessary for excessive eversion.

If the vesicostomy does not appear to be draining well and there is evidence of large amounts of residual bladder urine or large amounts of urine are voided by urethra, the suspicion of stomal stenosis should be raised. Stomal stenosis rates of 3% to 12% have been reported (18). The stenosis may be secondary to a small fascial opening or excessive tension on the vesicocutaneous anastomosis. Continuous drainage of urine into a diaper commonly may lead to peristomal dermatitis. Prolonged, severe dermatitis may ultimately lead to stomal stenosis. This can be prevented by air drying the skin or applying topical ointments used for diaper rash. Fungal superinfections may occur and are treated with antifungal creams and powders.

Some infants, particularly those with persistent vesicoureteral reflux, may have recurrent urinary tract infections despite patent vesicostomy and small bladder residuals. These children may benefit from intermittent catheterization through their vesicostomies.

The most common complication associated with pyelostomy is chronic skin irritation and dermatitis. As in other forms of diversion, chronic bacteriuria is also common. Less common complications of pyelostomy include stomal stenosis and prolapse of the renal pelvis. Chronic bacteriuria has been found in approximately two-thirds of patients with ureterostomies and is the most common complication in this group. Stomal stenosis occurs in 11% to 70% of patients undergoing end cutaneous ureterostomies (19). The incidence of stenosis and obstruction is related to the caliber of the ureter used as well as the type of stoma created. Chronic skin irritation may also result in scarring and stenosis.

Results

Although transurethral resection is often successful at relieving the infravesical obstruction, the untoward effects of valves on bladder function and the upper urinary tract may be irreversible. Intense and individualized care of bladder and renal function in boys with PUV is essential. Boys should be followed closely through adolescence because the bladder may change and late onset renal failure may occur (15).

Despite the ease of performing a vesical diversion and its effectiveness in relieving bladder outlet obstruction, controversy exists regarding both its necessity and ultimate effects on bladder function (5,7).

ANTERIOR URETHRAL VALVES

Anterior urethral valves occur 10 times less frequently than PUVs and may be located anywhere along the anterior urethra. In most cases, an anterior urethral valve is actually a congenital urethral diverticulum with the lip of the diverticulum preventing antegrade flow of urine. The bulging diverticulum may further obstruct the urethra by compressing the lumen. These children present with symptoms similar to those with a PUV, including varying degrees of hydroureteronephrosis; however, many also present with penile ballooning. As with PUV, the diagnosis is also made on VCUG. A renal ultrasound should be performed to complete the evaluation. Cystourethroscopy may miss the valve due to the retrograde flow of fluid during the procedure.

Although the obstruction is most commonly relieved endoscopically, a vesicostomy is a good temporizing procedure if the child is too small or too ill (20). Endoscopically, the distal lip is incised using a hook or right-angle wire electrode. If unsuccessful, the diverticulum may be excised and the urethra reconfigured in two layers over an 8Fr or 10Fr catheter using polydioxanone or polyglactin suture. A vascular dartos pedicle flap over the urethral repair may be useful to prevent fistula formation. Staged urethroplasty may be the best treatment option when faced with a large urethral diverticulum. Management of the hydroureteronephrosis would be similar to that in a patient with a PUV.

CHAPTER 98 HYPOSPADIAS

LAURENCE S. BASKIN

Hypospadias is defined by the three major anatomical defects: (a) the abnormal location of the urethral meatus, (b) penile curvature, and (c) abnormalities of the foreskin. The objective in treating patients with hypospadias is to reconstruct a straight penis for normal coitus and place the new urethral meatus on the terminal aspect of the glans to allow a forward-directed stream. There are five basic steps for a successful hypospadias outcome: (a) orthoplasty (straightening), (b) urethroplasty, (c) meatoplasty and glanuloplasty, (d) scrotoplasty, and (e) skin coverage. These various elements of surgical technique can be applied either sequentially or in various combinations to achieve a surgical success (1,2).

DIAGNOSIS

Meatal Abnormalities

Hypospadias is characterized by an abnormality in location and configuration of the urethral meatus and surrounding urethral spongiosum (Fig. 98.1). The urethral meatus may be ventrally placed just below a blind dimple at the normal meatal opening on the glans or so far back in the perineum that it appears as a “vaginal” hypospadias. Most patients present with the urethral meatus on the glans penis, coronal margin, or distal aspect of the glans. The configuration of the meatus may vary in form, diameter, elasticity, and rigidity. It can be fissured in both transverse and longitudinal directions or can be covered with delicate skin secondary to associated atresia of the supporting urethral spongiosum. In the case of the megameatus intact prepuce, the distal urethra is enlarged, tapering to a normal caliber in the penile shaft. Often, there is an orifice of a periurethral duct located along the urethral plate distal to the meatus that courses dorsal to the urethral channel for a short distance. It is blind ending and does not communicate in any way with the urinary stream. The periurethral duct corresponds with Guérin sinus or Morgagni lacunae. Unless these ducts are inadvertently closed, leading to a blind ending epithelial pouch, they are of no clinical consequence.

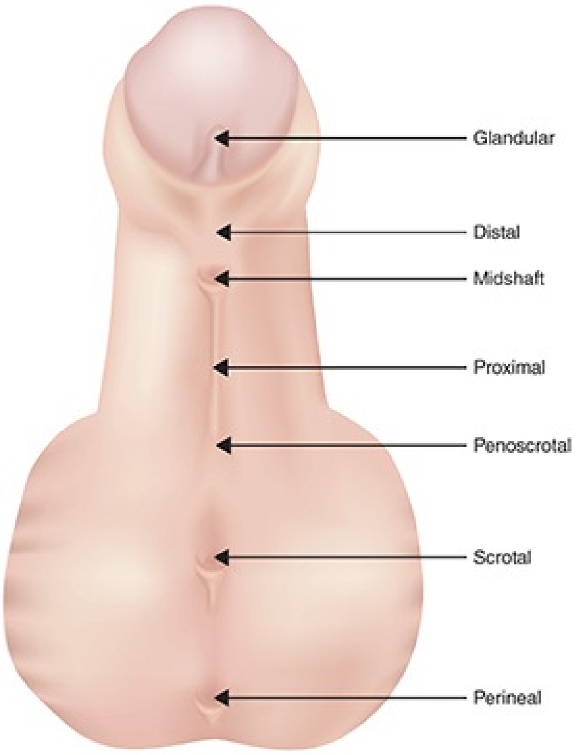

FIGURE 98.1 Location of the hypospadias meatus: glandular, distal, midshaft, proximal, penoscrotal, scrotal, and perineal.

Skin and Scrotal Abnormalities

The skin of the penis is changed as a result of the disturbance in the formation of the urethra. Prepuce formation is aborted distal to the abnormal meatus with excess dorsal foreskin. Proximal to the meatus, there is often a paucity of ventral skin, which may contribute to penile curvature. The frenulum is always absent in hypospadias. Vestiges of a frenulum are sometimes found inserting on either side of the open navicular fossa.

The skin proximal to the urethral meatus may be extremely thin, so much so that a catheter or probe passed proximally is readily apparent through a tissue paper thickness of skin.

The urethral plate defined as a rectangular segment of tissue from the abortive hypospadias urethral meatus to the glandular groove is often well developed. Even with a meatus quite proximal on the shaft, this normal urethral plate is quite elastic and typically nontethering. After degloving the penile shaft skin, artificial erection demonstrates no ventral curvature in these situations. A normal urethral plate may be incorporated into the surgical repair. However, in the rare severe case of hypospadias if the urethral plate is underdeveloped, it will act as a tethering fibrous band that bends the penis ventrally during artificial erection. When this fibrous chordee tissue is divided, the penile curvature will frequently improve.

Normally, the penis should develop in a cranial position above the two genital swellings. The penis may be caught between the two scrotal halves and become engulfed with fusion of the penoscrotal area resulting in penile scrotal transposition.

Penile Curvature

The curvature of the penis is caused by deficiency of the normal structures, most commonly on the ventral side of the penis. It has been labeled *chordee*; however, this term implies a strand of connective tissue stretched like a cord between the meatus and glans, which is rarely found in practice. Penile curvature can be from skin deficiency, a true fibrous chordee with tethering of the ventral shaft, or deficiency of the corpora cavernosa on the concave side of the penis (3).

There are occasional reports of other penile anomalies that represent variations of the embryologic defect causing hypospadias. They can be characterized as a defect in the course of the urethra such as congenital urethral fistula and a group characterized by curvature of the penis without hypospadias or so-called chordee without hypospadias.

SURGICAL TECHNIQUE

Hypospadias Surgeons

Success is directly related to the experience of the surgeon (4). For a successful result in hypospadias repair, the penile tissues must be handled with great care. Experience in mobilizing and rotating skin flaps is needed, as are the minutiae involved in plastic surgical techniques. It is not enough to review pictures and follow descriptions; training in the techniques is essential. Knowledge of a few methods is not enough because the one used must be the best for the individual situation of the child. A pediatric urology fellowship is the appropriate place to become competent in hypospadias surgery.

Preoperative Evaluation

Because hypospadias is typically an isolated anomaly, the entire genitourinary tract does not require evaluation. This assumes that the remainder of the physical exam is normal including a normally placed anus and no spine abnormalities. The absence of one gonad, perineal hypospadias, severe chordee, or a bifid scrotum suggests a disorder of sex development (DSD) and requires genotypic evaluation (5). If both gonads are not palpable, consider the possibility of congenital adrenal hyperplasia in a phenotypic female.

Age for Operation

Select a time between 6 and 9 months for surgery. At this age, the infants are also easiest to manage, are not walking, and remain in diapers. Babies appear to have less bladder spasms and require smaller doses of pain medication. They do not seem to remember the surgery as teenagers and adults.

The routine use of preoperative androgen stimulation is not indicated and remains controversial for patients with a small glans and penis that require an appropriate evaluation for a DSD (6). When considered indicated, testosterone may be administered to increase the size of the penis and especially the size and vascularity of the prepuce should it be needed for proximal and perineal hypospadias repair. A standard dose is 25 to 50 mg of testosterone enanthate in oil administered intramuscularly, repeated once or twice at 3-week intervals before operation.

Outpatient Repair

An uncomplicated hypospadias operation can be done without hospital admission. Preoperative education explaining the procedure, obtaining informed consent, answering the family's (and when age-appropriate, the patient's) questions, and reviewing the postoperative catheter care and pain management is the norm. Patient educational material has proved to be extremely helpful.

Nerve Block

A caudal nerve block placed by the anesthesia team is an excellent form of postoperative pain control. A good alternative is a penile nerve block. To place a penile nerve block in a healthy infant use 3 to 4 mL of 0.5% long-lasting bupivacaine mixed with 1% of quick-acting lidocaine. Inject it at the base of each crus just below the notch of the symphysis, or vertically in the midline deep to the notch of the symphysis and around the ventral aspect of the base of the penis, with a 1 1/2-inch 25-gauge needle. When placed at the beginning of an operation, it will reduce the amount of general anesthesia required and will provide anesthesia that will last well into the postoperative period.

Surgical Hints

Hemostasis

For hemostasis, use 1% lidocaine with 1:100,000 epinephrine and inject it through a 27- to 29-gauge needle within the glans and the area of abortive spongiosum. Wait 7 minutes for it to act. This vasoconstrictor will reduce the bleeding during the dissection, but if the operation is prolonged beyond 90 minutes, rebound vasodilation can be expected. Avoid electrocoagulation as much as possible; if it is necessary, use a bipolar cautery or touch a monopolar cautery to only the forceps unit set at a low current. Once the glans flaps are applied, bleeding improves, and a pressure dressing will usually assure hemostasis. On rare occasion, use of tourniquet that is typically used for artificial erections can facilitate hemostasis.

Artificial Erection

To induce a saline-induced erection, place a sterile rubber band or vascular loop around the base of the penis and snug it with a hemostat. Introduce a 25-gauge butterfly needle into the corpus cavernosum. Gently distend the penis with injectable normal saline solution; avoid overdistention. Maintain the erection during evaluation of the penile curvature. After the curvature has been corrected, create a second erection to check penile alignment.

Local Urinary Diversion in Children

Diversion of urine away from the suture lines has always been a problem in children because any indwelling tube, particularly one terminating in a balloon, induces bladder spasms that force urine around it into the repair. This disrupts the suture line and leads to formation of fistulas. Besides, the lumen of a balloon catheter is small compared to that of a straight catheter, especially a plastic one.

Many techniques have been tried to minimize these problems with diversion. The simplest method for infants, one that combines stenting with drainage, is to insert a fine silicone tube, such as 6Fr peritoneal shunt tubing or neurosurgical tubing with its wand-like end, into the bladder through the urethra and fasten the end to the glans in one or two places with nonabsorbable sutures.

Alternately, place a 6Fr Kendall catheter of soft Silastic, with a Luer-lock at the end to prevent internal migration and to allow irrigation. Whatever intubation system is used in infants, collect the urine in a double diaper. For older boys, use a feeding tube, or in teenagers, a urethral balloon catheter; tape it to the abdomen so that it cannot disturb the ventral glans repair. Drainage should be continued for 4 to 7 days for distal and penile shaft repairs and 7 to 10 days more severe hypospadias repairs.

Dressings

Apply a dressing to immobilize the area, to reduce edema, and to prevent the formation of a hematoma. Use transparent and permeable absorbent plastic film (Tegaderm or OpSite) applied over Telfa or tincture of benzoin. Let the catheter drain into an outer diaper. The dressing may be removed in 2 to 3 days after a few warm baths at home. Once the dressing has been removed, use K-Y jelly on the diaper to keep the repaired penis from sticking, typically for 4 to 5 days.

Setup for Operation

Instruments

Select instruments designed for delicate handling of tissues. A reasonable list would include loupe magnification, genitourinary fine and microsurgery sets, microsurgical knife (Weck), toothed and nontoothed forceps (Adson), fine Allis clamps, fine clamps, two pairs of Bishop–Harmon forceps or 0.5 platform forceps, sharp small tenotomy scissors, iris scissors, microtip Castroviejo scissors, microtip Castroviejo needle holders, plastic needle holders and ring retractor (Scott/LoneStar), and hooks. Also, have available bougie à boule, 5Fr and 8Fr infant feeding tubes, rubber bands, a marking pen, a 25-gauge butterfly needle and syringe, and a handheld Bovie, or an ophthalmic electrocautery. Have fine sutures of appropriate sizes and types at hand but unopened—for example, 5-0 Prolene on a C-1 tapered needle for glans traction, 7-0 polydioxanone suture (PDS) and Vicryl for urethroplasty, and 6-0 PDS for the skin.

Selection of the Operative Technique

Figure 98.2 presents an algorithm for the reconstruction of hypospadias. A tried and true approach is to start each repair by preserving the urethral plate, dissecting the skin to the penile scrotal junction, and assessing for the presence of penile curvature. If curvature is not present or mild to moderate and amendable to dorsal plications, then a one-stage approach is typically successful. The specific repair is now dependent of the meatal configuration and the surgeon’s preference (1).

FIGURE 98.2 Algorithm for hypospadias repair.

Treatment of Anterior Hypospadias

The Meatal Advancement and Glanuloplasty Technique

The hypospadiac penis that is amenable to the meatal advancement and glanuloplasty (MAGPI) is characterized by a dorsal web of tissue within the glans that deflects the urine from either a coronal or a slightly subcoronal meatus (7). Once the patient is asleep, the urethra itself must have a normal ventral wall, without any thin or atretic urethral spongiosum. The urethra also must be mobile so it can be advanced into the glans (Fig. 98.3).

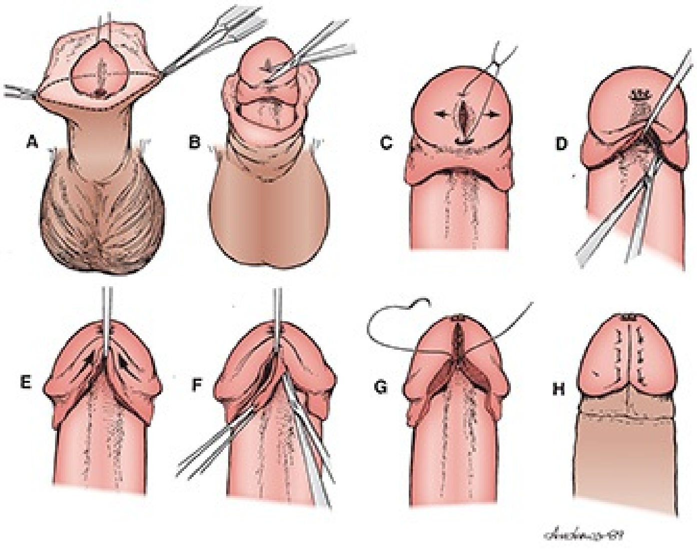

FIGURE 98.3 MAGPI procedure. Note the proximal location of the initial circumcising incision (*dotted line*) in relation to the urethral meatus (**A**). The dorsal meatotomy is as shown (**B** and **C**) (vertical incision closed horizontally). The glans is then detached from the lateral margin of the corpus spongiosum and the side of the corpora cavernosa (**D**). The edge of the glans on either side that will be approximated ventrally is identified (*arrows*) (**E**). The triangle of skin between these two points and the urethral meatus is excised completely (**F**). Dissection must stay right on the skin because the urethra here is usually thin and easily entered. Excising this skin allows exposure of the glans tissue which can now be reapproximated into a conical shape to complete reconstruction with the meatus in a terminal position (**G** and **H**).

The Glans Approximation Procedure

The glans approximation procedure (GAP) is applicable in a small subset of patients with anterior hypospadias who have a wide and deep glandular groove (8). These patients do not have a bridge of glandular tissue that typically deflects the urinary stream, as seen in patients who would be more appropriately treated with the MAGPI procedure. In the GAP procedure, the wide-mouth urethra is tubularized primarily, over a stent (Fig. 98.4). Ventral glandular tilt, meatal retraction, and splaying of the urinary stream can result from the inappropriate use of the MAGPI technique in these circumstances.

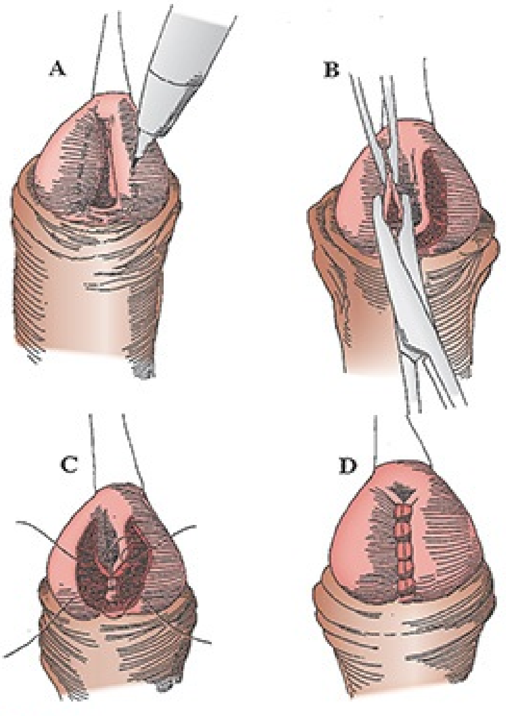

FIGURE 98.4 GAP hypospadias technique. **A:** Initial incision. **B:** Exposure of the glans mesenchyme by de-epithelialization of tissue, which is critical for a two-layer glans closure, allowing for good support of the urethroplasty. **C:** Tubularization of the neourethra, followed by glans closure. **D:** The completed repair. (Reproduced with permission from Grossfeld J, O'Neill J, Coran A, et al. *Pediatric Surgery*, 6th ed. Philadelphia: Elsevier, 2006. Copyright 2006 Elsevier.)

The Urethral Plate

Duckett has popularized the concept of preservation of the urethral plate, which is now standard practice for anterior as well as more severe posterior hypospadias surgery (9,10). The urethral plate serves as the dorsal urethral wall, and the ventral urethra is created by a vascular onlay flap of tissue from the inner prepuce. Extensive experience has shown that the urethral plate is rarely the cause of penile curvature. The concept of preserving the urethral plate yet undermining the plate and exposing the corporal bodies with the idea that chordee tissue could be released has not held true. In fact, careful anatomic studies have shown an extensive network of blood vessels supplying the urethral plate in the hypospadiac penis and lifting of the urethral plate defeats the purpose of preservation by violating this intricate blood supply (11).

Thiersch-Duplay or Primary Tubularization

Thiersch-Duplay or primary tubularization is applicable to patients with a wide urethral plate with mild to moderate amounts of penile curvature (12) (Fig. 98.5). The key concept of the operation is healthy urethral plate that can be primarily tubularized without compromising the glansplasty. In babies, the width of the plate should be a minimum of 11 mm. The urethroplasty is closed with either an interrupted or subcuticular fine suture. If abortive spongiosum is available, adjacent to the urethroplasty this can be incorporated as a second layer. An additional layer of coverage is provided by a de-epithelialized pedicle flap based on blood supply of the dorsal prepuce (see the following text). The flap can be buttonholed or wrapped around either side of the penis to cover the urethroplasty. Mobilizing the glans wings to 90 degrees in respect to the urethral plate allows a tension-free two-layer glansplasty.

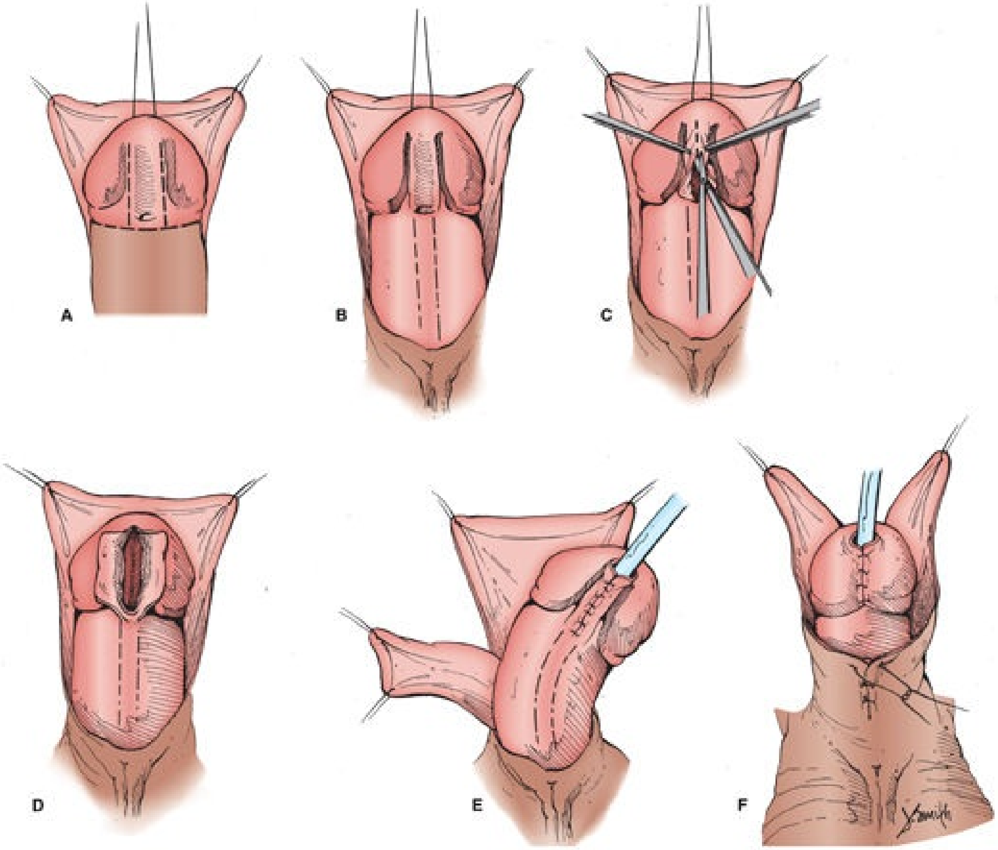

FIGURE 98.5 Thiersch-Duplay or primary tubularization with Snodgrass modification (Tubularized, incised plate [TIP] urethroplasty). **A:** *Horizontal line* indicates circumscribing incision to deglove penis. *Vertical lines* show junction of urethral plate and ventral glans. **B:** Parallel incisions separate urethral plate from glans. If the urethral plate is narrow, then an incision in the urethral plate allows for primary tubularization (Snodgrass modification). **C:** Midline incision of urethral plate from meatus to granular tip. **D:** Incision has widened and deepened the urethral plate. **E:** Plate tubularized over 6Fr stent. Dorsal subcutaneous tissues are rotated ventrally to cover the repair (de-epithelialized pedicle flap). **F:** Midline closure of glans wing, mucosa collar, and ventral shaft skin.

Tubularized Incised Plate Urethroplasty (Snodgrass Modification)

Historically, if the urethral groove was not wide enough for primary tubularization, then an alternative approach such as the Mathieu (perimeatal based random flap) or, for more severe hypospadias, a vascularized pedicle flap was performed. Recently, the concept of the incision in the urethral plate with subsequent tubularization and secondary healing has been introduced by Snodgrass (13) (Fig. 98.5D and E). Short-term results have been excellent, and this procedure is enjoying extensive popularity. More recently, this technique has been applied to more posterior forms of hypospadias. Theoretically, there is concern about the possibility of meatal stenosis from scarring as occurs in patients with urethral stricture disease where direct vision internal urethrotomy often leads to recurrent stricture. However, reports of meatal stenosis have been relatively rare. In hypospadias, the native virgin tissue with excellent blood supply and large vascular sinuses seems to respond to primary incision and secondary healing without scar. The tubularized incised plate urethroplasty is also conducive to preservation of the foreskin (14). To preserve the foreskin, the incision is made only on the ventrum; therefore, patients with significant penile curvature are not candidates for this procedure. A three-layer closure of the prepuce prevents foreskin fistulas. The fact that the foreskin cannot be used as a de-epithelialized flap theoretically increases the chance for urethra fistula.

Dorsal Onlay Flap

The blood supply to the hypospadiac preputial tissue is reliable. The abundance of cutaneous tissue on the dorsum of the penis is vascularized in a longitudinal fashion. This tissue may be dissected from the penile skin, creating an island flap from the inner layer of the prepuce. The transverse onlay flap is prepared by placing four holding on the dorsal prepuce to define a rectangular transverse flap (Fig. 98.6B). The flap is dissected by first separating just the skin of the proximal aspect of the rectangle. The onlay flap and its blood supply are then separated from the dorsal penile skin by dissecting as close as possible to the dermis. The penile skin will survive on its intrinsic blood supply and the flap on the vascular pedicle to the prepuce.

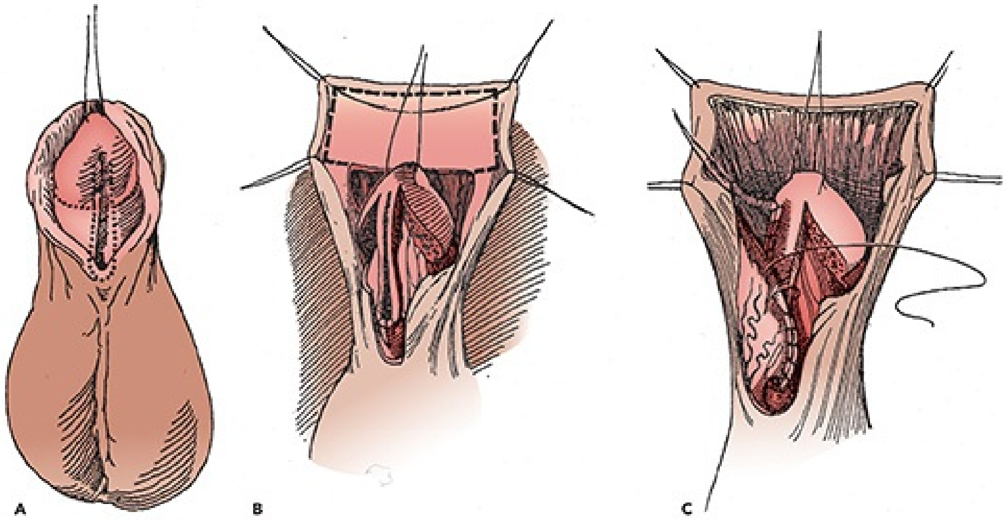

FIGURE 98.6 Transverse onlay island flap. A: Penile hypospadias. (Incision along *broken line*) B: Preservation of the urethral plate and *rectangular outline* of the onlay flap. C: Onlay of preputial island flap onto urethral plate.

For midshaft and distal shaft repairs, the flap may be created by splitting the prepuce in half, as described by Rushton and Belman (12). The inner foreskin flap of one side is used for the onlay and the outer foreskin of the same Byars flap is de-epithelialized for a vascularized layer of secondary coverage as described. (Fig. 98.7) (see the following text).

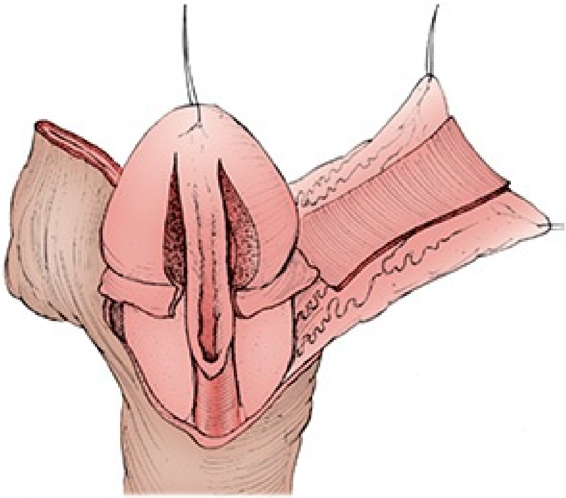

FIGURE 98.7 The prepuce is split vertically parallel to the blood supply to create both an onlay flap and secondary de-epithelialized urethroplasty coverage from one Byars flap.

Treatment of Posterior Hypospadias

Presently, in the majority of posterior hypospadias, including some perineal hypospadias, the urethral plate can be preserved and a vascularized flap used in an onlay fashion. In the rare case when the urethral plate needs to be resected, a two-stage technique can be employed (see the following text).

Onlay Island Flap

For posterior hypospadias (and anterior hypospadias with a thin urethral plate), all cases are approached by initially leaving the urethral plate intact. This includes patients with and without penile curvature. This technique can be applied to penile shaft as well as scrotal and perineal hypospadias. The intact dorsal plate essentially avoids complications of proximal stricture, and the excellent blood supply has decreased the fistula rate to approximately 5% to 10% for all cases of transverse onlay island flap hypospadias repair (see Fig. 98.6) (9,15). The onlay flap is appropriately trimmed and sutured to the urethral plate creating the new urethral. Long-term results with the onlay island flap have been very durable. For very severe hypospadias, the prepuce can be designed as a horseshoe style to bridge extensive gaps.

The Split Prepuce In Situ Onlay Hypospadias Repair

A modification of the onlay technique which can be applied to both anterior and midshaft hypospadias is to split prepuce in situ onlay. As described, in this procedure, the prepuce is split vertically, parallel to the blood supply to create both an onlay flap and secondary de-epithelialized urethroplasty coverage (16) (see Fig. 98.7). Long-term results have withstood the test of time with minimal complications.

Two-Stage Hypospadias Repair

An alternative approach for severe hypospadias is to transfer the dorsal prepuce to the ventrum after correction of penile curvature (Fig. 98.8). In severe cases, the urethral plate may need to be resected to correct penile curvature. Dermal grafting may be required, and performing an urethroplasty on top of the healing graft is not suggested. Byars flaps can be rotated from the dorsum setting up ventral coverage for subsequent urethroplasty (17). The second stage is performed at least 6 months after the first stage. To facilitate the urethroplasty within the glans, during the first stage, dorsal skin is tucked within the glans wings. Subcutaneous secondary coverage of the reconstructed urethra is performed to prevent fistula.

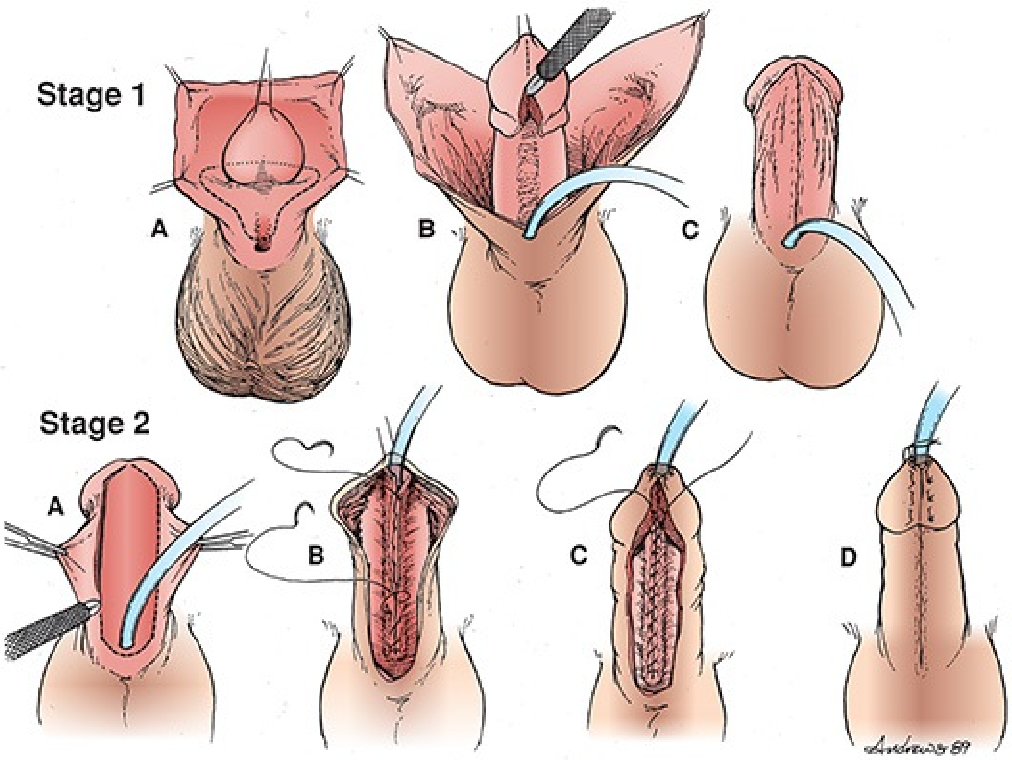

FIGURE 98.8 Two-stage repair. Stage 1: The penis is degloved (incision along *broken line*), the urethral plate resected, and the curvature corrected (A). The unfolded foreskin is brought out to the tip of the incised and mobilized glandular wings (B). Delicate sutures reapproximate the skin in the midline and fix the skin to the corpora cavernosa (C). Stage 2: A sufficient strip of skin is outlined that will form the urethra (A). Dissection of the shaft skin is lateral and away from the neourethra (Incision along *broken line*). Two layers of inverting sutures are used to close the neourethra (B). If the prepuce has been positioned sufficiently distal at the first stage, a normally positioned meatus with good ventral glandular support can be achieved (C). Any excess shaft skin is excised, but the dartos layer is preserved (de-epithelialization) to drape across the neourethral suture line (D).

Bracka Buccal Two-Stage Repair

For patients with prior surgery or with severe hypospadias, Bracka (18) has described a buccal free graft two-stage repair. In the first stage, the penis is straightened and the scarred urethra is discarded (Fig. 98.9). Buccal mucosa is harvested from either the cheek or lip and grafted to the prepared bed (19). Extensive quilting of the graft is performed to prevent hematoma from lifting off the buccal mucosa. During the first stage, glans wings are mobilized in preparation for the creation of a slit-like meatus during the second stage. The second-stage urethroplasty is undertaken at least 6 months after the first stage. In the second stage, excess buccal is trimmed off the glans setting up a two-layer glans closure. The buccal mucosa is rolled into the new urethra and subcutaneous tissue is used for secondary coverage.

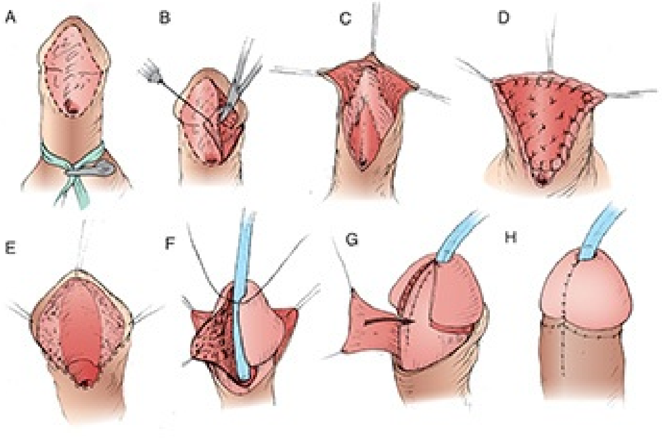

FIGURE 98.9 Schematic two-stage Bracka buccal hypospadias repair. **A–D:** First stage. **A:** Patient with a midshaft hypospadias and a paucity of available skin after multiple previous hypospadias repairs (incision along *broken line*). **B:** Resection of scar tissue. **C:** Mobilization of glans wings. **D:** Buccal free graft quilted into the resected scar. **E–H:** Second stage after 6 months of healing. **E:** Exposure of glans mesenchyme and trimming of buccal graft for subsequent urethroplasty. **F:** Urethroplasty. **G:** Secondary de-epithelialized pedicle coverage (*arrow*) of the urethroplasty. **H:** Two-layer glansplasty and completed repair. Penile Curvature (Chordee)

Correction of penile curvature has also evolved along with the concept of preservation of the urethral plate. Based on anatomic studies of the human fetal penis, a simpler approach of placing dorsal midline plication sutures in the nerve free zone at 12 o’clock is now advocated (11). The midline dorsal plication avoids the need for mobilization of the neurovascular bundle (Fig. 98.10). The midline plication can be applied to mild and moderate to severe degrees of curvature. If more than two rows of plication sutures or greater than four permanent sutures are necessary, then an alternative approach such as complete resection of the urethral plate and dermal grafting should be considered. During artificial erection, if the chordee cannot be corrected with your “finger,” the midline dorsal plication is not advised.

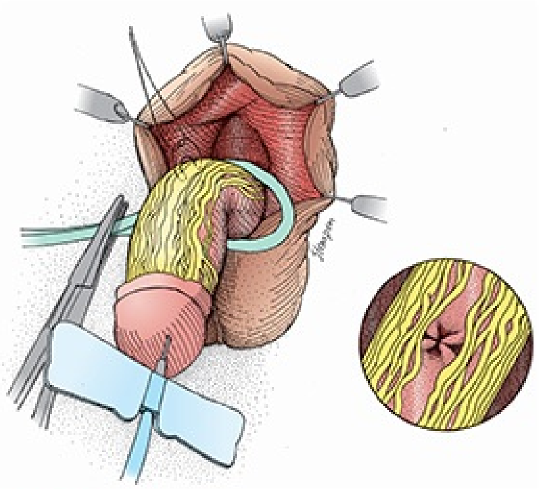

FIGURE 98.10 Midline dorsal plication technique. In this technique, plication sutures are placed in the tunica albuginea in the 12 o’clock position, which is free of both nerves and vascular structures (inset). This technique involves a minimum amount of manipulation to the penis. It is not necessary to incise into the corporeal body or extensively mobilize the fascia of Buck. A maximum of two rows of parallel plications at the 12 o’clock position can be placed for correction.

Postoperative Problems

Bladder spasms not only cause the child to move about in response to pain but also force urine through the repair. Proper pain control with operative nerve blocks and postoperative analgesics and antispasmodics, such as oxybutynin (Ditropan), is recommended. Narcotics and antispasmodic regimen may result in constipation leading to straining and urine leakage and can be prevented with a proper diet, adequate fluid intact, and occasional stool softeners and/or laxatives.

Bleeding is an infrequent problem. A compressive sandwich dressing will resolve the problem in all but the rare patient. In selected cases, give a broad-spectrum antibiotic such as trimethoprim (Septra) or a cephalosporin and continue it for a few days after the tubing has been removed.

Standard follow-up is to see the patient at the time of catheter removal, 6 weeks and 1 year after the repair. Reevaluate after potty training and at puberty to confirm patient satisfaction and the absence of fistula, stenosis, diverticulum, recurrent chordee, and cosmetic issues.

OUTCOMES

Results today cosmetically and functionally are better than those in the past. The use of a one-stage hypospadias repair at an early age with low complication rate encourages our current positive outlook for this condition. Curvature correction with the aid of an artificial erection is important for assuring satisfactory sexual function. With the placement of the urinary meatus at the tip of the glans, the infertility potential has been improved unless the patient has other coexisting testicular problems.

Evidence shows that the neourethra grows with the child, and subsequent repairs are seldom necessary.

Early hypospadias repair with minimal hospitalization helps to avoid separation anxiety and patient awareness of the procedure. We can now counsel parents confidently that there is an excellent outlook for a good cosmetic, functional, and emotional result in boys with all degrees of hypospadias.

Complications

Complications occur after 10% to 40% of hypospadias operations. These include meatal retraction, urethrocutaneous fistula formation, meatal stenosis, urethral stricture, development of a diverticulum (sometimes with hair, followed by stones), and persistent penile curvature. Of these, strictures, fistulas, and urethral diverticula account for most of the late problems. Manage these complications at least 6 months from the time of the initial surgery.

PRACTICAL CONCLUSIONS

1. Hypospadias should be repaired within the first year of life, preferable at 6 to 9 months of age. Pain control and catheters seem better tolerated and the baby's lack of mobility simplifies postoperative care.
2. A terminal slit-like meatus should be the goal with or without preservation of the foreskin depending on parental preference for all but the most severe forms of hypospadias.
3. Preservation of the urethral plate creates the best possible chance to recreate normal urethral anatomy by incorporating the abortive spongiosum to support the urethroplasty into the repair.
4. Midline dorsal plication is safe and effective for the correction of penile curvature in the majority of patients (placing more than two rows of sutures is a sign that another technique such as dermal grafting is indicated).
5. In the small percentage of patients who require resection of the urethral plate, a two-stage approach is generally warranted.
6. Vascularized pedicle onlay flaps are successful in primary and redo hypospadias surgery.
7. De-epithelialized vascular flaps should be used as a second layer for all urethroplasties.
8. Patients with a paucity of skin are best managed with the Bracka two-stage buccal repair.
9. Coronal fistulas require a redo glansplasty.
10. Surgical volume correlates with successful outcomes.

CHAPTER 99 COMPLETE PRIMARY REPAIR FOR EXSTROPHY

RICHARD W. GRADY

Bladder exstrophy is a congenital anomaly that has consistent external physical manifestations; the diagnosis of exstrophy is usually made immediately after birth, although it can be detected antenatally. The anterior portion of the bladder and/or urethra and abdominal wall structures are deficient, and the pubic symphysis is widely diastatic (Fig. 99.1); the bladder and urethra are herniated ventrally. The exstrophic defects are typically found in isolation; other organ systems are only infrequently affected with classic bladder exstrophy and epispadias. However, children with exstrophy typically have an anteriorly located anus. Female genital anatomy is altered, with a more vertically oriented vaginal opening after closure and a wider and shorter vagina than normal. The anterior component of the penis is also foreshortened in males compared to the general population.

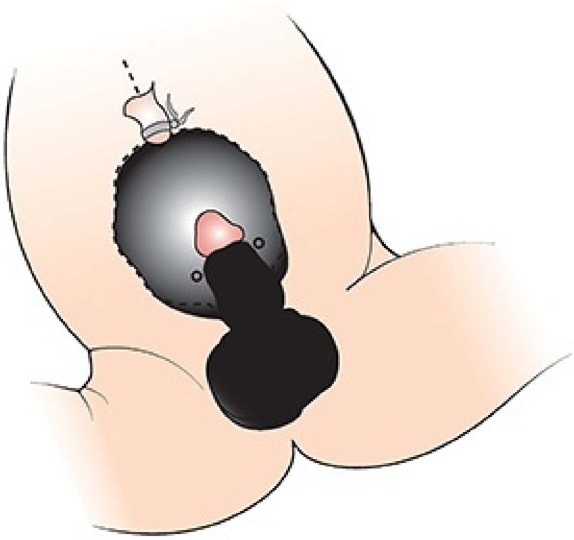

FIGURE 99.1 Initial dissection, inferior view. *Dashed lines* indicate lines of dissection. Note that the lines of dissection proceed around the umbilicus and superior to it. The line of dissection also extends subcoronally around the ventral aspect of the penis. See Figure 99.2 for another view of the initial lines of dissection.

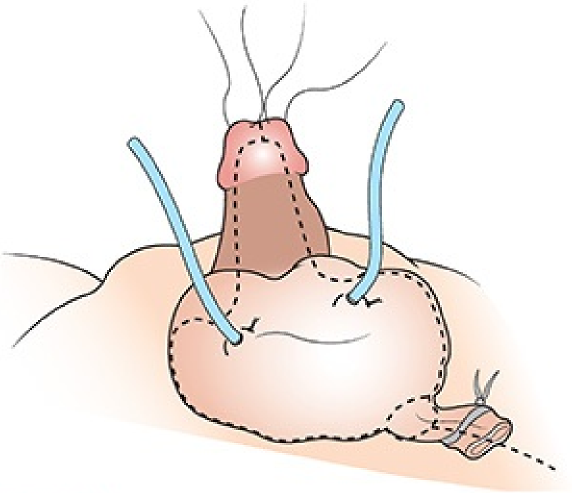

FIGURE 99.2 View of lines of dissection from Figure 99.1. The urethral dissection is carried along the lateral aspect of the urethral plate.

DIAGNOSIS

In some situations, the diagnosis may be made antenatally, although many affected fetuses are not detected before birth (1). In Gearhart's et al.'s review of 29 antenatal studies of 17 children born with exstrophy, only 3 were identified before delivery despite the presence of findings to suggest the diagnosis. Ultrasonography can reliably detect exstrophy before the 20th week of gestation (2,3). Ultrasonographic absence of the bladder is a hallmark of exstrophy. Other findings include a semisolid mass protruding from the abdominal wall, a lower abdominal protrusion, an anteriorly displaced scrotum with a small phallus in male fetuses, normal kidneys in association with a low-set umbilical cord, and an abnormal iliac crest widening.

Subtle findings such as low umbilical cord insertion and the location of the genitalia can be seen but only if the fetus is examined in a sagittal alignment with the spine (2). Because exstrophy affects the external genitalia, the diagnosis is easier to make in males than in females. Iliac crest widening can also be seen during the routine prenatal evaluation of the lumbosacral spine that is performed to evaluate for myelomeningocele. The iliac angle will be about 99 degrees rather than the 90 degrees that is normally seen. Because urine production is not affected for these fetuses, amniotic fluid levels should be normal.

Prenatal diagnosis allows optimal perinatal management of these infants. The infants can be delivered near a pediatric center equipped to treat babies with this unusual anomaly. Of equal importance, antenatal diagnosis also allows the parents the opportunity to discuss early management of the patient, which we recommend include the expertise of a pediatric urologist experienced in the treatment of bladder exstrophy. Patients with exstrophy can have a satisfactory long-term outcome and life expectancy with appropriate management.

INDICATIONS FOR SURGERY

Exstrophy anomalies are nonlethal in the developed world; children with exstrophy can survive untreated into adulthood (4). However, significant morbidity exists with these conditions if they are left untreated, including total urinary incontinence, bladder and kidney infections, skin breakdown, and tumor formation in the bladder plate. The surrounding skin around the exposed exstrophic bladder is often inflamed secondary to urine contact dermatitis, loss of skin integrity from constant wetness, and secondary infection. In contrast, when these patients receive effective surgical and medical treatment, they can lead productive, healthy lives with minimal morbidity from their underlying urologic abnormality.

SURGICAL TECHNIQUE

Primary goals for exstrophy reconstruction include the following:

1. Urinary continence with volitional voiding
2. Preservation of kidney function with low-pressure urinary storage
3. Functional and cosmetically acceptable external genitalia

Secondary goals for reconstruction include the following:

1. Minimization of urinary tract infections
2. Effective abdominal wall and pelvic floor support
3. Minimization of the risk for malignancy associated with the urinary tract
4. Minimization of the risk for urinary calculi

Surgical reconstruction of exstrophy and epispadias represents one of the most significant challenges for physicians who specialize in the urologic care of children. In the late 1980s, Mitchell devised an anatomic approach that integrated epispadias and exstrophy repair. This operation evolved out of a technique developed for the treatment of epispadias—the complete penile disassembly technique and was inspired by the published experience of Dr. Julian Ansell who employed neonatal reconstruction for these children (5). By employing this technique, the surgeon permits the tissue deformation in exstrophy to return more closely to an anatomically normal position. We have used this approach to surgically treat newborns with exstrophy since 1990. The principles of this operation can be employed in some reoperative repairs or delayed repairs for exstrophy.

Preoperative Care

After delivery, to reduce trauma to the bladder plate, the umbilical cord should be ligated with a zero suture rather than a plastic or metal clamp. A hydrated gel or occlusive dressing may be used to protect the exposed bladder from superficial trauma. These types of dressing are easy to use, keep the bladder plate from becoming desiccated, and stay in place to allow handling of the infant with minimal risk of trauma to the bladder. Plastic wrap is an acceptable alternative. Dressings should be replaced daily, and the bladder should be irrigated with normal saline with each diaper change. A humidified air incubator may also minimize bladder trauma.

We routinely use intravenous antibiotic therapy in the pre- and postoperative period to decrease the risk for infection following reconstruction. This is critical to the success of the immediate postoperative repair. We also perform preoperative ultrasonography to assess the kidneys and to establish a baseline examination for later ultrasonographic studies. Preoperative spinal sonographic examination should be considered if sacral dimpling or other signs of spina bifida occulta are noted on physical examination.

Operative Considerations

The primary exstrophy closure is typically performed in the neonatal period and as early as 1 to 2 days after birth. We routinely use general inhalation anesthesia. However, nitrous oxide should be avoided during primary closure as it may cause bowel distention, which decreases surgical exposure during the operation and increases the risk of wound dehiscence. Some advocate the use of nasogastric tube drainage to decrease abdominal distention in the postoperative period, but we do not routinely use it postoperatively. We do routinely place an epidural catheter to reduce the inhaled anesthetic requirement during the operation. Tunneling the catheter may reduce the risk for infection if it is left in for prolonged periods after surgery.

For patients older than 2 to 3 days or newborns with a wide pubic diastasis, we perform anterior iliac osteotomies at the time of the exstrophy repair to decrease the tension on the wound closure. Osteotomies assist closure and enhance anterior pelvic floor support, which may improve later urinary continence.

Factors that appear to be important in the operative period include use of osteotomies in selected cases and for newborn closures >48 hours after birth to decrease the tension on the repair, ureteral stenting and bladder drainage catheters placed intraoperatively for use in the postoperative period to divert urine, avoidance of abdominal distention, and use of intraoperative antibiotics.

Complete Primary Repair for Exstrophy Surgical Technique: Boys

After standard preparation of the surgical field, we place transversely oriented traction sutures into each of the hemiglans of the penis. We then mark the lines of dissection (Figs. 99.1 and 99.2). Care is taken in marking these lines to exclude dysplastic tissue at the edges of the exstrophic bladder and bladder neck. This is particularly important at the bladder neck, where dysplastic tissue left in continuity may impair later bladder neck function. Following this, we place 3.5Fr to 5Fr catheters into both ureters and suture them in place with 5.0 chromic suture. Bladder polyps are removed prior to beginning the dissection, since these will occupy space after the bladder is reconstructed (see Fig. 99.2). Initial dissection begins superiorly and proceeds inferiorly to separate the bladder from the adjacent skin and fascia, since it is usually easiest to identify tissue planes in this location. We use tungsten fine-tip electrocautery (Colorado tip) during this dissection to reduce blood loss. The umbilical vessels may be ligated if necessary. We also incise the periumbilical skin circumferentially at this time. The umbilicus will be moved superiorly to a more anatomically normal location and will be later used as the location to bring out the suprapubic catheter (Figs. 99.3 and 99.4).

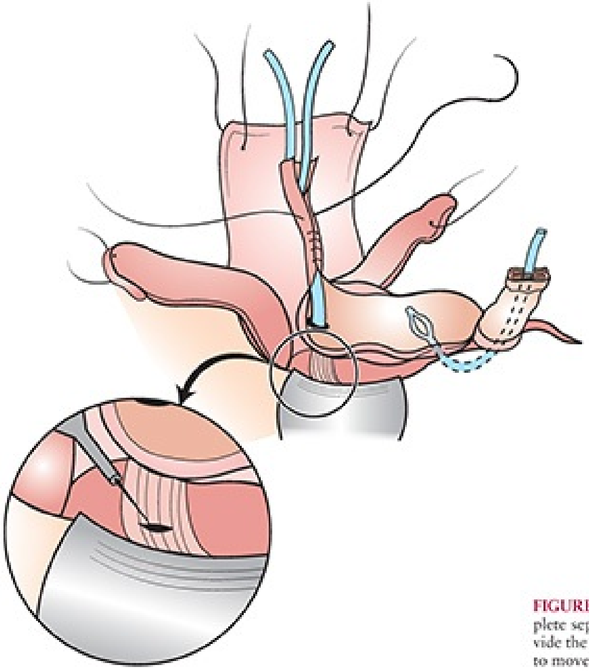

FIGURE 99.3 The exposure for deep dissection is optimal after complete separation of the corporal bodies. It is crucial to adequately divide the intersymphyseal band (*inset*) to allow the bladder and urethra to move posteriorly.

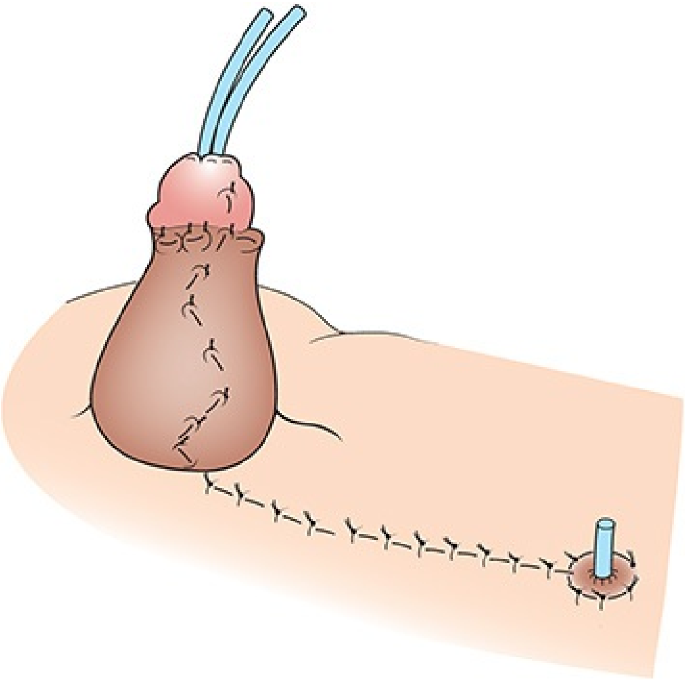

FIGURE 99.4 To adequately cover the penis dorsally, Z-plasty incisions may be necessary. We also employ tacking sutures dorsally.

Penile/Urethral Dissection

Traction sutures placed into each hemiglans of the penis aid in dissection at this point in the operation (see Fig. 99.2). The sutures will rotate to a parallel vertical orientation (Fig. 99.5) because the corporal bodies will naturally rotate medially after they are separated from the urethral wedge (urethral plate plus underlying corpora spongiosa). We begin the penile dissection along the ventral aspect of the penis as a circumcising incision (see line of dissection in Fig. 99.1). This step precedes dissection of the urethral wedge from the corporal bodies because it is easier to identify the plane of dissection above the Buck fascia ventrally (Fig. 99.6). The Buck fascia is deficient or absent around the corpus spongiosum; as the dissection progresses medially to separate the urethra from the corpora cavernosa, the plane shifts subtly from above the Buck fascia to just above the tunica albuginea. It is important to recognize this. Failure to adjust the plane of dissection will carry the dissection into the corpus spongiosum; this will result in excessive, difficult-to-control bleeding during the deep ventral dissection of the urethral wedge from the corporal bodies.

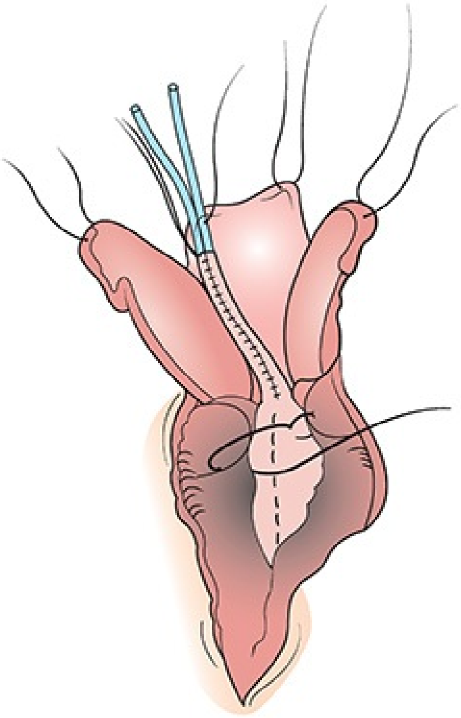

FIGURE 99.5 The urethra and bladder are reapproximated in a two-layer closure.

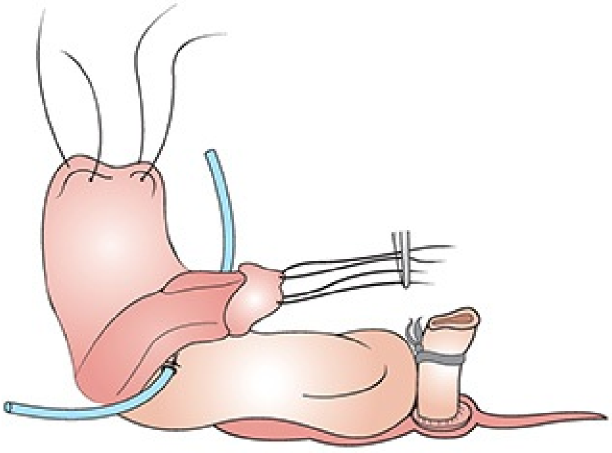

FIGURE 99.6 Ventral dissection is initiated most easily below the glans with a circumcising incision. The dissection may be carried proximally.

Applying methylene blue or brilliant green to the urethra can help identify the plane between urothelium and squamous epithelium. We routinely inject surrounding tissues with 0.25% lidocaine and 1:200,00 U per mL epinephrine to improve hemostasis. This may assist the dissection. Shallow incisions are made laterally along the dorsal aspect of the urethra to begin the dissection (Fig. 99.7). Sharp dissection is required to develop the plane between the urethral wedge and the corporal bodies. Careful dissection will preserve urethral width and length. This is particularly important because the urethra is often too short to reach the glans penis once the bladder has been moved into the pelvis.

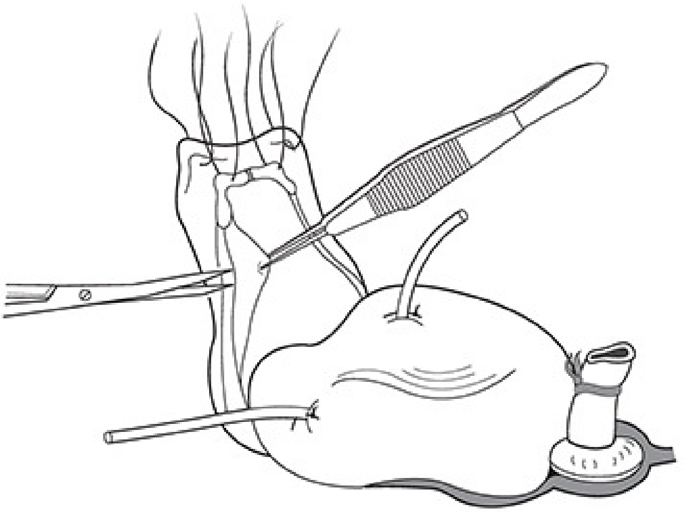

FIGURE 99.7 The urethra is dissected from the corporal bodies. This plane of dissection is developed from both a ventral and lateral perspective using sharp dissection.

Careful lateral dissection of the penile shaft skin and dartos fascia from the corporal bodies will avoid damaging the laterally located neurovascular bundles on the corpora of the epispadic penis. The lateral dissection on the penis should be superficial to the Buck fascia because of the lateral location of the neurovascular bundles in the epispadic penis.

Complete Penile Disassembly and Deep Dissection

Once a plane is established between the penis and the urethral wedge (Fig. 99.8), the penis may be disassembled into three components: (a) the right and (b) left corporal bodies with their respective hemiglans and (c) the urethral wedge (urothelium with underlying corpora spongiosa). This is done primarily to provide exposure to the intersymphyseal band and to allow adequate proximal dissection. We have found that the easiest plane of dissection to completely isolate the corporal bodies is proximal and ventral (Fig. 99.9). The plane of dissection should be carried out at the level of the tunica albuginea on the corpora. After a plane is established between the urethral wedge and the corporal bodies, this dissection is carried distally to separate the three components from each other (Fig. 99.10). Complete separation of the corporal bodies increases exposure to the pelvic diaphragm for deep dissection but is not always necessary as extensive dissection of the corporal bodies while leaving the glans attached often provides acceptable exposure to the pelvic diaphragm. The corporal bodies may be completely separated from each other because they exist on a separate blood supply (see Figs. 99.9 and 99.10). It is important to keep the underlying corpora spongiosa with the urethra; the blood supply to the urethra is based on this corporal tissue, which should appear wedge-shaped after its dissection from the adjacent corpora cavernosa. The urethral/corpora spongiosa component will later be tubularized and placed ventral to the corporal bodies. Paraexstrophy skin flaps are not recommended with this technique because this maneuver will place the blood supply to the distal urethra at risk. Because the bladder and urethra are moved posteriorly in the pelvis as a unit (with a common proximal blood supply), division of the urethral wedge is counterintuitive to the intent of the repair. In many cases, a male patient will be left with a hypospadias that will require later surgical reconstruction.

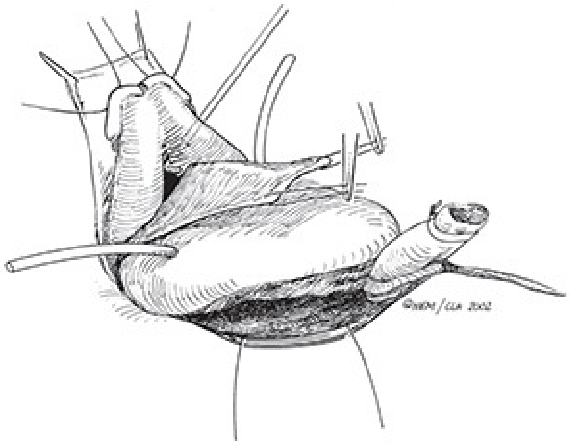

FIGURE 99.8 Disassembly of the corporal bodies from the urethra and corpora spongiosa (the urethral wedge) can often be most easily begun at the position depicted here. The dissection is carried distally to completely separate the glans penis.

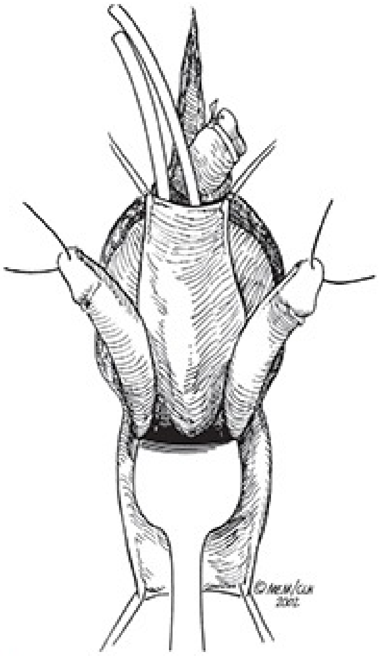

FIGURE 99.9 Perineal view of complete disassembly. Notice depth of dissection.

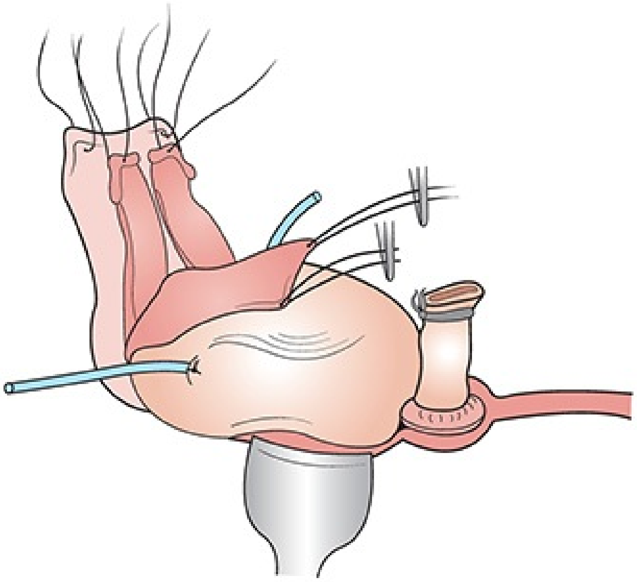

FIGURE 99.10 The urethra and corporal bodies are separated distally to allow deep dissection of the pelvic floor musculature.

Modifications. The urethra and corporal bodies do not always have to be separated; occasionally, the urethra is long enough and the bladder mobile enough to preserve the connection between them while still effectively carrying out the deep pelvic dissection that is integral to this repair. The surgeon should assess the mobility of the bladder and urethra to assess whether separation of the urethra and from the corporal bodies will assist in placing the bladder into the pelvis and whether separation will aid in penile length and straightening.

After separating the components distally, the urethral dissection is carried proximally to the bladder neck. Exposure to the pelvic diaphragm is optimized by complete separation of the urethra and corporal bodies (see Fig. 99.10). This creates the surgical exposure to perform the deep incision of the intersymphyseal band required to move the bladder and urethra posteriorly. When dissecting the urethral wedge from the corporal bodies medially, the dissection plane is on the tunica albuginea of the corpora cavernosa (see Fig. 99.9). This medial dissection should be carried down through the intersymphyseal band (the condensation of anterior pelvic fascia and ligaments) (see Fig. 99.3 inset).

Deep incision of the intersymphyseal band posterior and lateral to each side of the urethral wedge is essential to allow the bladder and bladder neck to achieve a posterior position in the pelvis. This dissection should be carried until the pelvic floor musculature becomes visible. Failure to adequately dissect the bladder and urethral wedge from these surrounding structures will prevent posterior movement of the bladder in the pelvis and create anterior tension along the urethral plate.

Primary Closure

Once the intersymphyseal band is adequately incised and the bladder and urethral wedge are adequately dissected from the surrounding tissues, the bladder and urethra can be reapproximated. This portion of the repair is straightforward and anatomic. To provide urinary drainage, we place a suprapubic tube and bring it out through the umbilicus. We then perform a primary closure of the bladder using a three-layer closure with monofilament absorbable suture (i.e., Monocryl and Vicryl). The urethra is tubularized using a one- or two-layer running closure with monofilament and braided absorbable suture (see Fig. 99.5). Because of the previous deep dissection, we can position the tubularized urethra ventral to the corpora in a tension-free fashion. If the urethra cannot be positioned ventrally without creating tension, it is likely that a deeper incision is required into the intersymphyseal band and pelvic fascia.

We reapproximate the pubic symphysis using two large (0 and no. 1) polydioxanone interrupted sutures placed in a figure-of-eight fashion. Knots are left anteriorly to prevent suture erosion into the bladder neck (Fig. 99.11). The rectus fascia is reapproximated using an interrupted or running 2-0 polydioxanone suture (PDS). We also place interrupted 6-0 PDS along the dorsal aspect of the corporal bodies to reapproximate them (Fig. 99.12). We provide penile skin coverage by using either a primary dorsal closure or reversed Byars flaps if needed. The skin covering the abdominal wall is reapproximated using a two-layer closure of absorbable monofilament suture.

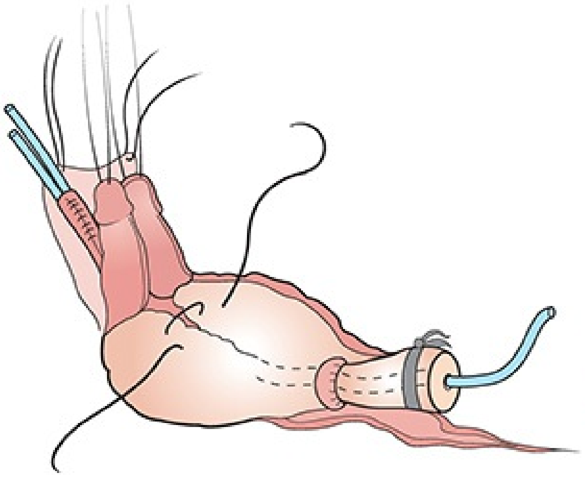

FIGURE 99.11 After the bladder and urethra are reconstructed, these structures will move posteriorly. The urethra will assume a more normal anatomic position. The pubic symphysis is reapproximated with two figure-of-eight sutures.

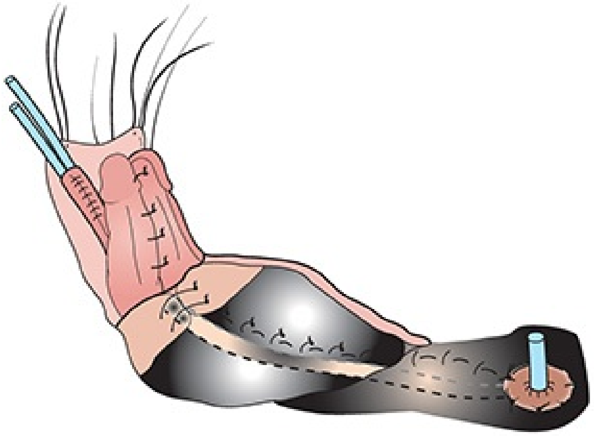

FIGURE 99.12 The corporal bodies will rotate medially so that the neurovascular bodies are located medially. The suprapubic tube can be brought out through the umbilicus. The umbilicus is moved superiorly to a more normal anatomic location.

The corporal bodies will rotate medially with closure (see Fig. 99.11). This rotation will assist in correcting the dorsal deflection and can be readily appreciated by observing the new vertical lie of the previously horizontally placed glans traction sutures. Occasionally, significant discrepancies in the dorsal and ventral lengths of the corpora will require dermal graft insertion to correct chordee.

If there is adequate urethral length, the urethra may be brought up to each hemiglans ventrally to create an orthotopic meatus (see Fig. 99.12). We reconfigure the glans using interrupted mattress PDS followed by horizontal mattress sutures of 7-0 monofilament suture to reapproximate the glans epithelium. The neourethra is matured with 7-0 braided polyglactin suture similar to our standard hypospadias repair. When needed, we also perform glans tissue reduction to create a conical-appearing glans and to eliminate the furrow between the glans halves. Tacking sutures are placed ventrally and dorsally to prevent penile shaft skin from riding over the corporal bodies and “burying” the penis (Figs. 99.4 and 99.13).

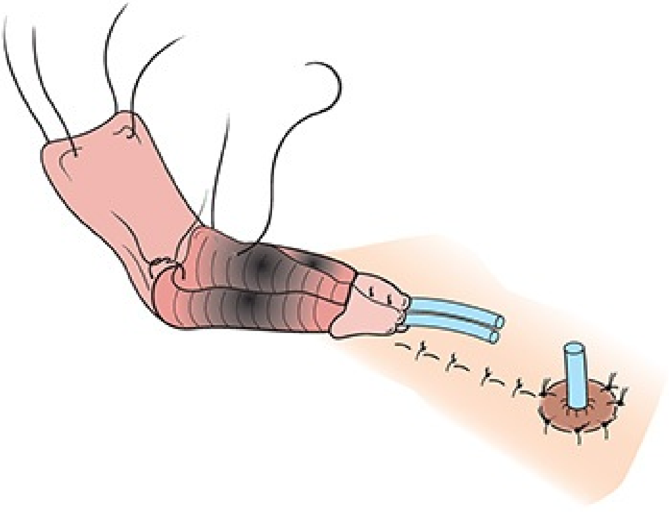

FIGURE 99.13 The ventral shaft skin is secured to the base of the penis to prevent the penile shaft skin from riding over the body of the penis. The ureteral catheters are brought out through the urethra.

In our hands, the urethra lacks enough length to reach the glans in about half the cases. In this situation, we mature the urethra along the ventral aspect of the penis to create a hypospadias. This can be corrected at a later date as a second-stage procedure (6,7). We often leave redundant shaft skin ventrally in these patients to assist in later penile reconstructive procedures.

The Primary Repair Technique: Girls

The principles of this single-stage technique are similar in boys and girls. After preoperative antibiotics are given, the patient is prepared and draped in a sterile field. We mark the planned lines of incision (Fig. 99.14) with the bladder neck, urethra, and vagina mobilized as a unit. We perform this dissection with a tungsten-tip electrocautery (Colorado tip) to minimize tissue damage while achieving hemostasis. The appropriate plane of dissection is found anteriorly along the medial aspect of the glans clitoris and proceeds posteriorly along the lateral aspect of the vaginal vault (Fig. 99.15). The vagina is mobilized with the urethra and bladder neck. Dissection along the vaginal wall extends quite laterally. Placement of a hemostat in the vaginal vault will help with retraction to identify the plane of dissection. The urethra and bladder neck should not be dissected from the anterior vaginal wall, as this will compromise the blood supply to the urethra. During the posterior lateral dissection, the intersymphyseal band will be encountered and should be deeply incised to allow the urethra and bladder neck to move posteriorly. The posterior limit of the dissection is reached when the pelvic floor musculature is exposed and the bladder, bladder neck, and urethra can move into the pelvis without tension.

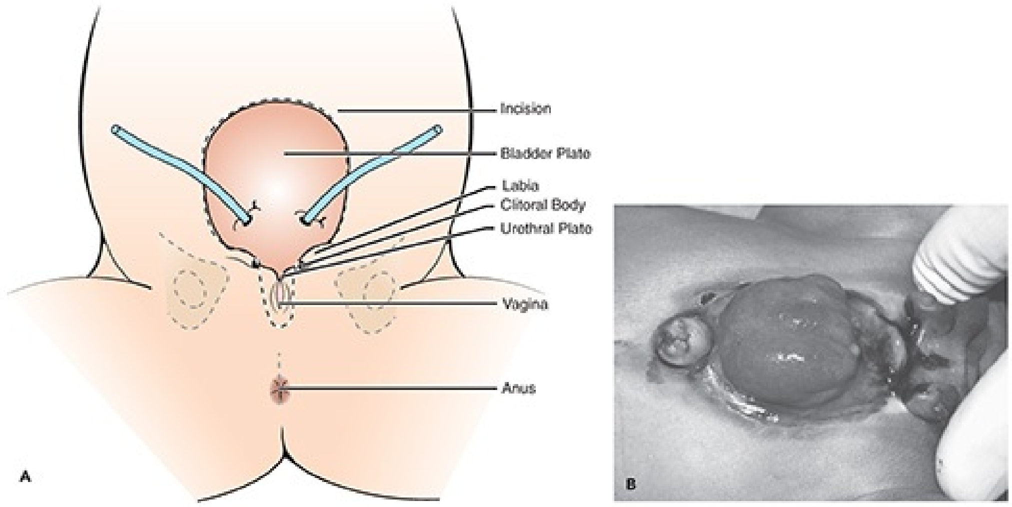

FIGURE 99.14 A: Schematic diagram of lines of incision for complete primary repair of a female infant with bladder exstrophy. This concept has been applied to the repair of female epispadias in the adjacent photograph (B), demonstrating lines of incision for an infant girl with epispadias. Note the posterior extent of dissection to allow movement of the vagina, bladder neck, and urethra as a unit posteriorly.

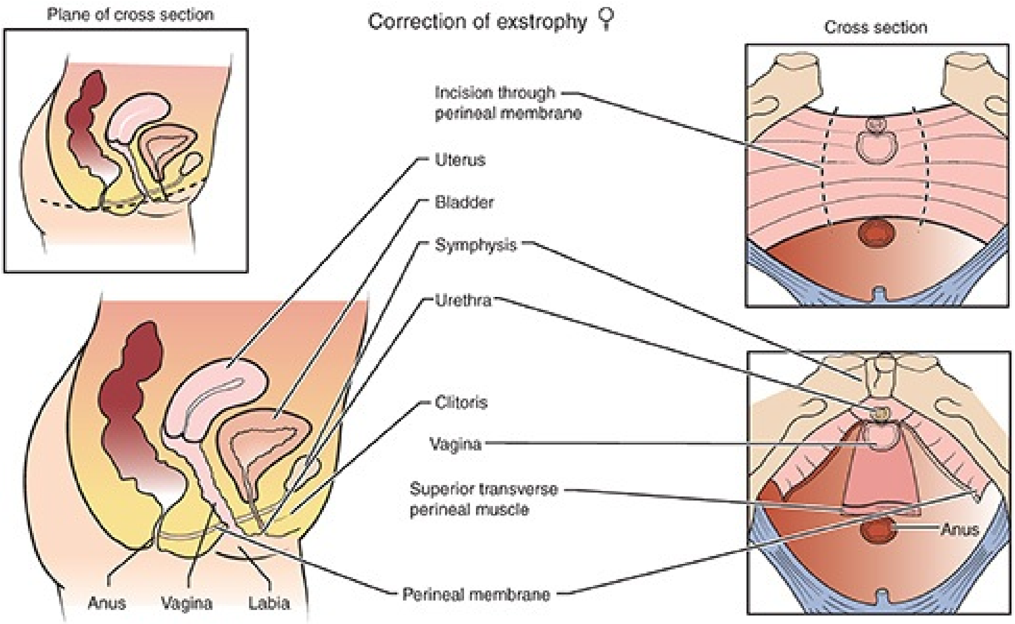

FIGURE 99.15 The plane of dissection lies adjacent to the urethra and vaginal vault (*dashed lines in upper right cross-sectional view*).

Following adequate dissection, the vagina, urethra, and bladder neck are moved posteriorly using a Y-V plasty if the vagina is anteriorly located (Fig. 99.16). The urethra is then tubularized using a two-layer closure of absorbable suture. Prior to the urethral closure, we routinely place a suprapubic tube to provide postoperative urine drainage. The pubic symphysis is reapproximated using two figure-of-eight no. 1 PDS (Fig. 99.17). Osteotomies may be necessary when a wide pubic diastasis prevents a low-tension reapproximation of the pubic symphysis or if the patient is older than 48 to 72 hours old. We use anterior iliac osteotomies in these situations. The rectus fascia can then be closed in the midline. We mature the neourethra with 5-0 Vicryl sutures and reapproximate the bifid clitoris but do make an effort to construct them as one unit (Fig. 99.18). The labia majora should be advanced posteriorly to the perineum at this time as well. A Z-plasty skin closure aids in skin closure. A simplified monsplasty technique described by Pippi-Salle et al. provides a satisfactory aesthetic result to the introital area and can be applied at the time of the primary repair (8).

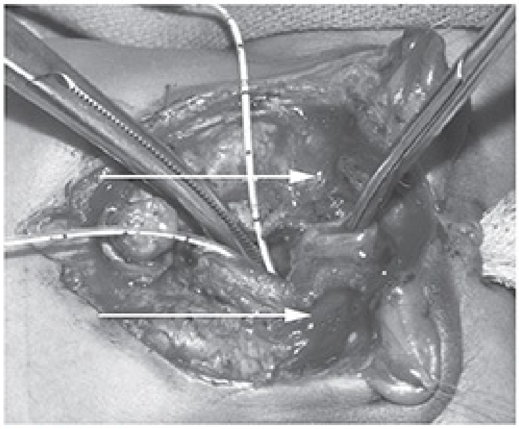

FIGURE 99.16 The intersymphyseal band is incised laterally (*white arrows*) to allow the urethra, bladder, and vaginal vault to move posteriorly as a unit.

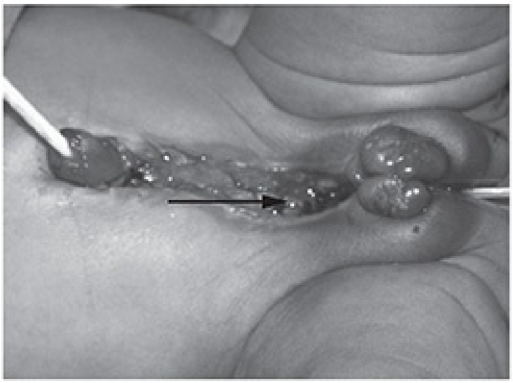

FIGURE 99.17 The pubic symphysis is reapproximated (*arrow*). With adequate dissection, the pubic symphysis can be reapproximated with minimal compressive effects on the urethra and bladder.

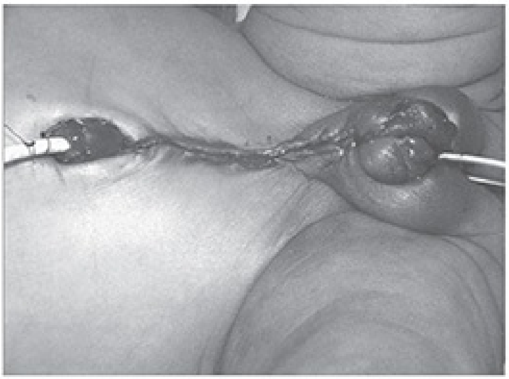

FIGURE 99.18 Final reconstruction demonstrates apposition of the labia and clitoral bodies. Denuding the epithelium on the clitoris medially improves the cosmetic results postoperatively but is not necessary and may damage the clitoris.

Adjunctive Aspect of Repair

Inguinal hernias are commonly associated with exstrophy in both male and female patients. The majority of these hernias occur indirectly. They arise as a consequence of enlarged internal and external inguinal rings combined with compromised fascial support and lack of obliquity of the inguinal canal. In a review of patients from the Toronto Sick Children's Hospital, 56% of classic male exstrophy patients and 15% of classic female exstrophy patients developed inguinal hernias over a 10-year period (9). The authors recommended that these hernias be repaired at the time of primary bladder closure to prevent incarcerated hernias, which could affect up to 50% of these patients in the first 2 years of life. Reinforcement of the transversalis and internal oblique fascia during hernia repair decreases the incidence of later direct inguinal hernias. Umbilical hernias, as a contiguous defect with the bladder plate, also uniformly occur with exstrophy and are repaired at the time of the primary repair.

POSTOPERATIVE CARE

The patient must be immobilized to decrease lateral stresses on the closure after the primary reconstructive procedure for exstrophy. A number of options exist for this purpose. We currently prefer to use a spica cast for 3 to 6 weeks to prevent external hip rotation and to optimize pubic apposition, which can facilitate early discharge and home care (Fig. 99.19). Modified Buck traction has been used by many groups with success or splinting techniques can be used as well (10). A posterior lightweight splint can be used in newborns when the child is out of traction to maintain hip adduction. We have stopped using Buck traction because spica casts are easier for the families to care for at home. External fixation devices have also been used with success (10). Fixator pins for these devices should be cleaned several times a day to reduce the chance for infection. Internal fixation may be necessary in older patients.

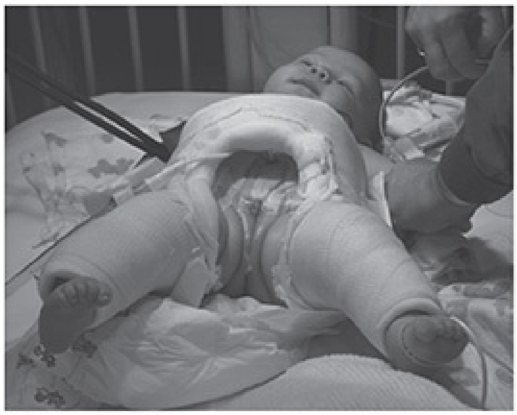

FIGURE 99.19 Use of a spica cast postoperatively to immobilize the pelvis and prevent hip abduction.

Because of the high incidence of vesicoureteral reflux, we prescribe low-dose suppressive antibiotic therapy for all newborns after bladder closure. This is continued until the vesicoureteral reflux is corrected or resolves spontaneously. Some surgeons perform neoureterocystotomies at the time of initial closure. The success of this approach has not been reported.

Postoperative factors that appear to directly impact the success of initial closure include postoperative immobilization, use of postoperative antibiotics, ureteral stenting catheters, adequate postoperative pain management, avoidance of abdominal distention, adequate nutritional support, and secure fixation of urinary drainage catheters.

OUTCOMES

Complications

Complications can occur with this form of exstrophy closure. The most commonly reported complication is urethrocutaneous fistula formation (at the penopubic angle dorsally) in males. These fistulas will often close spontaneously. They may initially be managed conservatively by providing urinary diversion via catheter drainage. If the fistula does not close after conservative management, the bladder and urethra should be examined cystoscopically for the possibility of obstruction at the bladder neck or urethra.

Other complications have been reported following a primary reconstructive technique. These include atrophy of the corpora cavernosa and urethra. These complications can occur if the blood supply to the corporal bodies or urethral wedge is damaged during dissection or during closure (11). Similar complications have been described following the initial stage of a staged reconstruction (12,13). In experienced hands, such complications are unusual and underscore the importance of involving surgeons experienced in the surgical management of these patients in their care.

If a child develops chronic bladder and kidney infections following exstrophy closure, he or she should be evaluated for possible outlet obstruction. We routinely maintain our patients on suppressive antibiotic therapy because of the high incidence of vesicoureteral reflux in this population.

Results

The longest series reporting outcomes of complete primary repair of exstrophy (CPRE) is from Seattle Children's Hospital, spanning 20 years. Median follow-up for 39 patients was reported as 58 months. When the authors assessed children older than 4 years of age, 74% reported daytime continence with volitional voiding and 20% of boys and 43% of girls achieving continence without bladder neck reconstruction or tailoring. Bladder neck procedures prior to achieving continence were performed for other children in the series. The majority of these bladder neck modifications were performed at the same time as ureteral reimplantation procedures and were performed using a Mitchell bladder neck technique. An 18% complication rate was reported in this series (7). In another series using CPRE, Borer and colleagues noted that five of eight patients (63%) 4 years old or older had grossly inadequate bladder outlet resistance and either had or will require bladder neck reconstruction (14). This same group also reported on urodynamic findings between patients who had undergone exstrophy repair using a complete primary repair technique compared to a modern stage repair technique. Patients undergoing a complete primary repair universally had bladder stability and bladder compliance versus those who had been repaired using a staged approach. Bladder capacity was equivalent between the two groups. Interestingly, patients repaired with a complete repair technique also had normal electromyelography results during this study (14–16).

CHAPTER 100 EXSTROPHY AND EPISPADIAS—MODERN STAGED APPROACH

EZEKIEL E. YOUNG, JOHN P. GEARHART, AND BRIAN M. INOYUYE

Bladder exstrophy is a rare, severe congenital defect that affects the lower urinary tract, genitalia, abdominal wall, and pelvis. The reported incidence ranges from 1:10,000 to 1:50,000 live births, with boys being affected 5 to 6 times more frequently than girls (1). Bladder exstrophy is usually an isolated defect, and in its classic form, associated chromosomal abnormalities or defects of the central nervous system, heart, and digestive tract are extremely uncommon.

Until the middle of the 19th century, bladder exstrophy was treated primarily nonsurgically. Early forms of repair focused on abdominal wall closure using skin flaps for partial reconstruction, leaving a fistula to attach a urinal for dryness. Trendelenburg recognized that pubic reapproximation would not only prevent prolapse of the reconstructed bladder but also be crucial to achieve continence. Although his theoretical assumptions were correct, his surgical efforts were not successful (2). Early failures led to an abandonment of interest in primary closure with a shift toward urinary diversion. In 1942, Hugh Hampton Young performed the first successful primary closure of a female exstrophy patient (3). Although similar reports about continent, primary closures were published in the same era, the numbers were small and most surgeons were not able to reproduce these favorable results. Both Jeffs (4) and Cendron (5) published their descriptions of successful staged anatomic reconstruction in the mid-1970s, and their pioneering work set the standard for the modern staged repair of exstrophy (MSRE). Grady and Mitchell (6) subsequently developed the complete primary repair of exstrophy (CPRE), in which the primary closure is combined with epispadias repair by complete penile disassembly, often resulting in a hypospadias position of the urethral meatus (7).

While older techniques have evolved and alternative approaches have been developed, the primary objectives of modern exstrophy management remain consistent:

1. Secure closure of the abdominal wall, pelvis, bladder, and urethra.
2. Reconstruction of a functional and cosmetically acceptable penis in the male and external genitalia in the female.
3. Urinary continence, preferably via urethral voiding, with preservation of renal function.

The complex embryology and genetics of exstrophy are not well understood. A number of theories have been proposed, which include premature rupture of the cloacal membrane, arrested mesenchymal ingrowth, and failure of cranial yolk sac progression during development (1). In its classic form, bladder exstrophy describes the condition in which an exteriorized bladder template develops in association with a diastasis of the pubic symphysis. This pubic separation results in characteristic genital and pelvic abnormalities. The pubic diastasis is found in association with foreshortened, externally rotated anterior pubic rami and a wide pelvic inlet. The perineum is short and broad and there is anterior displacement of the anus. The appearance of the genitalia varies by gender. In boys, the urethra lies in an epispadiac position, splayed open on the dorsal surface of the corporal bodies. The pubic diastasis results in corporal shortening and severe dorsal chordee. The testes are usually descended, but inguinal hernias are extremely common, especially in boys. In girls, the pubic diastasis results in an absence of a mons pubis, with a bifid clitoris and lateral displacement of the labia. Girls usually present with a bifid clitoris and a shortened vagina, often with a stenotic orifice. In isolated epispadias, which can be viewed as the least severe form of exstrophy, the bladder is closed and covered by a normal abdominal wall, but the pubic separation and genital abnormalities persist. Degrees of epispadias vary in a manner analogous to hypospadias from the very proximal "complete" epispadias in which the urethra is open through the bladder neck, to minor distal variants. A number of other exstrophy variants have been described (8).

DIAGNOSIS

The definitive diagnosis of bladder exstrophy is made upon recognition of the characteristic physical examination findings at the time of birth. Diagnosis by prenatal ultrasound is becoming more common with advances in sonographic techniques. Ultrasound findings include an absence of bladder filling, an anterior abdominal mass, a low-set umbilicus, abnormal widening of the iliac crests, and an anteriorly displaced scrotum with a small phallus in male fetuses (9). The differential diagnoses include cloacal exstrophy, omphalocele, and gastroschisis. Children with a prenatal diagnosis of exstrophy should be delivered at term via cesarean section. The principal implication of prenatal diagnosis of exstrophy is that most parents will seek early counseling regarding the nature of the disease and will temporarily relocate, if necessary, to a center with experience in exstrophy management. Some parents ultimately decide to terminate their pregnancies. The regionalization of complex surgical care such as that required for exstrophy patients is the subject of current debate and outcomes research.

INDICATIONS FOR SURGERY

Historically, some children with bladder exstrophy have survived without surgical reconstruction. As mentioned previously, the earliest attempts at treatment focused on providing a suitable drainage apparatus that would help to manage chronic wetness and odor. The importance of treating this condition, however, can be inferred from several studies that have investigated the profound negative impact of urinary incontinence and sexual dysfunction on quality of life and social and psychological well-being (10,11). Furthermore, it is known that chronic exposure of the exposed bladder mucosa to the environment results in painful ulceration and metaplastic and ultimately neoplastic changes (12). It seems reasonable to conclude that all children with exstrophy should receive appropriate surgical reconstruction, regardless of their economic circumstances.

ALTERNATIVE THERAPY

Urinary Diversion

Historically, a number of different urinary diversion techniques have been successfully used in the management of exstrophy (13). Although incontinent conduits are rarely indicated in contemporary pediatric practice, reconstructive urologists should be comfortable employing them in very select circumstances. Ureterosigmoidostomy was the first successful continent diversion performed for exstrophy, and such patients have demonstrated very good rates of continence without the need for intermittent catheterization (14). The role of ureterosigmoidostomy has decreased with the application of anatomic reconstructions, but it is still used in some centers today. The Mainz II pouch is a modification of the ureterosigmoidostomy that reconfigures the sigmoid into a theoretically lower pressure reservoir, thereby promoting continence and renal preservation (13). Long-term concerns for malignancy at the ureterocolonic anastomosis and renal deterioration necessitate ongoing postoperative surveillance. Urinary diversion remains an important salvage approach in children who fail anatomic reconstruction.

Anatomic Reconstruction

MSRE will be described in detail as performed at Johns Hopkins. Alternate anatomic reconstructions have been proposed and are used in some centers. As is fully described in a separate chapter, Grady and Mitchell (6) developed the one-stage closure in the newborn period, combining primary closure of the bladder, urethra, abdomen, and pelvis with epispadias repair by penile disassembly. Proponents of CPRE believe that this approach will promote bladder growth and better continence outcomes by initiation of bladder cycling early on (6). Schrott (15) describes bladder closure, ureteral reimplantation, epispadias repair, and bladder neck reconstruction in the newborn period, applying the same technique to even older children without osteotomies. Primary newborn exstrophy closure followed by subsequent combined bladder neck reconstruction and epispadias repair has been described by Baka-Jakubiak (16). The combination of bladder closure with modified Cantwell–Ransley epispadias repair has been reported in a series of delayed and secondary exstrophy closures (17).

SURGICAL TECHNIQUE

Preoperative Considerations

A type and screen with baseline complete blood count and coagulation studies should be obtained. A plain film of the pelvis allows for precise measurement of the pubic diastasis. A baseline renal/bladder ultrasound is recommended to establish the presence of both units and for purposes of later comparison. Three-dimensional magnetic resonance imaging is obtained in all of our patients preoperatively but remains investigational. The umbilical cord should be ligated with a heavy silk suture. If a plastic cord clamp was used initially, this should be changed in order to prevent it from irritating the bladder mucosa. Likewise, the bladder template should be kept moist with periodic saline irrigation and covered with either a hydrated gel or Saran-type dressing. Petroleum-based gauze dressings are discouraged as they may dry and denude the mucosa when removed. Latex precautions are recommended, as many of these children will develop latex sensitivity or allergy later in life.

Timing and Staging

Modern staged closure has defined strict criteria for the selection of patients suitable for this approach. The technique includes early bladder, posterior urethral, and abdominal wall closure, usually with pelvic osteotomy in the newborn period, subsequently followed by an early epispadias repair at 6 months of age after intramuscular testosterone stimulation. Around age 4 to 5 years, a competent bladder neck is reconstructed along with bilateral ureteral reimplantation, when adequate bladder capacity is reached and the child demonstrates the maturity necessary to participate in a postoperative voiding program (18).

Successful initial bladder and posterior urethral closure is the most important factor for achieving eventual urinary continence and sufficient bladder capacity. The primary objective in initial, functional closure is to convert the bladder exstrophy into an incontinent penile shaft epispadias, balancing posterior outlet resistance in order to preserve renal function while stimulating bladder growth. The size and the functional capacity of the detrusor muscle are ultimately the most important determinants of success (19). In the presence of a small, fibrotic bladder template without elasticity or contractility, the operation should be deferred until adequate template growth has taken place. If sufficient size is not reached 4 to 6 months after birth, alternative options should be considered. Inguinal hernia repairs should be considered early if the closure is delayed in order to guard against incarceration during this time interval.

The role of pelvic osteotomy performed at time of initial closure ensures a tension-free approximation of the bladder, posterior urethra, and abdominal wall, and placement of the urethra deep within the pelvic ring, enhancing bladder outlet resistance, and aligning the large pelvic floor muscles to support the bladder neck. Usually, osteotomies are not needed in the patient <72 hours old with malleable pubic bones that are easily brought together in the midline by medial rotation of the greater trochanters. However, if the pubic bones are >4 cm apart or unable to be reapproximated without tension under anesthesia, osteotomies are mandated to ensure a secure closure.

Osteotomy

The bilateral anterior innominate and vertical iliac osteotomy has been used in our institution because it has numerous advantages over the posterior approach. The patient is placed in a supine position, preparing and draping the lower body below the costal margins and placing soft absorbent gauze over the exposed bladder. The pelvis is exposed from the inferior wings inferiorly and the pectineal tubercle posteriorly to the sacroiliac joints. The periosteum and sciatic notch are carefully elevated and a Gigli saw is used to create a transverse innominate osteotomy exiting anteriorly at a point halfway between the anterosuperior and the anteroinferior spines (Fig. 100.1). This osteotomy is created at a slightly more cranial level than that described for a Salter osteotomy to allow placement of external fixator pins in the distal segments. Also, the posterior ileum may be incised from the anterior approach in an effort to correct the deformity more completely. This is important because anatomic studies have shown that the posterior portion of the pelvis is also externally rotated in patients with exstrophy, and as patients age, they lose the elasticity of their sacroiliac ligaments. An osteotome is used to create a closing wedge osteotomy vertically and just lateral to the sacroiliac joint. The posterior iliac cortex is kept intact and used as a hinge. Two fixator pins are placed in the inferior osteotomized segment and two pins are placed in the wing of the ilium superiorly. Radiographs are obtained to confirm pin placement, soft tissues are closed, and the urologic procedure is performed. At the conclusion of the exstrophy closure, external fixators are applied between the pins to hold the pelvis in a correct position.

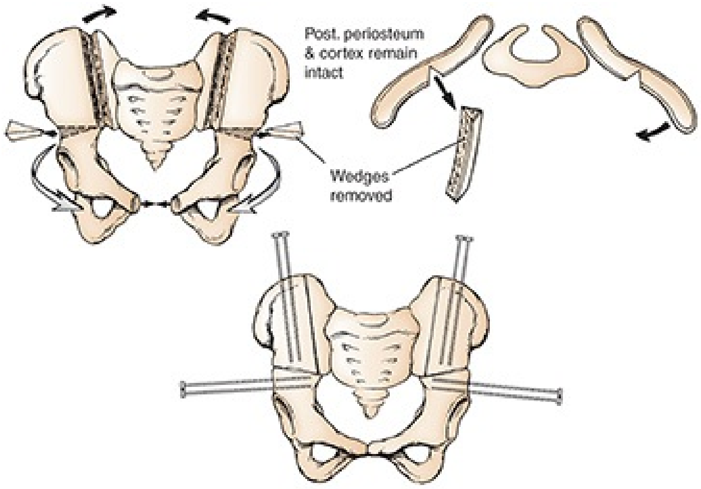

FIGURE 100.1 Combined transverse anterior innominate and anterior vertical iliac osteotomies with pin placement and preservation of the posterior periosteum and cortex. (Drawings by Timothy Phelps after Leon Schlossberg. Copyright © 2013 Brady Urological Institute, with permission.)

Radiographs are taken 7 to 10 days postoperatively. If the diastasis has not been completely reduced, the right and left sides can be gradually approximated using the fixator bars over several days. Light longitudinal Buck skin traction is used to keep the legs still. The patient remains supine in traction for approximately 4 weeks to prevent dislodgement of tubes and destabilization of the pelvis. The external fixator is kept on for approximately 6 weeks, until adequate callus is seen at the site of osteotomy. The pins are removed under light sedation at the bedside. Postoperatively, newborns undergoing closure without osteotomy are immobilized in modified Bryant traction for 4 weeks with the hips in 90 degrees of flexion.

Staged pelvic closure in the setting of an extreme (>8 cm) pubic diastasis has been described with good results in a series of children with both classic and cloacal exstrophy. In this approach, osteotomies are performed in conjunction with interfragmentary pin placement during the initial procedure. The pelvis is then gradually reduced under sedation at the bedside over the next several weeks, and ultimately, the pubis is secured with an interpubic stainless steel plate that is placed at the time of bladder and urethral closure (20).

The use of spica casting and mummy wrapping for immobilization following exstrophy closure has been described. In our experience, these techniques are associated with higher rates of complications and inferior surgical outcomes and are not recommended (21). Okubadejo et al. (22) reviewed the orthopedic complications of exstrophy management in 624 patients from Johns Hopkins: 26 complications were noted (4%), of which four were identified as being specifically caused by traction.

Bladder, Posterior Urethral, and Abdominal Wall Closure

The various steps in primary bladder closure are illustrated in Figure 100.2. A 2-cm wide strip of mucosa is outlined for prostatic and urethral reconstruction, extending from the distal trigone well onto the penile shaft in boys, and to the vaginal orifice in females (Fig. 100.2A). With the advent of the modified Cantwell–Ransley epispadias repair, the urethral plate should not be incised unless the length of the urethral groove, from the verumontanum to the glans, is so short that it produces dorsal angulation and will likely interfere with eventual penile length. In this situation, the urethral groove is lengthened. Figures 100.2B to 100.2D show marking of the incision from just above the umbilicus down around the junction of the bladder and the para-exstrophy skin to the level of the urethral plate. The appropriate plane is entered just above the umbilicus and a plane is established between the rectus fascia and the bladder (Fig. 100.2E and F). The umbilical vessels are doubly ligated and incised and allowed to fall into the pelvis. The peritoneum is taken off the dome of the bladder to be deeply placed into the pelvis at the time of closure. The plane is continued caudally down between the bladder and rectus fascia until the urogenital diaphragm fibers are encountered bilaterally. With electrocautery, these urogenital diaphragm fibers between the bladder neck, the posterior urethra, and the pubic bone are sharply taken down in their entirety to the levator hiatus (see Fig. 100.2F). A double-pronged skin hook can be inserted into the pelvic bone and pulled laterally to accentuate the urogenital diaphragm fibers. If this maneuver is not performed adequately, the vesicourethral unit will be brought anteriorly with pelvic closure in an unsatisfactory position for later reconstruction.

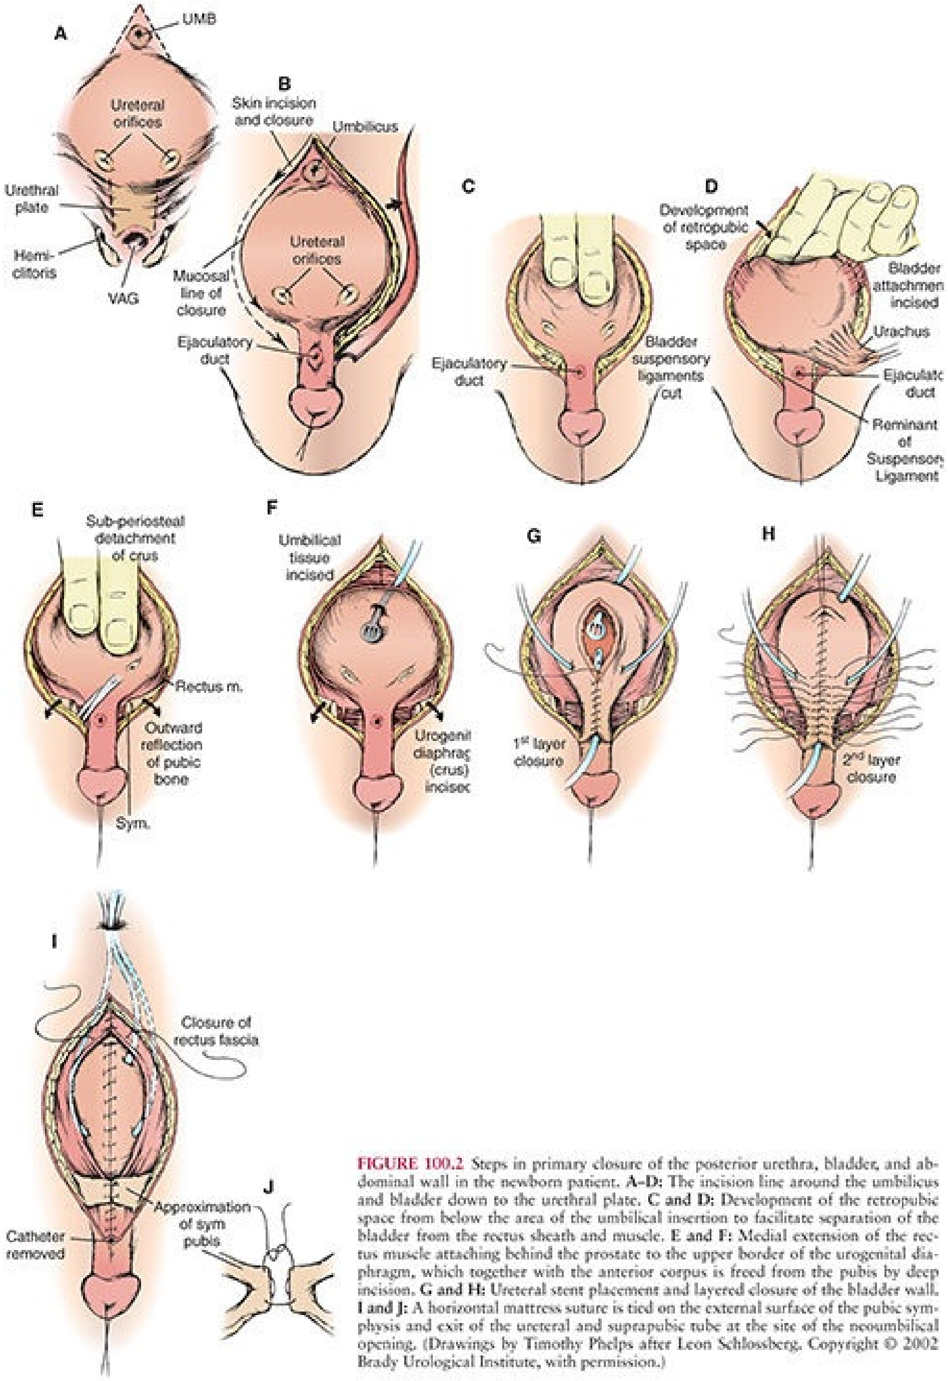

FIGURE 100.2 Steps in primary closure of the posterior urethra, bladder, and abdominal wall in the newborn patient. **A–D:** The incision line around the umbilicus and bladder down to the urethral plate. **C and D:** Development of the retropubic space from below the area of the umbilical insertion to facilitate separation of the bladder from the rectus sheath and muscle. **E and F:** Medial extension of the rectus muscle attaching behind the prostate to the upper border of the urogenital diaphragm, which together with the anterior corpus is freed from the pubis by deep incision. **G and H:** Ureteral stent placement and layered closure of the bladder wall. **I and J:** A horizontal mattress suture is tied on the external surface of the pubic symphysis and exit of the ureteral and suprapubic tube at the site of the neoumbilical opening. (Drawings by Timothy Phelps after Leon Schlossberg. Copyright © 2002 Brady Urological Institute, with permission.)

If the decision is made to transect the urethral groove, then it is cut distal to the verumontanum with continuity maintained between the thin, mucosa-like non–hair-bearing skin adjacent to the posterior urethra and bladder neck and the skin and mucosa of the penile glans. Thin skin flaps are then developed and rotated distally to reconstruct the urethral groove, resurfacing the penis dorsally. The corporal bodies are not brought together because later Cantwell–Ransley epispadias repair requires the urethral plate to be brought underneath the corporal bodies. If the urethral plate is left in continuity, it must be mobilized up to the level of the prostate to create as much urethral and penile length as possible. Apparent penile lengthening is achieved by exposing the corpora cavernosa bilaterally and freeing the corpora from their attachments to the suspensory ligaments. After the urogenital diaphragm is completely incised bilaterally, freeing the bladder neck and urethra well from the pubis, the mucosa and muscle of the bladder and posterior urethra are closed in the anterior midline down onto the midshaft penis (Fig. 100.2G). The resulting orifice should be easily passed by a 12Fr sound, creating enough resistance to aid in bladder adaptation and prevent prolapse but not so much as to cause undue outlet resistance altering the upper tracts. A second layer is closed if possible (Fig. 100.2H). Bladder drainage is achieved using a suprapubic nonlatex Malecot catheter for 4 weeks.

The urethra is left unstented to prevent necrosis. Ureteral stents are left in place for 10 to 14 days, until swelling goes down.

By applying gentle pressure over the greater trochanters bilaterally, the pubic bones are approximated in the midline. A horizontal mattress suture of no. 2 nylon is placed between the fibrous cartilages of the pubic rami and tied anteriorly to the pubic closure to avoid the neourethra (Fig. 100.2I and J). A second stitch is placed caudal to the insertion of the rectus fascia if possible for added support. Should the sutures work loose or cut through the tissues during subsequent healing, the anterior placement of the knot of the horizontal mattress suture ensures that it will not erode through into the urethra. At a point corresponding to the normal position of the umbilicus, a V-shaped flap of abdominal skin is tacked down to the abdominal fascia, and the drainage tubes exit this neoumbilicus.

Postoperatively, before removing the suprapubic tube, the bladder outlet is calibrated to ensure free passage of urine. Repeated ultrasound examinations are obtained before discharge and every 3 months thereafter to monitor for upper tract dilatation and residual urine. Continuous, prophylactic antibiotic therapy is advised to prevent upper tract infection from ureteral reflux. Yearly gravity cystograms under anesthesia are performed to receive quality information about reflux and, more importantly, bladder capacity. Successful continence procedures necessitate a minimal bladder capacity of 100 mL (19). An increase in bladder capacity is typically seen after epispadias repair, which is why the bladder neck procedure is performed after the urethral reconstruction.

Epispadias Repair

Four key concerns have to be addressed: (a) a functional and cosmetically pleasing penis, (b) correction of dorsal chordee, (c) urethral reconstruction, and (d) penile skin closure and glandular reconstruction. In patients undergoing delayed repair or reclosure, a combined epispadias/exstrophy closure using the modified Cantwell–Ransley repair is possible.

The modified Cantwell–Ransley repair is begun by placing a nylon suture through the ventral glans for traction. A meatal advancement and glanuloplasty incorporated (MAGPI) incision is made in the urethral plate distally and closed with 6-0 polyglycolic sutures in a transverse fashion to flatten the distal urethral plate and advance the urethra to the tip of the phallus (Fig. 100.3A). The reconstructed neourethra will be in excellent glandular position once the wings are closed. Next, two parallel pre-marked incisions are made along the dorsum of the penis, outlining an 18 mm wide strip of urethral mucosa extending from the prostatic urethral meatus to the tip of the glans (see Fig. 100.3A). Triangular mucosal areas of the dorsal glans are excised adjacent to the urethral strip, and thick glanular flaps are constructed bilaterally. Lateral skin flaps are mobilized and undermined.

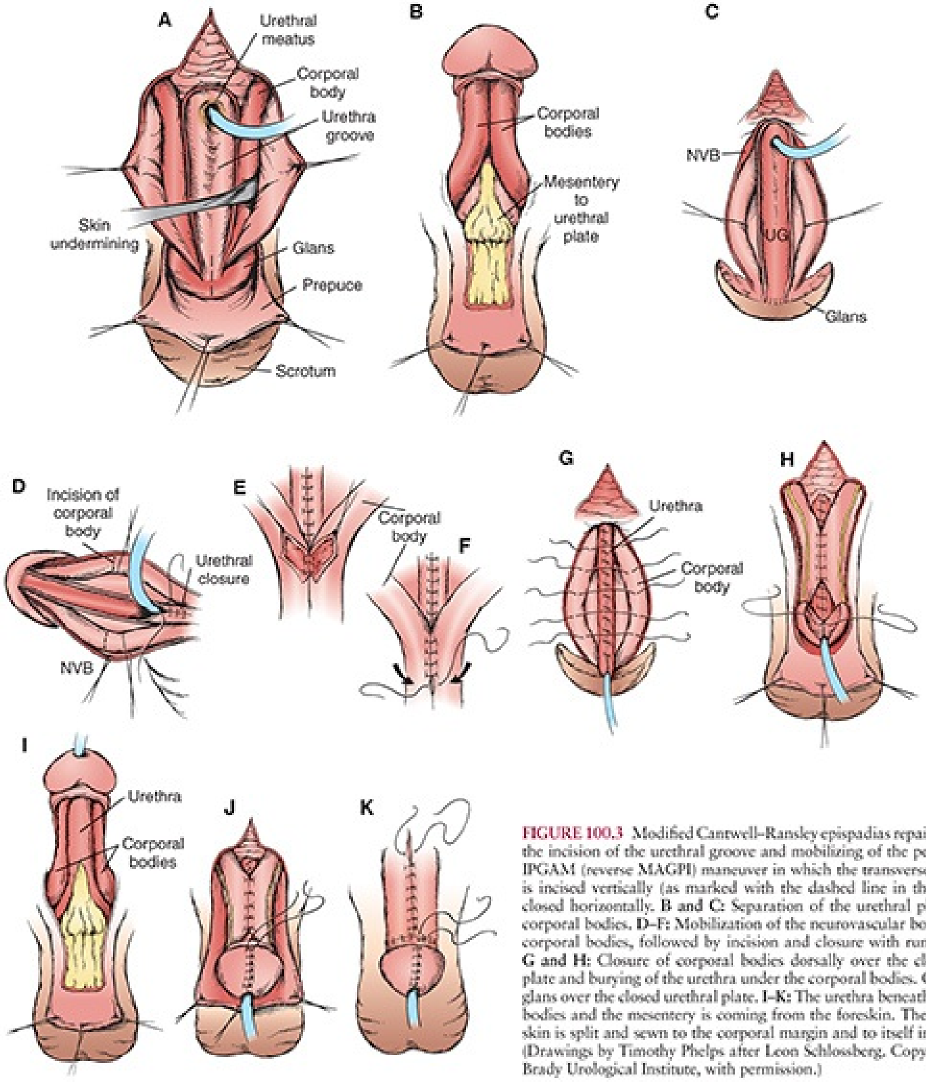

FIGURE 100.3 Modified Cantwell–Ransley epispadias repair. **A:** Marking the incision of the urethral groove and mobilizing of the penile skin and IPGAM (reverse MAGPI) maneuver in which the transverse urethral bar is incised vertically (as marked with the dashed line in the glans) then closed horizontally. **B and C:** Separation of the urethral plate from the corporal bodies. **D–F:** Mobilization of the neurovascular bodies from the corporal bodies, followed by incision and closure with running sutures. **G and H:** Closure of corporal bodies dorsally over the closed urethral plate and burying of the urethra under the corporal bodies. Closure of the glans over the closed urethral plate. **I–K:** The urethra beneath the corporal bodies and the mesentery is coming from the foreskin. The ventral foreskin is split and sewn to the corporal margin and to itself in the midline. (Drawings by Timothy Phelps after Leon Schlossberg. Copyright © 2002 Brady Urological Institute, with permission.)

A Z-incision of the suprapubic area permits exposure and division of the suspensory ligament and old scar tissue from the initial exstrophy closure. The ventral skin is taken down to the level of the scrotum (Fig. 100.3B). Care is taken to preserve the mesentery to the urethral plate, which arises proximally and extends upward between the corpora as a blood supply to the urethral plate. The corpora are dissected ventrally on the surface of the Buck fascia. The plane is followed closely bilaterally until one exits on the dorsum of the penis between the corpora spongiosum and the corporal body (Fig. 100.3C).

After placement of loops, the urethral plate is dissected just on the corporal bodies to the level of the prostate and the glans, respectively (Fig. 100.3D). Care is taken to leave the most distal 1-cm attachment of the mucosal plate to the glans intact. The neurovascular bundles are dissected free from the corporal bodies only if rotating the corpora over the urethra does not straighten the penis. The urethral strip is closed in a linear manner from the prostatic opening to the glans over an 8Fr silicone stent with 6-0 polyglycolic sutures. Afterward, the corporal bodies are incised at the point of maximal curvature, leaving a diamond-shaped defect (Fig. 100.3E). The corpora are then closed over the neourethra with two running sutures of 5-0 polydioxanone suture (PDS), with the adjacent areas of the diamond sutured to each other (Fig. 100.3F). The now ventrally placed urethra is secured in place with further 5-0 polyglycolic acid sutures between the corpora, especially at the coronal level (Fig. 100.3G–I). The glans wings are closed in a subcuticular manner with 5-0 and the glans epithelium with 6-0 polyglycolic acid. Finally, the ventral skin is brought up and sutured to the ventral edge of the corona, while the flaps provide coverage of the dorsum. The skin as well as the Z-plasty at the base of the penis is reapproximated with interrupted 5-0 or 6-0 polyglycolic acid sutures (Fig. 100.3J and K). The silicon stent is secured and left for 10 to 12 days.

In girls, the mons and external genitalia are reconstructed at the time of initial exstrophy closure. The bifid clitoris is denuded medially and brought together at the midline, along with labia minora reconstruction, creating a fourchette.

Postoperatively, it is critical to control pain and bladder spasms to prevent urine extravasation and fistula formation. This is best achieved by preoperative placement of a caudal epidural catheter and the administration of anticholinergic medication. At the time of discharge, the postoperative plastic occlusive dressing is left intact and the patient is supplied with oral broad-spectrum antibiotics, pain medications, and antispasmodics.

Continence and Antireflux Procedure

When the child is sufficiently mature and motivated to be dry and has finished an extensive voiding improvement program, bladder neck reconstruction is considered if the bladder capacity is greater than 100 mL and urodynamics demonstrate bladder stability.

The bladder is opened through a vertical incision that is extended transversely at the bladder neck (Fig. 100.4A). Figure 100.4 depicts a Cohen transtrigonal ureteral reimplantation or a cephalotrigonal reimplantation for either moving the ureter across the bladder above the trigone or, if the ureters are too low, moving them on the upper aspect of the trigone (Fig. 100.4B). The modified Young–Dees–Leadbetter procedure is begun by selecting a posterior strip of mucosa 15 to 18 mm wide and 30 mm long that extends from the midtrigone to the prostate or posterior urethra (Fig. 100.4C). The bladder muscle lateral to the mucosal strip is denuded of mucosa and sponges, soaked in 1:200,000 epinephrine, and applied to control bleeding for better visualization. Tailoring of the muscle triangles is aided by multiple small incisions on the free edge bilaterally that allow the area of reconstruction to assume a more cephalic position (Fig. 100.4D). A transverse, full-thickness muscular incision is not performed as described in the original Young–Dees–Leadbetter procedure because there is a significant risk of denervation and ischemia to the bladder neck. The edges of the mucosa and underlying muscle are closed with interrupted sutures of 4-0 polyglycolic acid (Fig. 100.4E). The adjacent denuded muscle flaps are overlapped and sutured firmly in place with a 3-0 PDS to provide reinforcement of the bladder neck and urethral reconstruction (Fig. 100.4F and G). Two or three of the overlapping sutures are left long, brought through the rectus fascia, and tied as bladder suspension to elevate the bladder neck (see Fig. 100.4G). An 8Fr urethral stent may be used during construction but is removed afterward. Exposure is essential for the creation of a continent bladder neck. Therefore, if visualization of the posterior urethra is problematic, the intrasymphyseal bar has to be cut and afterward approximated with 0 PDS nylon sutures. In this case, the child should be immobilized postoperatively.

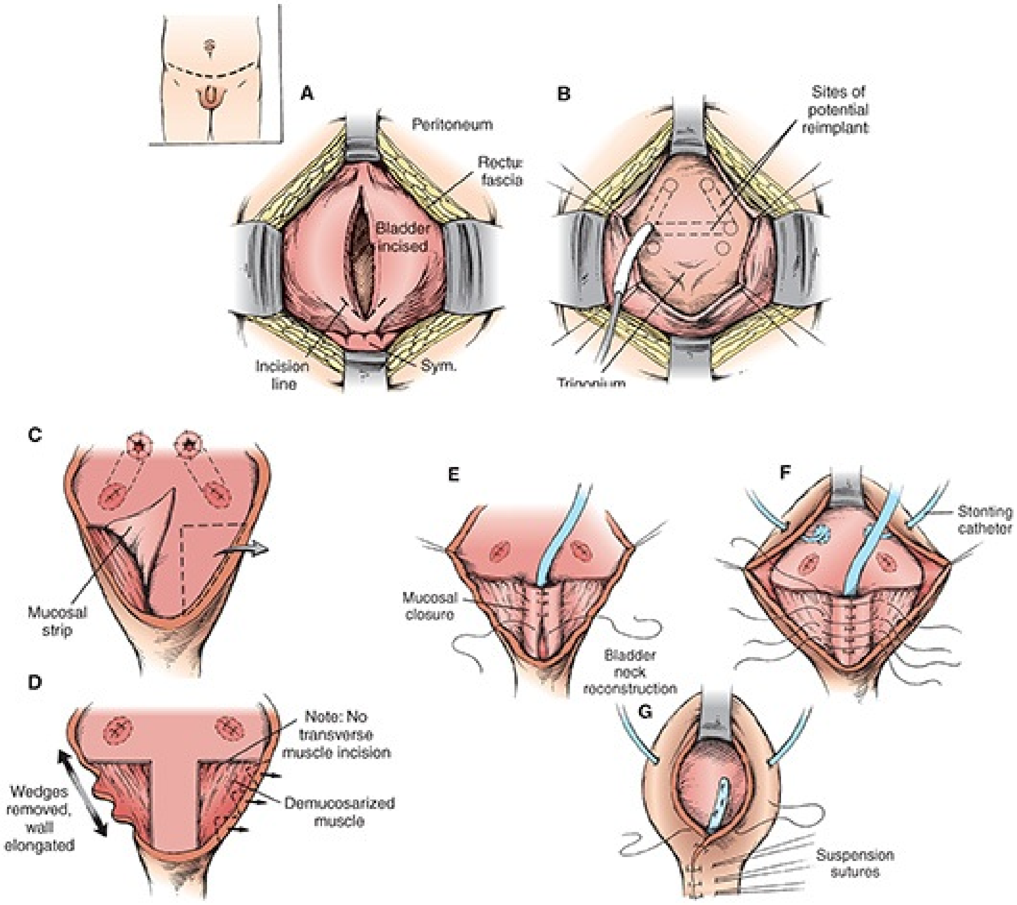

FIGURE 100.4 Modified Young–Dees–Leadbetter bladder neck repair. **A:** Through a Pfannenstiel incision (*inset*), a vertical bladder incision is made with transverse extension distally. **B and C:** Ureteral mobilization for ureteral reimplantation. **C–E:** Use of mucosal trigone strip to form the bladder neck and prostatic urethra. Lengthening of the denuded muscle triangles by several incisions. Note: No transverse muscle incision. **E–G:** Double-breasted closure and exact suture placement of the bladder neck reconstruction. The bladder neck and urethra are unstented at the end of the operation. (Drawings by Timothy Phelps after Leon Schlossberg. Copyright © 2002 Brady Urological Institute, with permission.)

The ureteral stents are left in place until pelvic healing is confirmed by X-ray, typically around 4 weeks. The suprapubic catheter is also usually first clamped around 4 weeks, for no longer than 1 hour on the first occasion. After residual-free voiding is achieved, the suprapubic catheter is removed. The patient is followed up with frequent bladder and renal ultrasounds in the first few months.

OUTCOMES

Complications

Failure of the closure is marked by dehiscence, prolapse, or outlet obstruction. It is possible that these complications are underreported secondary to patients changing surgeons following an initially undesirable outcome. Osteotomy is mandatory at the time of secondary closure in all cases. Outlet obstruction may develop early following removal of the urethral catheter. Surveillance of residual volumes and upper tract dilation with ultrasound is important following removal of the urethral catheter and prior to removing the suprapubic tube. The development of pyelonephritis is likewise a cause for evaluation of the bladder outlet following primary closure. In some cases, calibration and temporary catheter replacement are sufficient. We prefer to calibrate under anesthesia with a cystoscope because this allows for precise catheter placement if needed.

The incidence of urethrocutaneous fistulas following Cantwell–Ransley epispadias repair is 19% at 3 months (23). Some of these will close spontaneously. The majority, however, will require operative repair as an outpatient procedure. Residual chordee is a common indication for revision surgery, usually as an adolescent, prior to becoming sexually active.

It is clear that the bladder needs time to adjust to the increased resistance added by the reconstructed bladder neck. Bladder spasms and detrusor instability are expected and should be treated with oral anticholinergics. The biggest challenge for the child and the parents after bladder neck reconstruction is the initiation of a voiding trial. If the child cannot void, an 8Fr catheter is placed under anesthesia and left in place for 5 days before a second voiding trial. Ultimately, if the child is not dry for a period of 3 hours during the day within 12 months of the operation, the bladder neck reconstruction has failed. Multiple options are available for these children to achieve future continence, but few will void through their urethra.

Results

Long-term functional results are highly related to the success or failure of the initial closure. Bladders that dehisce or prolapse and require repeat closure are not likely to grow and reach the capacity needed for bladder neck reconstruction. In a review of 23 patients with one or more failed closures, we found that only 6 children reached sufficient capacity for bladder neck reconstruction, with a success rate of 50% (24). The use of osteotomy in conjunction with pelvic and lower extremity fixation has produced the best success rates at our institution and is recommended for all closures beyond the first 72 hours of life (i.e., delayed or secondary closures) (20). In a group of 194 primary MSRE closures at Johns Hopkins, 63 of which had simultaneous osteotomy, there were four failures (two dehiscences and two prolapses) (25). Interpretation of continence rates requires consideration for the definition applied and the manner in which the child voids/empties. The ultimate goal remains continence, day and night, with volitional voiding and stable renal function. Daytime dry intervals vary in the literature from 1 to 3 hours. “Social” continence refers to an adequate daytime dry interval with bedtime wetness. The use of catheterizable stomas, with or without bladder augmentation and additional outlet procedures such as artificial urinary sphincters, slings, or bladder neck, should likewise be noted when reviewing published continence rates.

Chan et al. (26) reported complete and social continence rates of 77% and 91%, respectively, with urethral voiding following bladder neck repair in children treated exclusively at Johns Hopkins. Preoperative bladder capacity measured under anesthesia appears to be the primary determinant of success in these patients. Patients with capacities >100 mL are good candidates for modified Young–Dees–Leadbetter procedures (18). Variable continence outcomes of children undergoing CPRE with subsequent Mitchell bladder neck repair have been recently reported (27). Like MSRE, the results of bladder neck repair following CPRE appear to be related to a successful primary closure, and in one report, this was highly associated with the use of osteotomy (17).

There are a number of options for salvage procedures in patients who fail bladder neck repair. Ultimately, however, several series have reinforced the fact that very few of these children will obtain continence with volitional voiding (28,29). Upper tract dilation following exstrophy closure is common, as most of these children have significant degrees of vesicoureteric reflux. It is uncommon for exstrophy patients to develop chronic renal dysfunction following ureteral reimplantation at the time of continence surgery in the MSRE.

It is important to differentiate between functional and cosmetic outcomes of genitoplasty. Cosmetic outcomes rely on subjective patient interpretation. Regarding cosmesis, VanderBrink et al. (30) recently reported a 92% esthetic satisfaction rate in 65 male patients undergoing genitoplasty for exstrophy/epispadias. Nineteen revision procedures were required to obtain this outcome. The majority of these cases were treated with a Cantwell–Ransley technique. From a functional standpoint, prospective studies of sexually active adults are needed to ascertain long-term outcomes. North et al. (31) reported International Index of Erectile Function (IIEF-15) and Female Sexual Function Index (FSFI) scores for a group of adult exstrophy males and females, respectively. When compared to controls, adult males with exstrophy reported similar scores for erection, orgasm, desire, and satisfaction. Females, on the other hand, had poor sexual satisfaction and lower scores when compared to controls in all FSFI domains. The reason for this gender dichotomy is not clear.

CONCLUSION

The modern reconstruction of bladder exstrophy can be quite successful in experienced hands. A successful initial closure can place the child on the road to eventual continence and volitional voiding, while failed closures are likely to result in less satisfactory outcomes that often involve augmentation or continent diversion. If possible, these surgeries should be performed in exstrophy centers in order to provide the greatest chance of improved outcomes and the resultant quality of life.

CHAPTER 101 PEDIATRIC CRYPTORCHIDISM, HYDROCELES, AND HERNIAS

ANGELA M. ARLEN AND CHRISTOPHER S. COOPER

Between 3% and 5% of full-term male infants are born with an undescended testicle, and a similar percentage will have an inguinal hernia or hydrocele (1). Cryptorchidism is often associated with a patent processus vaginalis, which predisposes to hydrocele and inguinal hernia formation. The treating urologist must therefore be familiar with the anatomy (Fig. 101.1) and operative techniques employed in treating these common pediatric conditions.

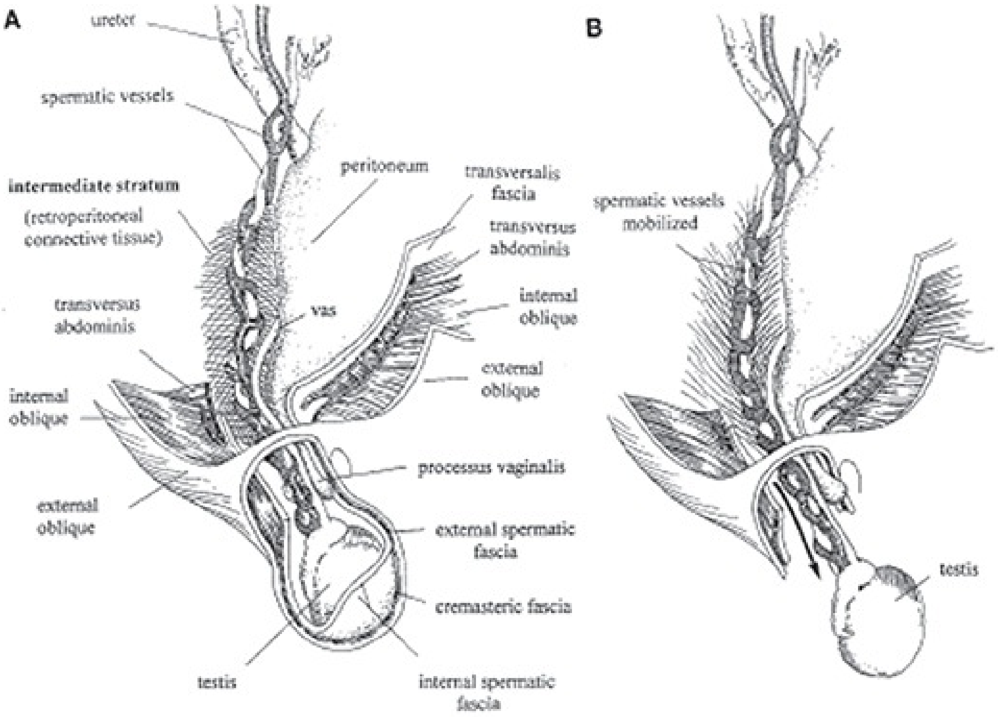

FIGURE 101.1 Anatomy of inguinal orchiopexy. **A:** Relationship of the vas deferens, spermatic vessels, and processus vaginalis to investing fascial layers. The transversalis fascia is contiguous with internal spermatic fascia. **B:** With tension applied to the cord (*arrow*), the orientation of the fibers of the intermediate stratum investing the retroperitoneal spermatic cord is changed so that fibers become parallel to cord structures. Freeing the vas and vessels from this investing fascia is the most important step in achieving distal testicular displacement. (Reprinted with permission from Hutcheson JC, Cooper CS, Snyder HM III. The anatomical approach to inguinal orchiopexy. *J Urol* 2000;164:1702–1704. Copyright © 2000 American Urological Association, Inc. Published by Elsevier Inc. All rights reserved.)

CRYPTORCHIDISM

Cryptorchidism includes the strict definition of an absent or nonpalpable testicle as well as an undescended testis that is palpable in the inguinal canal but fails to reach the scrotum. Twenty percent of boys with cryptorchidism have a nonpalpable testis. Of nonpalpable testes, 20% are intra-abdominal, 40% are canalicular or ectopic, and 40% are atrophic or absent. True undescended testicles stop along their normal path of descent into the scrotum. The testis may be located in the abdominal cavity (least common), inguinal canal, or just caudal to the external ring (suprascrotal, most common). Testes may also pass through the external ring into an ectopic location, most commonly located in a superficial inguinal pouch. Up to 10% of cases are bilateral (2), and the incidence of cryptorchidism increases to 30% in premature infants. Low birth weight has also been associated with cryptorchidism, independent of gestational age (3). The majority of testicles descend within the first 6 months of life, and by 1 year of age, the prevalence is 0.8% to 1%.

Diagnosis

Upon initial evaluation, a thorough history and physical examination is mandatory. Antenatal as well as maternal history for the use of gestational steroids or hormones should be elicited, as well as birth history. Record of physical exam at the time of birth should be obtained if possible. The presence of palpable gonads, hypospadias, and prior inguinal herniorrhaphy should be noted as well as a family history of cryptorchidism and other genitourinary anomalies. The size of the contralateral testis should be documented in cases where compensatory hypertrophy is suspected.

The diagnosis of cryptorchidism relies solely on physical examination. Absence of an identifiable testicle on ultrasound, computerized tomography, or magnetic resonance imaging does not prove testicular agenesis and therefore does not negate the need for surgical exploration (4,5). In children referred to a urologic specialist for undescended testicle, approximately 80% will have a palpable testis on exam. A careful physical examination in a nonthreatening, warm environment is crucial to identifying a subtle but palpable testicle. One hand is placed near the anterior superior iliac spine and the other on the scrotum. The first hand is swept caudally along the inguinal canal to gently draw the testicle toward the scrotum. Placing soap on the fingertips of the palpating hand may improve the sensitivity of palpation. A true undescended or ectopic testis may slide or "pop" under the examiner's fingers during this maneuver. A low ectopic or retractile testicle will be felt by the second hand as the testis is milked toward the scrotum. To distinguish a retractile testis, the testicle is brought into the scrotal position and held in place for several minutes, fatiguing the cremaster muscle. After this maneuver, a retractile testicle remains in the scrotum while an undescended testicle immediately pulls up and out of the scrotum.

A child with bilateral nonpalpable testes should undergo hormonal evaluation for testicular absence (6). Elevations in luteinizing hormone (LH) and follicle-stimulating hormone (FSH) and absence of detectable müllerian inhibiting substance (MIS) suggest lack of testicular tissue (7). Human chorionic gonadotropin (HCG) has a stimulatory effect on testicular steroidogenesis; therefore, testicular absence can be confirmed by a negative HCG stimulation test. HCG stimulation is performed by the administration of 2,000 IU of intramuscular HCG daily for 3 days (8). Elevated gonadotropin levels (LH and FSH) *and* a lack of testosterone rise following HCG indicate bilateral absent testes, and a formal surgical exploration is not necessary. When one or both components are lacking, or there is detectable MIS, surgical intervention is warranted.

Indications for Surgery

Surgical intervention for undescended testicle offers the possibility of improved fertility, correction of associated patent processus vaginalis, prevention of testicular torsion, and improvement in body image. Controversy remains over whether orchiopexy decreases the risk of malignancy, but placement of an undescended testis into the scrotum allows for testicular examination by health care providers as well as the patient (9,10).

At birth, the undescended testicle has been shown to have normal histology; however, delayed germ cell development has been documented in the older infant (11). Histology correlates with testicular position, with worse features associated with higher testes. Because histologic changes related to fertility occur in the undescended testis as early as 1 year of age and spontaneous descent rarely occurs after 6 months, optimal surgical timing is between 6 and 12 months of age. Early surgical intervention has been shown to improve testicular growth (12) and adult Leydig cell function (13). In postpubertal presentation of cryptorchidism, sperm are rarely noted and the testes are at significant risk for malignant change (14,15). Orchiectomy may be considered in this patient cohort if the contralateral testis is located in the scrotum.

Alternative Therapy

Hormonal therapy is an option in the treatment of cryptorchidism because its etiology may be related to an incomplete manifestation of hypogonadotropic hypogonadism. HCG is the only hormone approved for use in cryptorchidism in the United States. Three meta-analyses of randomized controlled studies have been published; all report an overall efficacy of approximately 20%, which on follow-up is decreased to about 15% due to secondary reascent of the testis (16–18). This is compared with up to a 95% success rate of primary orchiopexy, which remains the standard of care for the undescended testis.

Surgical Technique

Prior to surgical intervention, the patient should be re-examined under anesthesia. On occasion, a retractile testis descends under anesthesia or a previously nonpalpable testicle becomes palpable, altering the surgical approach. For a palpable testis, an open inguinal or scrotal approach orchiopexy is performed. Prior to the 1970s, surgical management of the nonpalpable testicle also consisted of inguinal exploration with extension of the dissection into the peritoneum if a testis, nubbin, or blind-ending vessels could not be identified. In 1976, Cortesi et al. (19) described using diagnostic laparoscopy for nonpalpable testis, revolutionizing the diagnosis and surgical management of the intra-abdominal undescended testicle.

Diagnostic Laparoscopy

Indications for diagnostic and therapeutic laparoscopy are identical to the goals of open orchiopexy: Determine if a testicle is present and viable, and if so, relocate it into the scrotum. Historically, laparotomy was performed to localize an intra-abdominal testis or diagnose blind-ending vessels if cord vessels were not observed on initial inguinal exploration. This was most often accomplished with a high inguinal (i.e., Jones incision) or Pfannenstiel incision. It is now common practice, especially as the child grows beyond infancy, to proceed with diagnostic laparoscopy when the testicle is nonpalpable.

During diagnostic laparoscopy for the nonpalpable testis, there are three scenarios that are commonly encountered. If blind-ending vessels and vas deferens are present proximal to the internal ring, a vanishing testis is diagnosed and no further action is required. Approximately 10% of boys with nonpalpable testis are found at the time of diagnostic laparoscopy to have blind-ending vessels, indicating the absence of testicular tissue (20). If the vessels and vas deferens are present and appear to enter the internal ring, then inguinal or scrotal exploration is warranted. The final scenario includes the presence of an intra-abdominal testis, which can be located in a variety of positions. For an intra-abdominal testicle the surgeon will need to assess which therapeutic modality is the most appropriate for treatment. If the testicle appears to be atrophic or grossly abnormal, then orchiectomy should be considered. If the testicle appears relatively normal, the ability to mobilize it to the scrotum is assessed, based on the distance of the testicle to the internal inguinal ring and redundancy of the spermatic vessels and vas. Deciding whether to perform a single-stage procedure leaving the vessels intact or to perform a one- or two-stage Fowler–Stephens procedure in which the spermatic vessels will be transected is challenging as no specific set of criteria have been determined. As part of the decision-making process, intraoperative measurement of the distance between the testis and the internal ring, observation of the cord anatomy, or assessment of the ability of the intra-abdominal testicle to reach the opposite inguinal ring after dissection may be helpful. Bilateral laparoscopic orchiopexies can be performed simultaneously or at separate procedures, depending on perceived risk of atrophy.

Diagnostic Laparoscopy Technique. Inhaled NO_2 should be avoided in order to avoid bowel distention, and an oral gastric tube should be inserted to decompress the stomach and maximize visualization in the abdomen. The patient is secured to the bed in the supine position at the level of the chest and low thigh with his arms tucked and the legs placed in a slightly abducted position. Securing the child to the table allows for Trendelenburg positioning. Prep and drape the patient for possible conversion to an open procedure. In the sterile field, a Foley catheter is placed to avoid potential bladder injury with trocar placement. Figure 101.2 demonstrates the preferred setup and trocar placement for performing laparoscopic orchiopexy.

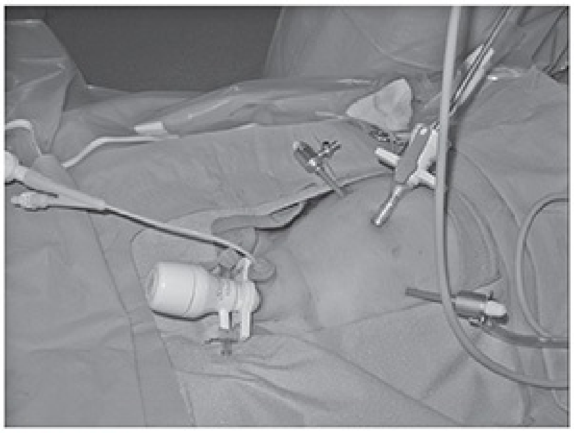

FIGURE 101.2 Preferred setup for a left single-stage laparoscopic orchiopexy. A 5-mm radial dilating trocar is placed at the umbilicus. Two 3-mm working ports are placed lateral to the rectus muscles just inferior to the umbilicus. Care is taken to avoid injury to the epigastric vessels. In the event a larger port is needed to accommodate a clip applier, a 5-mm trocar would be used on the contralateral side to ligate the testicular vessels. A 10-mm scrotal port is placed in the final stage of the case when the mobilized intra-abdominal testicle is delivered into the scrotum.

Access into the peritoneum may be achieved via an open Hasson fashion at the umbilicus. Alternatively, Veress needle access to establish pneumoperitoneumin has been shown to be safe and efficacious in children of all ages (21). A 5-mm hidden infraumbilical incision is made in the skin, and scissor dissection is performed at approximately 15- to 20-degree cephalad angle through the umbilical fascia into the underlying adherent peritoneum.

For the umbilical camera port, a 5-mm Step trocar will accommodate a 5-mm camera with a 0-degree lens. The child is placed in Trendelenburg position, and the abdomen is insufflated at 1 to 2 L per minute to a pressure of 10 to 12 cm H_2O. General survey of the abdomen is undertaken, inspecting the peritoneal structures for injury that might have occurred during port placement. Next, attention is focused on the evaluation of the pelvis. If an instrument is needed to aid in the inspection, a 5-mm port is placed on the ipsilateral side of the nonpalpable testis, lateral to the rectus and just caudal to the level of the umbilicus. An atraumatic instrument may then be used to sweep the bowel cephalad. Placement of an additional trocar on the contralateral side (lateral to the rectus and just caudal to the umbilicus) is reserved for the need of an additional working port.

In the case of unilateral undescended testicle, the internal ring of the descended testicle is examined first to gain an appreciation of the anatomy. Possible findings on inspecting the affected side of the “nonpalpable” testicle may include blind-ending vessels, cord structures entering the internal ring, or an intra-abdominal testis. Note the status of the processus vaginalis; most undescended testicles are associated with a patent processus.

Blind-Ending Testicular Vessels

Blind-ending gonadal vessels indicate the absence of a testicle. This is the result of in utero testicular torsion that is either an intra-abdominal or intrascrotal event. Vessels will have a “horse tail” appearance; they diverge, do not exit the internal ring, and do not supply obvious testicular tissue (Fig. 101.3). If found during exploration, no further investigation is warranted and the procedure is terminated. It is important to note that the finding of a blind-ending vas deferens during laparoscopy is insufficient to conclude the absence of testicular tissue. Further cephalad inspection toward the aortic origin of the gonadal vessels is then necessary.

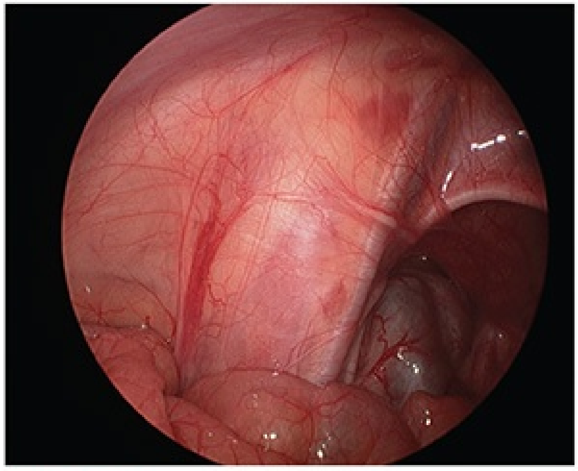

FIGURE 101.3 Finding blind-ending and divergent testicular vessels is evidence of a vanishing testicle.

Cord Structures Entering the Internal Ring

Cord structures may be visualized entering a closed internal ring or a patent processus vaginalis (Fig. 101.4). In the instance of a closed internal ring, a groin or scrotal exploration may be performed. If a patent processus vaginalis is present, the laparoscope may be used to inspect the inguinal canal via an antegrade approach. Alternatively, gentle manual retrograde pressure can be placed over the inguinal canal in an attempt to push groin contents (viable testicle versus nubbin) intra-abdominally. In the instance of a nubbin or testicular remnant, laparoscopic orchiectomy is performed. This is accomplished by either clipping or dividing the cord contents or using a 5-mm instrument designed to seal and divide smaller vessels (i.e., LigaSure or harmonic scalpel). The specimen is grasped and removed from the contralateral 5-mm port. This incision can be widened as needed by spreading the fascia with any clamp while under direct vision from the camera port.

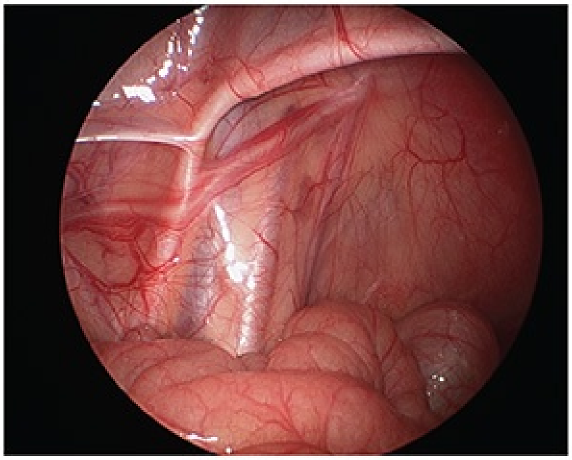

FIGURE 101.4 Laparoscopic view of the inguinal ring with normal cord structures exiting the internal ring.

Intra-abdominal Testis

There are three minimally invasive reconstructive options to address an intra-abdominal testicle: (a) primary laparoscopic orchiopexy, (b) one-stage laparoscopic Fowler–Stephens orchiopexy, and (c) two-stage laparoscopic Fowler–Stephens orchiopexy. Laparoscopic orchiectomy is reserved for an intra-abdominal nonviable testis (atrophic nubbin) or a testis that cannot be brought into the scrotum based on an extreme ectopic location or limiting vas or vessel length.

The initial measured distance of the testicle from the internal ring will determine which laparoscopic approach should be utilized and is therefore a predictor of success. “Peeping testes” or those located in close proximity to the internal ring (<2 cm away) can usually be mobilized into the scrotum in a single stage without dividing the testicular vessels (Fig. 101.5). It is important to counsel parents that intra-abdominal ectopic testes and those located >2 cm from the internal ring are at increased risk for surgical failure.

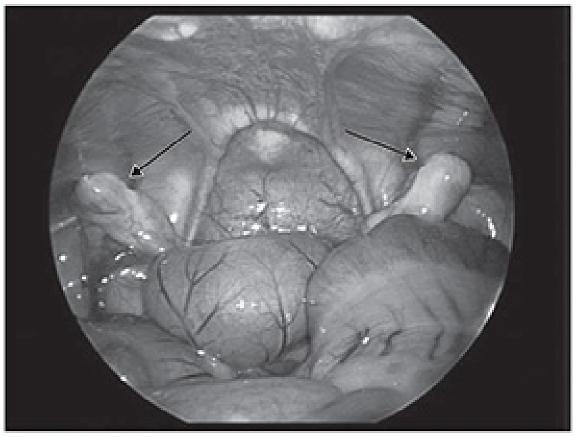

FIGURE 101.5 Bilateral intra-abdominal “peeping” testicles at the internal rings in a 6-month-old with nonpalpable gonads. Bilateral single-stage laparoscopic orchiopexies were performed.

Single-Stage Laparoscopic Orchiopexy

Following abdominal access, insufflation, and additional trocar placement, as outlined earlier, attention is focused on the ipsilateral testicle and internal ring. Fig. 101.6 demonstrates the surgical “map” needed to mobilize a triangular flap of peritoneum demarcated by the testicular vessels laterally and vas deferens medially. The preliminary goal is to create two continuous peritoneotomies parallel to the testicular vessels and vas in order to mobilize the testicle on a well-vascularized peritoneal pedicle.

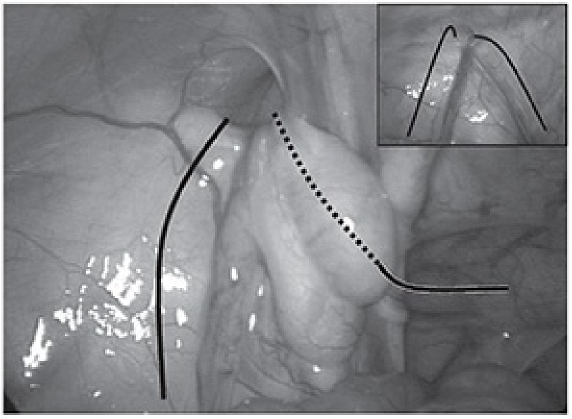

FIGURE 101.6 A left intra-abdominal testicle in an 8-month-old boy at the internal ring. The *dark lines* represent where peritoneotomies are made parallel to the testicular vessels (lateral) and vas deferens (medial) in order to mobilize the testicle on a vascularized peritoneal pedicle flap. The *insert* shows the same landmarks when a nonpalpable intracanicular testicle is milked into the abdomen and then mobilized via laparoscopic orchiopexy.

The testicle, epididymis, and extent of vasal descent distally into the inguinal canal are evaluated. It is critical from the onset to define the gubernacular attachments and identify a long-looping vas, if present. Scissors are used in the preliminary dissection. Care must be taken to avoid use of electrocautery in proximity to the vessels and vas. The first peritoneotomy is made lateral to the testicular vessels at the most proximal position. The incision is directed toward the internal ring. Often after the first incision, pneumoperitoneum will diffuse into the plane between the peritoneum and pelvic side wall. In this regard, CO_2 can aid in isolating the peritoneum to be dissected.

The second line of dissection will again begin at the level of the internal ring distally but will parallel the vas medially. Care is taken not to injure the iliac vessels and ureter that lie beneath the vas. It is also critical that dissection is not performed within the distal triangular area enclosed by the gonadal vessels and vas (Fig. 101.7). Critical collateral microvasculature within this flap will flow from the vasal artery to the testicle and should be maintained if possible. This is especially relevant if a single-stage Fowler–Stephens orchiopexy is performed; dividing the testicular vessels and interrupting collateral blood flow will invariably lead to testicular atrophy. Widely mobilizing the peritoneal flap laterally and medially leaves only the distal gubernacular attachments. A window is created distally, allowing the gubernaculum to be divided while visualizing the course of the vas deferens. An indication that dissection has maximized the flap length is that the testicle can reach the contralateral internal ring without tension. The ipsilateral ring is not closed since there is not an increased risk for a clinically significant hernia to develop. The patent processus is ablated by the peritoneal incisions, division of the gubernaculum, and, if necessary, incision of the anterior peritoneum. Subsequently, peritoneal regrowth obliterates the previously patent tract.

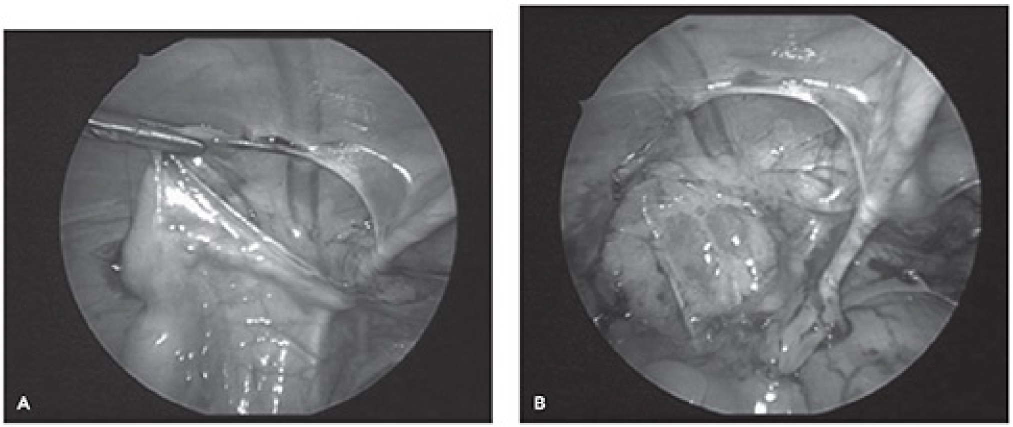

FIGURE 101.7 After lateral mobilization, medial dissection follows the course of the vas deferens (**A**). Collateral paravasal blood supply to the testicle is visualized. Cephalad traction following release of the distal gubernacular attachments (**B**) demonstrates the extent of the peritoneal flap and clarifies the boundaries where the neoinguinal hiatus is to be created between the inferior epigastric vessels and the medial umbilical ligament.

Various methods to deliver the testicle into the scrotum have been described. The authors feel the testis is most safely and effectively delivered to the scrotum using a radially dilating 5- or 10-mm trocar with assistance of laparoscopic instruments. A 12-mm ipsilateral scrotal incision is first made, and a subdartos pouch created. A 5- or 10-mm Step trocar (depending on testicular size) is then placed via the scrotum into the peritoneum under direct visualization from the laparoscope. This creates the neoinguinal hiatus. Care is taken to place the instrument over the pubis and between the medial umbilical ligament and epigastric vessels. After the instrument is passed through the scrotum, the Foley catheter is checked for hematuria. A bladder injury, which is very rare, would most likely occur during this step of the procedure. Proper placement of the instrument in the position described earlier should minimize the risk of this complication (Fig. 101.8). The 5- or 10-mm trocar obturator, depending on the size of the testicle, is then inserted, creating the neoinguinal hiatus. A locking grasper is introduced into the abdomen through the scrotal trocar, and the testicle is grasped at the gubernaculum and then delivered into the scrotum (Fig. 101.9). It is imperative for the surgeon to personally monitor the tension on the cord during scrotal delivery to ensure the vessels are not avulsed.

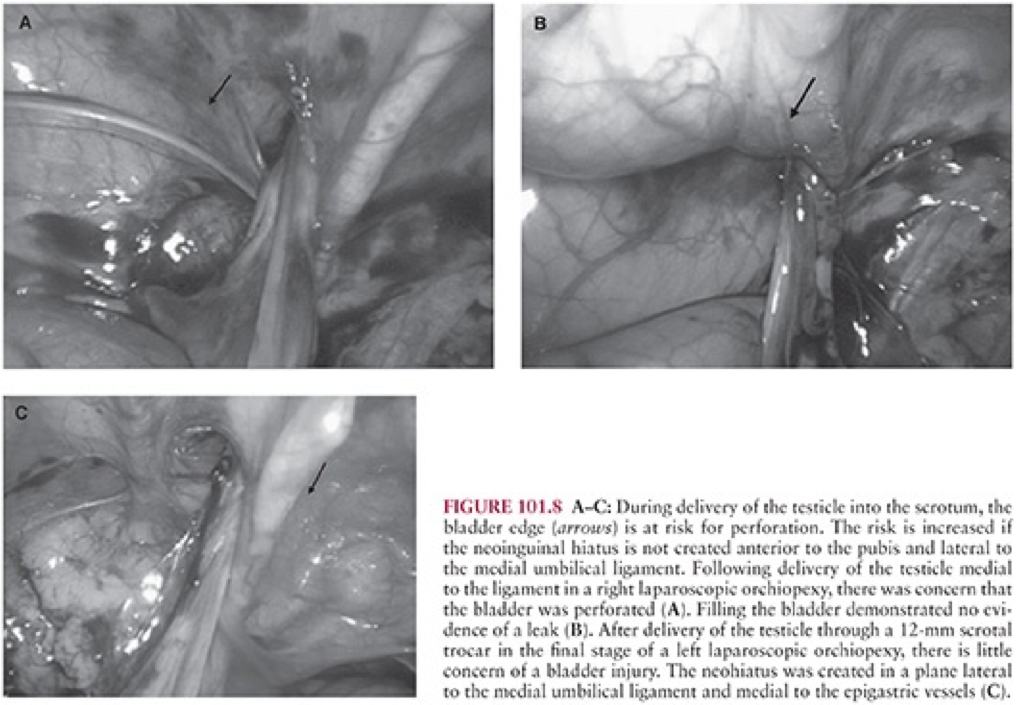

FIGURE 101.8 **A–C:** During delivery of the testicle into the scrotum, the bladder edge (*arrows*) is at risk for perforation. The risk is increased if the neoinguinal hiatus is not created anterior to the pubis and lateral to the medial umbilical ligament. Following delivery of the testicle medial to the ligament in a right laparoscopic orchiopexy, there was concern that the bladder was perforated (**A**). Filling the bladder demonstrated no evidence of a leak (**B**). After delivery of the testicle through a 12-mm scrotal trocar in the final stage of a left laparoscopic orchiopexy, there is little concern of a bladder injury. The neohiatus was created in a plane lateral to the medial umbilical ligament and medial to the epigastric vessels (**C**).

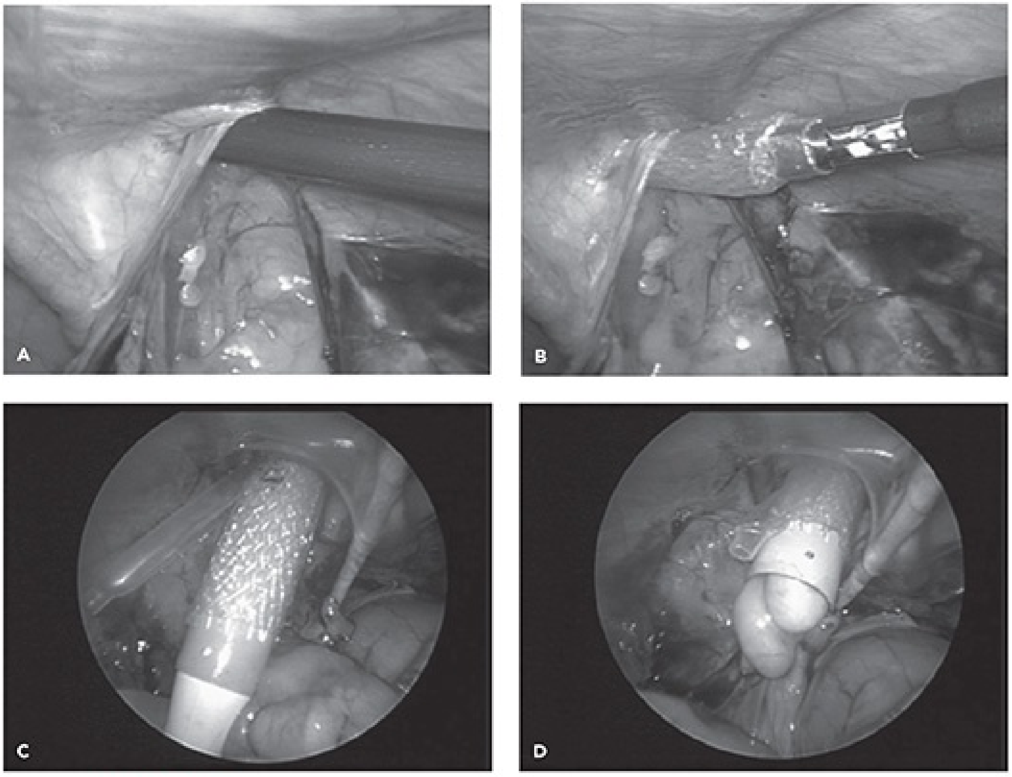

FIGURE 101.9 Delivering the testicle into the scrotum requires developing a neohiatus (A–C) to facilitate passage of the testicle, epididymis, and cord structures into the scrotum without resistance. This technique minimizes the risk of an avulsion injury (D).

After delivering the testicle into the scrotum, if there is tension and/or additional length is needed, further dissection can be carried out laterally and cephalad toward the kidney. An option at this point is to divide the peritoneum overlying the testicular vessels to provide extra cord length and release any remaining tension (Fig. 101.10). If incising the peritoneum does not achieve sufficient length, consideration can be given to dividing the testicular vessels, therefore performing a one-stage Fowler–Stephens orchiopexy. The contralateral working port must be 5 mm in order to accommodate a clip applier. Consideration must be given to the higher risk of testicular atrophy after a one-stage Fowler–Stephens procedure. When the testicle lies tension-free in the scrotum, the orchiopexy can be completed (Fig. 101.11). The testicle is harnessed in the dartos pouch, and the scrotal skin is closed by any of the preferred technique(s) utilized by the surgeon.

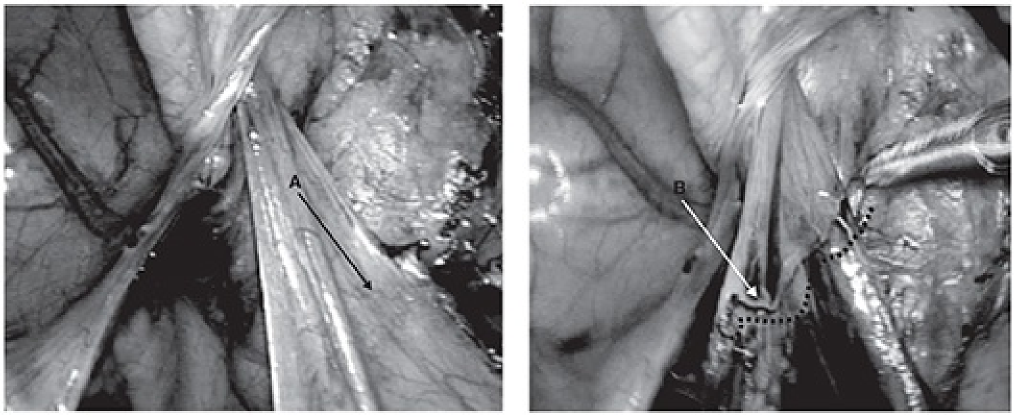

FIGURE 101.10 Delivering the testicle into the scrotum provides the traction and assistance of a "third arm." If there is tension and/or additional length is needed, further dissection can be carried out laterally and cephalad. The peritoneum overlying the testicular vessels (*A*) may also be divided (*B*) to release tension and provide extra cord length.

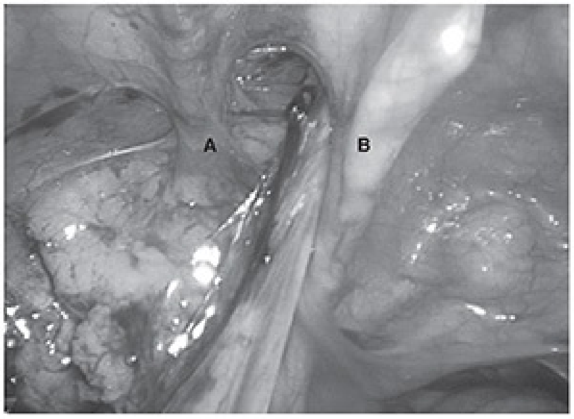

FIGURE 101.11 Antegrade view of a left neoinguinal hiatus created between the inferior epigastric vessels (*A*) and the medial umbilical ligament (*B*). The testicle is fixed to the scrotum after maximal length on the cord has been reached without residual tension.

The abdomen is surveyed a final time and the pneumoperitoneum pressure is lowered. Any occult bleeding should be identified and addressed at this time. While maintaining pneumoperitoneum, the two lateral ports are removed sequentially and inspected for bleeding. Pneumoperitoneum is evacuated through the umbilical port. The umbilical trocar and camera are removed while inspecting for bleeding. The umbilical port fascia is closed with an interrupted 2-0 Vicryl; this can be performed with a Carter-Thomason device if necessary. The skin is then closed in a subcuticular fashion, and dressings or skin glue are applied.

Two-Stage Fowler–Stephens Procedure

As a general rule, the further the intra-abdominal testicle lies from the internal ring (i.e., >2 cm), the higher the likelihood that a staged procedure is necessary. Staging the procedure will enable delivery of the testicle into the scrotum without tension and at a decreased risk for atrophy. This may be accomplished by ligating the testicular vessels by using a 5-mm clip applier through the contralateral port (Fig. 101.12). A laparoscopic second-stage Fowler–Stephens orchiopexy is performed approximately 6 months later, when collateral blood flow from the deferential artery has matured.

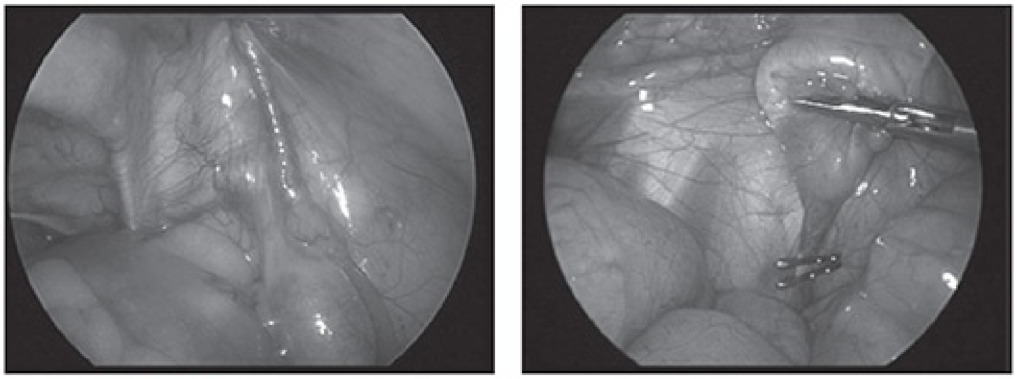

FIGURE 101.12 A right intra-abdominal testicle in a 9-month-old boy was found >2 cm from the internal ring (**left**). The testicular vessels were clipped in the first stage of a two-stage Fowler–Stephens reconstruction (**right**). Note that clips are applied without dissecting the peritoneal attachments free from the vessels.

Inguinal Orchiopexy

A 2- to 3-cm incision along the lines of Langer is made in a groin crease one-third of the way between the pubic tubercle and the anterior superior iliac spine (Fig. 101.13). The incision is carried through subcutaneous fat and Scarpa fascia to the level of the anterior aspect of the inguinal canal using Metzenbaum scissors. Overlying fat and fascia are cleared off the external oblique fascia, allowing visualization of the shelving edge. The external ring is visualized and the anterior aspect of the inguinal canal is incised by nicking the fascia with a scalpel blade; an ectopic testicle may be visualized exiting through the ring. An incision placed too far medial makes cord identification more difficult, whereas an incision too far lateral inhibits fascial closure. Metzenbaum scissors with the tips facing upward are inserted into the nick and used to spread the adjacent tissue away while taking care to identify and preserve the underlying ilioinguinal nerve. The roof of the inguinal canal is then opened along the course of its fibers downward toward and through the external ring. The spermatic cord is identified, elevated, and dissected free of the anterior cremaster fibers using blunt dissection and DeBakey forceps.

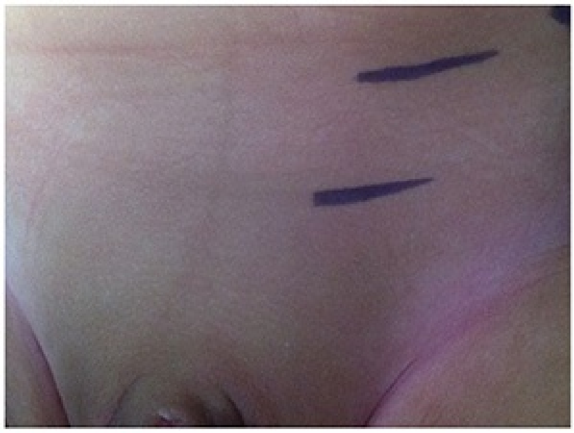

FIGURE 101.13 Incision for left inguinal orchidopexy is created one-third of the distance between the pubic tubercle (*lower line*) and the anterior superior iliac spine (*upper line*).

If no cord structures are identified, attention is turned to the level of the internal ring, and by application of abdominal pressure and retraction in the internal ring frequently, a testicle may be identified just inside the internal ring. If no testicle is identified, the peritoneum is opened and a search is performed for either a testicle or a blind-ending vas and vessels. Blind-ending spermatic vessels must be identified to confirm absence of a testicle as a blind-ending vas does not guarantee testicular absence.

After identification of the testicle and spermatic cord in the canal, the gubernaculum is divided either sharply or with electrocautery. Placement of a hemostat on the proximal end for traction provides a means of manipulating the testicle and cord structures safely. Care must be taken at this point to avoid a long-looping vas deferens that sometimes extends distally. Elevation of the cord permits blunt sweeping dissection of the inferior cremaster fibers proximally to the level of the internal ring. By placing a retractor in the internal ring and pulling the cord and attached peritoneum medially, the surgeon gains access to the retroperitoneal space along the lateral aspect of the internal ring, which is enveloped in the endopelvic fascia. The cord and peritoneum may then be swept anterior and medial with blunt dissection in the retroperitoneal space.

The intermediate stratum, an extension of connective tissue that envelopes the spermatic vessels and vas deferens in the retroperitoneum, is located between the inner striatum (connective tissue of the peritoneum) and the outer striatum (transversalis fascia). As the vas joins the vessels in the inguinal canal, the fibers of the intermediate stratum attenuate and the structures (vas, vessels, processus vaginalis) are enveloped by the internal spermatic fascia, which is an extension of the transversalis fascia from the floor of the inguinal canal. To free the remaining anterior and medial retroperitoneal attachments to the spermatic vessels and vas deferens, the internal spermatic fascia must be divided, allowing separation of the processus and contiguous peritoneum from the vas and vessels and complete access to the retroperitoneum (Fig. 101.14).

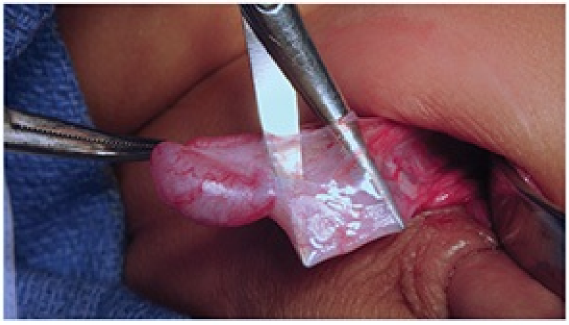

FIGURE 101.14 Isolation of cord structures during orchiopexy.

With a nonpatent processus vaginalis, a hemostat providing anterior traction on the tip of the peritoneal reflection permits dissection of the underlying cord from the internal spermatic fascia binding it to the peritoneum. With a patent processus vaginalis, the posterior cord is exposed, the internal spermatic fascia is swept off the cord structures, and the processus vaginalis is freed to the level of the peritoneum. The processus vaginalis is incised and the edges readily dissected away from the underlying cord. The processus is twisted and ligated at the level of the internal ring with a 3-0 or 4-0 Vicryl suture.

The anterior and medial retroperitoneal attachments to the cord may be approached by placing a retractor anterior to the vessels in the internal ring, allowing the bands of the retroperitoneal fascia to be bluntly dissected from the vessels to obtain increased cord length. The beginning of the retroperitoneum is marked by the divergence of the vas medially and inferiorly. The circumferential dissection of the vessels can be extended in the retroperitoneum up to the level of the renal hilum if the need arises to gain additional cord length so the testicle can reach the scrotum without tension. True skeletonization of the vas and vessels should be avoided as this can lead to testicular atrophy. The limiting factor on length is most often the spermatic vessels rather than the vas deferens (Fig. 101.15). To gain additional length, a Prentiss maneuver can be performed by using a right angle to puncture through the floor of the inguinal canal near the pubic tubercle and then passing the testicle directly under the transversalis fascia toward the scrotum, in effect moving the course of the vessels toward the midline with alignment of the internal and external rings.

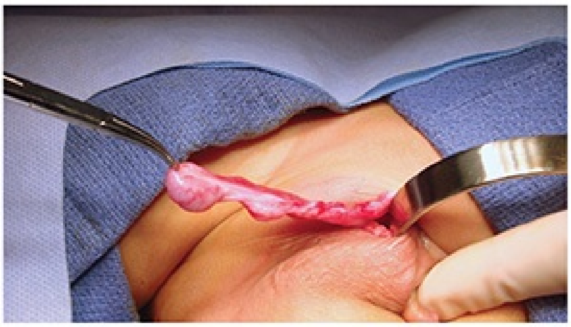

FIGURE 101.15 After dissection, adequate spermatic cord length is demonstrated.

With an absent testicle, blind-ending vas and vessels may be encountered in the inguinal canal. The tubular structures in the canal must be traced proximally to the internal ring, where the divergence of the vas and vessels helps the surgeon positively identify the spermatic vessels. With visualization of blind-ending spermatic vessels, no further exploration for a testis is indicated. However, a blind-ending vas deferens is not sufficient reason to stop the exploration because there are patients with a wide separation of the vas and an intra-abdominal testis. When no spermatic cord structures are identified in the inguinal canal, the dissection is carried to the internal ring and into the retroperitoneum. If no structures are identified, the peritoneum is opened and the testicle or blind-ending spermatic vessels are sought.

Repeat inguinal exploration for a failed orchiopexy is associated with scar tissue surrounding the testicle and spermatic cord causing adherence to the underside of the external oblique fascia. Following the inguinal incision, the testicle should be identified and freed from surrounding scar tissue. Once this is accomplished, the cord can usually be freed along its posterior aspect extending through the inguinal canal. No attempt is made to dissect the cord from the scar extending along its anterior surface and the overlying external oblique fascia. By cutting the fascia along the medial and lateral sides of the cord and then connecting these incisions above the internal oblique muscle, a strip of fascia is left attached to the cord as described by Cartwright et al. (Fig. 101.16). The peritoneum may then be opened and the spermatic vessels freed as described earlier. At the peritoneal level, there is rarely any significant scar tissue.

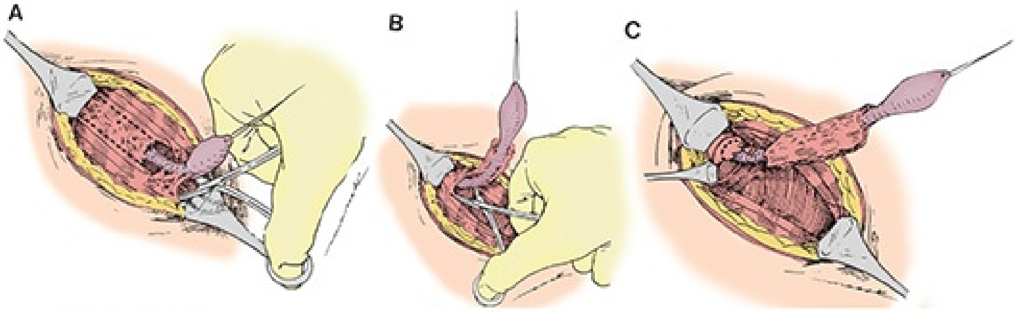

FIGURE 101.16 Reoperative orchiopexy demonstrating external oblique fascial incisions lateral and medial to the cord structure. The adherent scar tissue is dissected with the spermatic cord and no attempt is made to dissect the spermatic cord from the scar. **A:** Demonstrates a plane being dissected beneath the testicle and spermatic cord and the lines of incision in the fascia and surrounding scar lateral and medial to the cord. **B:** Demonstrates dissection proximally to the level of the internal oblique muscle. **C:** Demonstrates the dissection after a transverse incision has been made connecting the medial and lateral incisions above the internal oblique muscle. Multiple methods have been described for fixing the testis to the scrotum, although the subdartos pouch is the authors' preferred method. Following a transverse incision in the hemiscrotum (Fig. 101.17), a pocket for the testicle is created by dissecting the scrotal skin superiorly and inferiorly from the adherent underlying dartos using Ragnell orchiopexy scissors (Fig. 101.18). Care must be taken not to develop the pouch too lateral or too inferior because this could result in an ectopic testis location. The testicle is exposed by opening the tunica vaginalis. A testicular biopsy is not routinely indicated for prepubertal patients. Once adequate cord length has been obtained, the testicle is passed down from the inguinal incision using a hemostat attached to the gubernaculum. The testicle is brought through the dartos and placed in the pouch, taking care to ensure correction testicular orientation and avoid torsion of the cord. A small portion of the parietal tunica vaginalis is secured to the dartos inferiorly and superiorly with an absorbable suture, allowing for scarring and fixation. The scrotal skin is then closed with subcuticular sutures (Fig. 101.19). For the inguinal incision, the fascia is closed with interrupted 3-0 Vicryl suture, taking care not to close the external ring too tightly, followed by closure of the subcuticular tissue with 4-0 Vicryl and skin with absorbable suture. For postoperative pain control, anesthesia can administer a caudal block, or a local nerve block with 0.25% Marcaine can be performed by the surgeon just prior to closure.

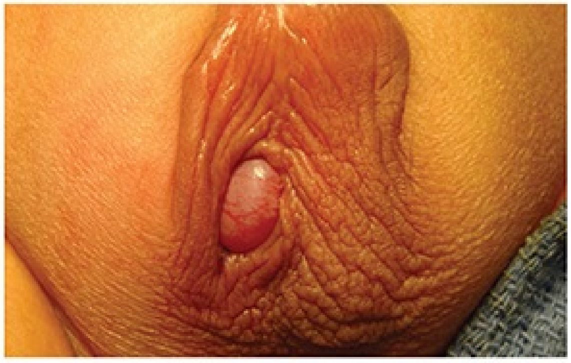

FIGURE 101.18 Creation of dartos pouch using Ragnell orchiopexy scissors.

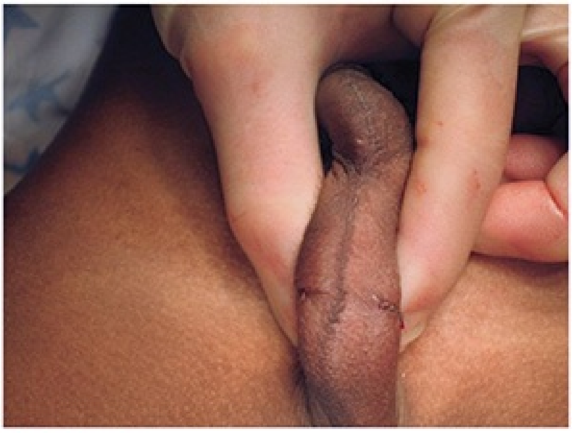

FIGURE 101.19 Successful orchiopexy shows both testes in the scrotum.

Scrotal Orchiopexy

In the 1980s, a single incision, transscrotal technique was introduced by Bianchi and Squire (22).

Benefits of using this approach include reduced operative times, less postoperative pain, and an esthetically pleasing single scrotal wound. Initial concern focused on a high incidence of hernias or hydroceles if ligation of the sac was not high enough, or that reascent may occur if the proximal attachments were not divided. The scrotal incision orchiopexy has been shown to be highly successful in children with palpable undescended testis that can be brought down following induction of anesthesia to the scrotum with caudal traction by the surgeon (23). Patency of the processus vaginalis is not a contraindication to performing scrotal approach orchiopexy if the testis can be brought down to the scrotum preoperatively. The processus vaginalis is dissected free of cord structures and, if patent, then high suture ligation is performed. Testicular fixation is performed as described earlier.

Outcomes

Successful therapy, as defined by a viable testis positioned in the scrotum, is dependent on the preoperative anatomic position of the testis as well as operative technique. In a meta-analysis, Docimo (24) reported success rates associated with the preoperative anatomic position of the testis, including 74% for abdominal, 82% for peeping, 87% for canalicular, and 92% for those distal to the external ring. The success rate of various open techniques included 89% for standard inguinal orchiopexy, 67% for Fowler–Stephens, 77% for staged Fowler–Stephens, 81% for transabdominal, 73% for two-stage, and 84% for microvascular (24). All of these results suggest an advantage to maintaining intact vessels where possible, and when performing a Fowler–Stephens approach, staging has been shown to yield higher success rates (25). In a large multi-institutional analysis, Baker et al. (26) reported excellent laparoscopic success rates superior to that of historical open orchiopexy and no significant difference in success or complication rates between low- and high-volume centers.

Paternity rates among men who had attempted to father children were 65%, 90%, and 93% in men with bilateral cryptorchidism, unilateral cryptorchidism, and normally descended testicles, respectively (27). If only one testis is undescended, the sperm count will be subnormal in 25% to 33% and the serum FSH concentration will be slightly elevated (28,29). The presence of these abnormalities suggests that both testes are abnormal, perhaps congenitally, although only one fails to descend. If both testes are undescended, the sperm count usually will be severely subnormal and the serum testosterone may be reduced (29).

Complications

Retraction is the most common complication of orchiopexy and usually occurs secondary to an incomplete initial dissection and tension on the testicle. It is possible that some cases of retracted testicle after an orchiopexy occur because of dislodgement of the testis from the scrotum. To prevent this possibility, straddle toys are avoided for at least 4 weeks following the operation. Older children are instructed to avoid bicycles and team sports for 4 weeks postoperatively.

The most significant complication is testicular atrophy, which occurs in 1% to 2% of cases following orchiopexy, although complete devascularization of the testis is rare. The dissection of the testicular vessels and/or postoperative swelling and inflammation can result in ischemic injury with subsequent testicular atrophy. The failure rate with orchiopexy is 8% for distal undescended testes and 26% for intra-abdominal undescended testes (24). Other potential complications include ascent of the testis requiring reoperative orchiopexy, infection, bleeding, ilioinguinal nerve injury, or damage to the vas deferens.

Complications associated with laparoscopic orchiopexy compare favorably to that of open inguinal approach. In a large multi-institutional review of laparoscopic orchiopexy, a major complication rate of 3.0% and a minor complication rate of 2.0% were reported (26). Major complications that have been reported include acute testicular atrophy, bowel perforation, cecal volvulus, vascular injury, bladder perforation, ileus, laceration of the vas, testicular vessel avulsion, and wound dehiscence/infection.

The prevention of complications associated with laparoscopy starts with proper positioning and padding to reduce the risk of neuromuscular injuries. Although injuries are less likely to occur with pelvic laparoscopy, extremes in table positioning are often necessary. Close attention to placement of straps and/or tape and adequate padding should limit positioning-related injuries. As in adults, abdominal visceral injuries related to access are encountered; however, an understanding of the unique anatomic aspects of the pediatric abdominal wall can decrease these risks. The pediatric abdomen requires less force for entry, so penetration injury to the abdominal viscera can easily occur. The smaller pediatric working space also sets up the potential for injury to the visceral structures from the laparoscopic working elements.

An appreciation of the anatomic landmarks within the pelvis will aid in avoiding laparoscopic complications. During testicular mobilization, care must be taken to avoid injury to the vas, testicular, femoral, and iliac vessels as well as the ureter. When mobilizing the vas on the medial aspect of the peritoneal flap, these structures lie directly posterior and medial. In general, complications can be limited by careful intra-abdominal mobilization, using limited cautery in short bursts, and execution of meticulous technique. The laparoscopic approach facilitates this by allowing extensive and high retroperitoneal mobilization of the testicular vessels in an atraumatic manner.

HYDROCELE/HERNIA

A hydrocele consists of a collection of fluid in the tunica vaginalis surrounding the testicle. In children, the vast majority are associated with a patent processus vaginalis that permits flow of peritoneal fluid into the tunica vaginalis (communicating hydrocele). An indirect inguinal hernia forms when bowel or any other tissue from the abdominal cavity protrudes into the patent processus. Between 0.8% and 4.4% of newborns and up to 30% of premature infants have an inguinal hernia. Boys are 6 times more likely than girls to have a hernia and right-sided hernias occur twice as frequently as left-sided hernias, with bilateral hernias occurring about 10% of the time.

Diagnosis

Children with a hydrocele or hernia present with swelling in the groin and scrotum/labia. This swelling can be persistent or intermittent and may not be directly observed by the physician. Often, it is noted by the parents only when the child is crying or straining and the intra-abdominal pressure is elevated. In this case, the diagnosis depends on a reliable history from the parents describing the intermittent groin and scrotal swelling. Older children may be examined while standing and performing a Valsalva maneuver to increase the intra-abdominal pressure. Rarely, children will present with large abdominoscrotal hydroceles that cross the internal inguinal ring and contain an intra-abdominal component resulting in a palpable abdominal mass.

With increasing size of the hydrocele, the testicle becomes more difficult to palpate and often is not palpable. Usually, a hydrocele becomes narrow at the level of the internal ring, and the examiner is able to detect this narrowing and get above the swelling. With a hernia, the swelling extends through the internal ring. The fluid in a hydrocele sac will transilluminate; however, bowel can also be transilluminated, making this a nonspecific finding for either a hydrocele or a hernia.

Ultrasonography may help define the testicle and rule out any testicular pathology as well as help differentiate a hydrocele from a hernia.

Surgical Technique

A similar inguinal incision is made for indirect hernias or communicating hydroceles as previously described in surgical technique for inguinal orchidopexy. After the inguinal canal is opened, the cremaster fibers may be bluntly spread off the anterior aspect of the spermatic cord. The bulging shiny hernia sac or patent processus vaginalis, which is typically located anterior and medial, is identified and grasped with a hemostat. By elevation of the hernia sac, the cord is brought up and freed from surrounding cremaster attachments, permitting the surgeon's finger to be placed beneath the entire spermatic cord and hernia sac. Extensive dissection of cremasteric fibers need not be performed. The sac is teased off the underlying cord by breaking apart the internal spermatic fascia that encases the cord structures and the hernia sac. As this is done, the cord structures are separated from the hernia sac by passing a hemostat from lateral to medial and spreading at a 90-degree angle to separate cord from hernia sac. When the cord structures are completely freed, the sac is transected and then dissected up to the internal inguinal ring. It is important to identify the internal spermatic fascia and break this down so that when the sac is twisted and ligated, the cord structures will not become incorporated.

The hernia sac is twisted and high ligation is performed with two 3-0 or 4-0 Vicryl sutures and divided close to the level of the internal ring. The distal sac or hydrocele is then delivered along with the testicle into the wound, and the sac is opened down to the level of the testicle, taking care not to injure the cord structures. The authors routinely evert and sew the hydrocele sac behind the cord or testis in a Bottle technique with an absorbable suture to prevent the possible reformation of the hydrocele. Repair of the dilated internal inguinal ring may be required and is accomplished by approximation of the transversalis fascia to itself at the level of the internal ring, taking care not to strangulate the cord. The conjoined tendon may also be sutured to the shelving edge of the inguinal ligament. The testicle is then drawn back into the scrotum with traction on the scrotal skin and gubernaculum. The external oblique aponeurosis and wound are then closed as described earlier for inguinal orchiopexy.

Outcomes

Open inguinal hernia repair with high sac ligation has excellent results, with an approximately 99% success rate (30,31). Recurrence after herniorrhaphy may be attributed to a failure to ligate the sac high enough at the internal ring, injury to the floor of inguinal canal because of operative trauma, failure to close the internal ring in girls, or postoperative wound infection and hematoma (32).

Complications

Recurrence or persistence of the hernia or hydrocele may occur if the patent processus is not well ligated and occurs in approximately 1% of cases. Injury to the underlying spermatic and/or vas deferens vessels may result in testicular atrophy, which has been reported in up to 1% to 2% of cases (33). Displacement of the testicle to an extrascrotal location may occur after surgery. To prevent this complication, every hydrocele and hernia repair should be concluded by confirmation of the testis location in its normal dependent scrotal position.

CHAPTER 102 PEDIATRIC LAPAROSCOPIC AND ROBOTIC PYELOPLASTY

PASQUALE CASALE AND WALID A. FARHAT

Historically, open pyeloplasty has been the standard treatment for congenital or acquired ureteropelvic junction (UPJ) obstruction in adults and children, with overall success rates of 90% to 100% (1–3). Although endopyelotomy (4) and retrograde dilation (5) are alternative methods of managing UPJ obstruction in children (6), the success of these two procedures is inferior to that reported for conventional dismembered pyeloplasty (7). Advances in technology have played a significant role in the therapeutic management of UPJ obstruction and have enabled the introduction of laparoscopic and robot-assisted laparoscopic pyeloplasty over the last few years. Continued interest in minimally invasive treatment for UPJ obstruction has inspired new questions about the optimal laparoscopic approach for treating this disease.

Laparoscopic pyeloplasty was introduced in adults in 1993 (8,9). In the initial reports, the operative time ranged from 3 to 7 hours, but the procedure has gradually gained in popularity and acceptance with a reported success rate of over 95% (10–16). Yeung et al. (15) reported their initial experience with retroperitoneal laparoscopic pyeloplasty in 13 children, one of who required open conversion. The mean operative time was 143 minutes (range 103 to 235 minutes). El-Ghoneimi et al. (16) reported their experience with 50 retroperitoneal laparoscopic pyeloplasties in children aged between 22 months and 15 years. Conversion to open surgery was necessary in four cases due to technical difficulties during suturing. Mean hospital stay was 2 days, and return to full activities occurred within 5 days of surgery. The longer time needed for the retroperitoneal approach is almost certainly related to the limited working space that renders suturing more difficult.

DIAGNOSIS

Approximately 1% of prenatal ultrasounds detect hydronephrosis in the fetus. In 50% of these cases, UPJ obstruction causes the condition. UPJ obstruction is more common in males and affects the left kidney more often than the right. About 10% to 30% of cases occur in both kidneys (bilaterally) (11). Congenital abnormalities are the most common cause of UPJ obstruction in children. The condition often results from an abnormality in the muscles that surround the UPJ causing an intrinsic narrowing. It may also be caused by an abnormality in the structure or position of the ureter such as a high insertion onto the renal pelvis. Lower pole renal blood vessels crossing over the ureter can cause an obstruction as well. Other etiologies of UPJ obstruction are compression of the ureter caused by inflammation, retroperitoneal fibrosis, kidney stones, or scar tissue from previous surgery to correct UPJ obstruction. Symptoms of UPJ obstruction are typically seen in the older children but can be seen in infants and include the following: back or flank pain, hematuria, failure to thrive, flank mass, and/or pyelonephritis.

UPJ obstruction that causes hydronephrosis is usually diagnosed by prenatal ultrasound. Neonatal patients suspected to have this condition are evaluated for the obstruction using renal ultrasound and diuretic renography. Magnetic resonance urography has also become part of the armamentarium for radiologic imaging. In some children, a voiding cystourethrogram (VCUG) might be utilized to rule out vesicoureteral reflux as a cause of the hydronephrosis or as a concomitant finding.

INDICATIONS

Laparoscopic pyeloplasty includes two modalities of delivery: conventional laparoscopy and robotic-assisted laparoscopy. For this chapter, both modalities will be referred to as laparoscopic pyeloplasty. A section of the chapter at the end will discuss added nuances of the robotic platform.

The indications for laparoscopic pyeloplasty are similar to those for an open pyeloplasty. They encompass increasing hydronephrosis, progressive deterioration of renal function, recurrent urinary tract infection (UTI), and persistent pain. The introduction of refined instrumentation and more experience with intracorporeal suturing allows reconstructive laparoscopy to be implemented in the pediatric population, with multiple techniques of pyeloplasty described in the literature (12). One of the earliest descriptions of the transperitoneal Anderson–Hynes laparoscopic pyeloplasty in pediatric patients by Tan et al. (13) recommended that it should not be performed in children younger than 6 months of age. The advent of improved 3-mm instrumentation and laparoscopic telescopes has allowed better suture manipulation and visualization, making it feasible even in the infants younger than 6 months of age (14). The key point to performing a laparoscopic pyeloplasty in the infant is based on the geometry of the patient's body habitus. A triangle is constructed utilizing the umbilicus as the apex with the remaining points being lateral to the ipsilateral rectus muscle subcostal and at the level of the anterior superior iliac spine.

Whereas open pyeloplasty has long been described, laparoscopic pyeloplasty has only recently been reported, and long-term outcome data are still being evaluated. As laparoscopic pyeloplasty is technically challenging, this procedure was initially restricted to those medical centers with advanced laparoscopic surgeons. With increasing experience, however, laparoscopic pyeloplasty in children is more commonly being considered as the initial treatment for UPJ obstruction (17). This procedure maintains the benefits of the endoscopic approaches, including decreased postoperative pain, short hospitalization, and reduced postoperative recovery time while demonstrating success rates comparable to those of the conventional open approach (18,19).

ALTERNATIVE THERAPY

Open pyeloplasty still remains the gold standard for correcting UPJ obstruction with a high success rate done either through a flank, dorsal lumbotomy, or anterior muscle-splitting incision. Proponents of open pyeloplasty have shown that this procedure can be done without placement of an indwelling ureteral stent along with simple percutaneous drainage either by a nephrostomy tube or single Penrose drain (1–2).

Endopyelotomy and retrograde dilation are also alternative methods of managing UPJ obstruction in children. Endopyelotomies are performed in the same fashion as in adults either by a percutaneous approach or ureteroscopically in a retrograde manner (4). The long-term success rate of endopyelotomy is less than the standard open or laparoscopic approaches (4,12–14). Retrograde dilation has virtually no role in pediatrics due to its high failure rate requiring a subsequent procedure (5).

LAPAROSCOPIC SURGICAL TECHNIQUE AND STEPS

Initial cystoscopy and ureteric stenting is left to the discretion of the surgeon and may not be necessary (20,21). An indwelling Foley catheter is placed to gravity drainage.

Positioning of the patient is crucial as it facilitates optimal ergonomics for the surgeon and increased access to the operative space. For both a transperitoneal and retroperitoneal approach, the patient is placed in a lateral or semilateral decubitus position in close proximity to the posterior edge of the table, the table is flexed, the kidney rest is elevated, appropriate padding is applied, and the patient is secured with 2-inch tape and a safety belt. An option for the retroperitoneal approach described by Yeung et al. (15) is a modified semiprone position with the left flank up or a 45-degree right lateral decubitus position (for right-sided obstruction) to allow the subsequent ureteropelvic anastomosis using the right hand (for a right-handed surgeon). Another option utilized for the transperitoneal approach is to place the patient supine with a slight 30-degree rotation of the ipsilateral side. The patient is then secured to the table with 2-inch silk tape (Fig. 102.1). The table can then be rotated as needed after visualization of the intraperitoneal field. This approach can be utilized on the left side allowing the colon to stay lateral to the left kidney so a transmesenteric window is unobstructed. As far as trocar placement, a fundamental concept that is important to implement is that conventional laparoscopy is ergonomically favored by triangulation of ports, whereas the robotic platform will function better with the ports arranged in as straight a line as possible with at least 4 cm between all ports.

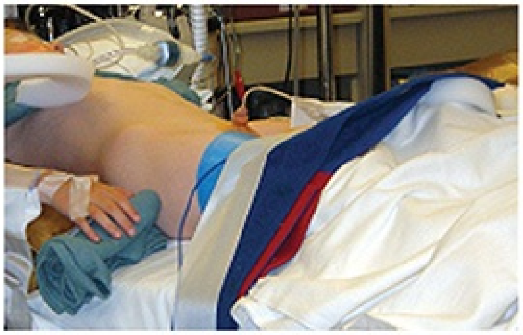

FIGURE 102.1 Supine positioning for transperitoneal approach in left-sided and bilateral cases.

Retroperitoneoscopic Approach

Appropriate placement of the trocars is of the utmost importance and three or four laparoscopic ports are inserted at the surgeon's discretion. Retroperitoneal access is achieved through the first trocar incision 15 mm long and 10 mm from the lower border of the tip of the 12th rib (Fig. 102.2). Our preferred method to achieve access to the retroperitoneal space is that Gerota fascia is approached by a muscle-splitting blunt dissection then opened under direct vision. A working space is created by gas insufflation dissection, and the first trocar fixed with a purse-string suture applied around the deep fascia to ensure an airtight seal. Another approach to create the retroperitoneal space is a modification of Gaur balloon technique to dissect the retroperitoneum. Two index fingers of a powder-free surgical glove are placed one inside the other and ligated onto the 5/10-mm trocar sheath. The dissection is then performed by instilling 500 mL of warm saline through the insufflation channel of the trocar. After completed dissection, the trocar is reinserted without the balloon and pneumoretroperitoneum is established (maximum pressure 12 mm Hg or age dependent). A 5- or 10-mm 0-degree telescope is inserted through the first trocar. A second 3-mm trocar is inserted posteriorly near the costovertebral angle, whereas the third 3-mm trocar is inserted 10 mm above the top of the iliac crest at the anterior axillary line. To avoid transperitoneal insertion of this trocar, the working space is fully developed and the deep surface of the anterior wall muscles identified before the trocar is inserted. The insufflation pressure is <12 mm Hg and the flow rate of CO_2 is progressively increased from 1 to 5 L/min.

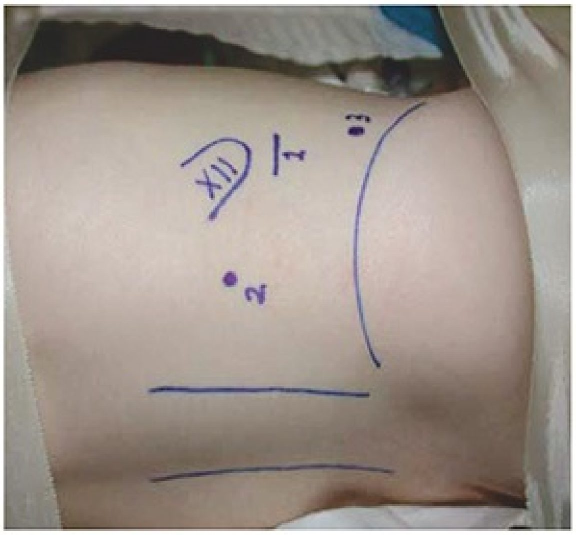

FIGURE 102.2 Port placement for retroperitoneal approach.

The kidney is approached posteriorly, Gerota fascia is incised parallel to the psoas muscle, and the perirenal fat is dissected to reveal the lower pole of the kidney in which the renal pelvis is first identified and then mobilized. The UPJ is identified and minimally dissected to free the UPJ from connective tissue and small vessels are divided using bipolar electrocoagulation. The anterior surface of the UPJ is cleared to identify any polar crossing vessels. In order to dissect the UPJ adequately with minimal trauma, stay sutures of 5-0 Prolene are placed at the UPJ for easy manipulation (Fig. 102.3).

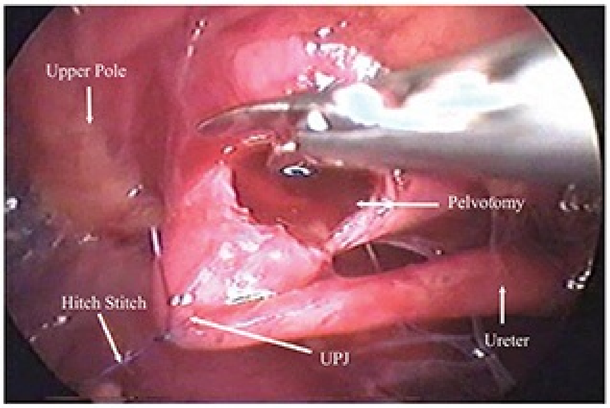

FIGURE 102.3 Retroperitoneal view of 5-0 suture as a hitch stitch at the UPJ.

The traction sutures do not only help to mobilize the UPJ but also facilitate the alignment of the ureter to the trocar axis so that spatulation and suturing is easily accomplished.

Once complete dissection of the UPJ is done, the renal pelvis is partly divided by scissors at the most dependent part, then the ureter is partly divided and spatulated. At all times, the anterior surface of the kidney is left adherent to the peritoneum so that the kidney is retracted medially away from the anastomosis. Nevertheless, if inadvertent dissection of the kidney anteriorly is performed, a fourth trocar (3 mm) is inserted lateral to the lumbosacral muscles near the iliac crest to facilitate medial retraction on the kidney.

The pelviureteric anastomosis begins using 6-0 polydioxanone sutures and a tapered 3/8 circular needle. To facilitate passage of the needles through the 3-mm trocars, needles may be flattened out in the shape of a ski and lubricated. The first suture is placed from the most dependent portion of the pelvis to the most inferior point or vertex of the ureteric spatulation. In the initial few cases, the suture is tied using the intracorporeal technique with the knots placed outside the lumen. In order to facilitate the suturing part of this procedure, two 6-0 undyed polydioxanone 6 cm in length were tied together and one was colored utilizing a surgical marker, thus eliminating a cumbersome step during intracorporeal tying of the crotch stitch. Once the ureter is approximated to the pelvis, the UPJ is maintained on traction and the suture line stabilized. Once half of the anastomosis is accomplished, a 4.7Fr polyurethane ureteral stent is inserted through the suture line to the bladder at the end of the anterior layer reconstruction. Our preferred method for this is through a percutaneous placement of a 12Fr angiocatheter; however, the stent can also be inserted through the costovertebral trocar (Fig. 102.4). To ascertain the position of the stent in the bladder, retrograde filling of the bladder with methylene blue saline is done. The stent remains indwelling for 4 to 6 weeks. Perirenal drainage in the form of a Penrose drain is used. The Foley catheter is left in situ in all patients for 24 hours after surgery. Prophylactic antibiotics (third-generation cephalosporin) are routinely prescribed.

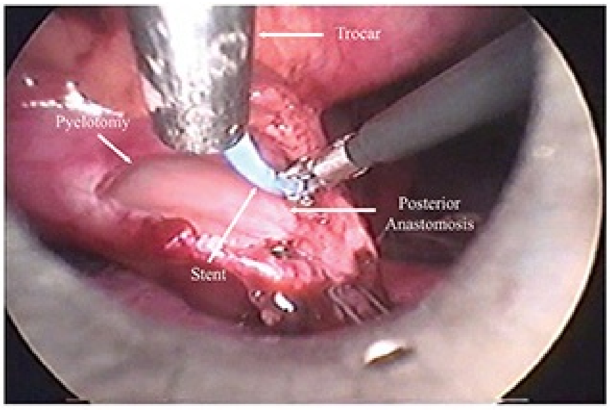

FIGURE 102.4 Retroperitoneal view of the double pigtail ureteral stent inserted through a trocar traversing the ureter antegrade.

Transperitoneal Approach

The first trocar is placed at the umbilicus either through a small open technique or after insufflation with a Veress needle. Utilization of 3- or 5-mm trocars depends on the patient size. Under a year of age, 3-mm trocars are sufficient. However, in any age group, 5-mm trocars with 3-mm instrumentation have been proven the easiest for suture passage in our experience. The abdomen is insufflated with low pressures and high flow to accommodate for suture passage and potential loss of pneumoperitoneum. A 3- or 5-mm 0-degree telescope is inserted through the first trocar. A second trocar is inserted subcostally lateral to the ipsilateral rectus muscle, while the third trocar is inserted 10 mm above the top of the iliac crest lateral to the ipsilateral rectus muscle. A transmesenteric window is performed if the UPJ obstruction is on the left kidney. If the UPJ obstruction is on the right, the colon is mobilized to expose the UPJ (Fig. 102.5).

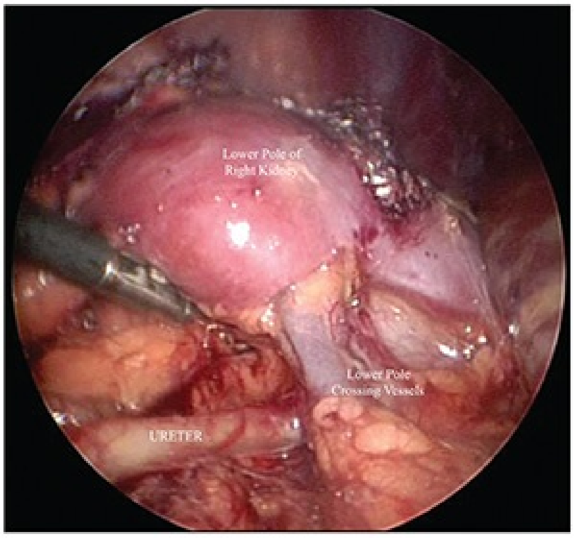

FIGURE 102.5 Transperitoneal view of right lower pole crossing vessels.

The UPJ is identified and mobilized as just described above for the retroperitoneal approach with stay sutures and a hitch stitch. The hitch stitch is placed through the anterior abdominal wall, traversing the renal pelvis, then back through the anterior abdominal wall. It is held in place with a clamp to allow traction control to lift and relax the pelvis as necessary. Once complete dissection of the UPJ is done, the renal pelvis is partly divided by scissors at the most dependent part, then the ureter is partly divided and spatulated.

The anastomosis and percutaneous stent placement is performed as described in the previous section on retroperitoneoscopic pyeloplasty (Fig. 102.6). The stent remains indwelling for 4 weeks. No perirenal drainage is used. The Foley catheter is left in situ in all patients for 24 hours after surgery. Prophylactic antibiotics (third-generation cephalosporin) are routinely prescribed until the catheter is removed. The patients are placed on prophylactic antibiotics until the stent is removed.

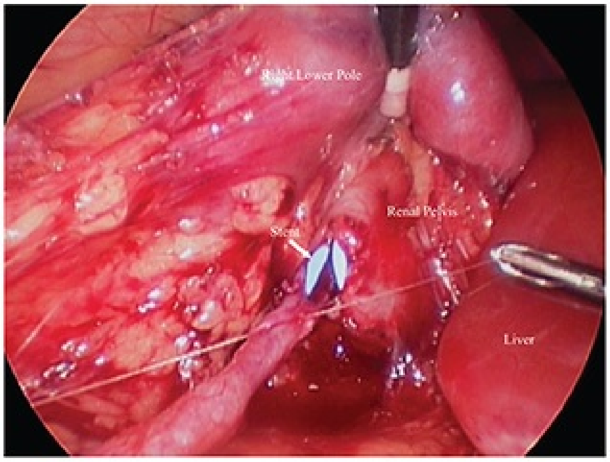

FIGURE 102.6 Completed posterior anastomosis and stent in place. The stent was placed percutaneously after completion of the posterior anastomosis as described.

Special Considerations

Although various reconstructive methods of laparoscopic pyeloplasty such as dismembered or Y-V plasty have been reported, it remains to be determined which methods are most appropriate for which cases of obstruction. For instance, when an aberrant crossing vessel is identified, the polar vessel is dissected and dismembered pyeloplasty is performed to enable the UPJ transposition. After placing the stay suture, the ureter is completely divided and the UPJ and pelvis delivered anterior to the vessels with the help of the stay suture. In some retroperitoneoscopic cases, when we encounter a long segment of obstruction that precludes the creation of a tension-free anastomosis, we perform a transperitoneal laparoscopic approach, and a Y-V plasty can be performed more readily. A concomitant caliceal or renal calculi that cannot be easily accessed via a laparoscopic procedure is not an absolute contraindication if access to the stone is possible, implementing ureteroscopy through one of the access trocars (Fig. 102.7).

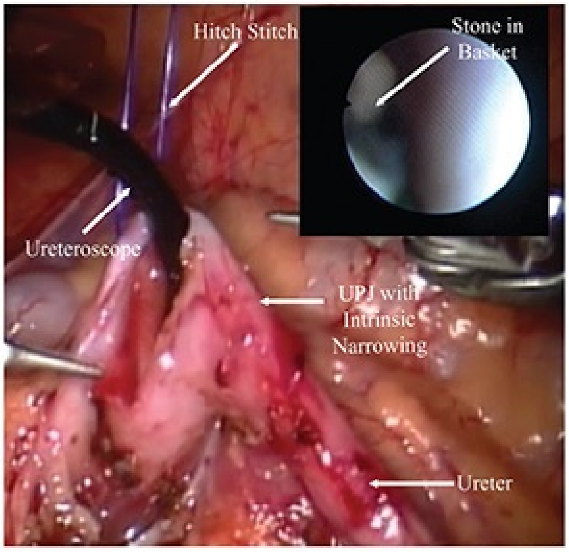

FIGURE 102.7 Concomitant stone extraction. Note the *inset* showing the ureteroscopic view seen during the procedure. The stone is extracted with a basket though an accessory port.

ROBOTIC PYELOPLASTY

Today's surgical robots, or what the true enthusiasts call "surgical actuators," allow 7 degrees of freedom facilitating laparoscopy and broadening the use of minimally invasive surgery. The current industry supported platform, the da Vinci Surgical System (Intuitive Surgical, Sunnyvale, California), provides the advantages of delicate manipulation for reconstructive surgery coalesced with three-dimensional (3D) visualization. It was made for manipulation in hard to reach places. Robotics can overcome many impediments of laparoscopic surgery and decrease the learning curve for minimally invasive surgery, especially for pediatric reconstructive procedures. Robotics also allows the seasoned laparoscopist to become more proficient and refined providing a greater "tool box" to expand minimally invasive surgery to more complex reconstructive procedures (Fig. 102.8). The procedure most performed with the da Vinci system in pediatric urology is pyeloplasty for UPJ obstruction. Complex UPJ surgery has been implemented successfully and safely with the robotic platform. One study showed excellent results of ureterocalicostomy for redo surgery as well as a primary modality for extreme cases of intrarenal collecting systems.

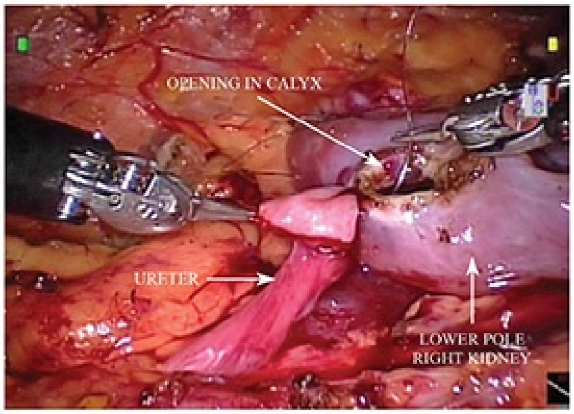

FIGURE 102.8 View of a right robotic ureterocalicostomy.

The techniques and technology have evolved, allowing identical results and utilizing 5-0, 6-0, and 7-0 suture as in open surgeries. The robot has instruments that are available in both 8- and 5-mm sizes. A 5-mm endoscope is available but is monocular and cannot provide the 3D image of the larger scope which makes suturing easier. A fourth arm is available for grasping and retraction. The outcomes for both conventional laparoscopy and robotic-assisted approaches are comparable to the open gold standard. Table 102.1 shows a selected series of pyeloplasty and one series of ureterocalicostomy as examples of this minimally invasive modality even in difficult cases.

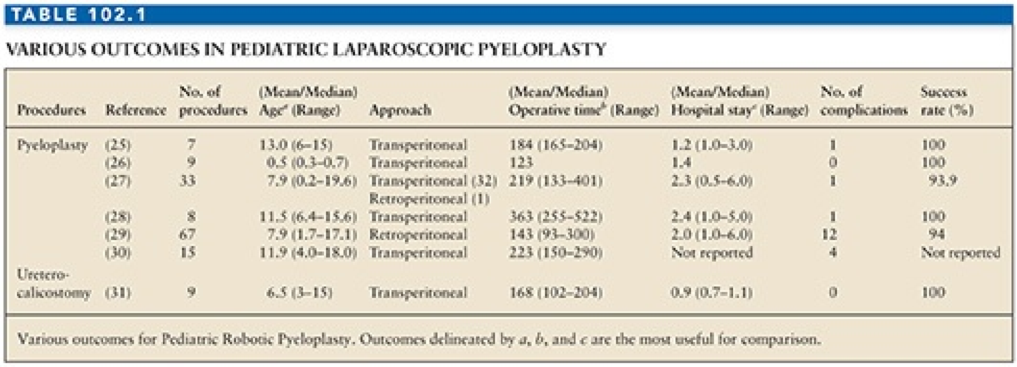

TABLE 102.1

VARIOUS OUTCOMES IN PEDIATRIC LAPAROSCOPIC PYELOPLASTY

Procedures	Reference	No. of procedures	(Mean/Median) Age^a (Range)	Approach	(Mean/Median) Operative time^b (Range)	(Mean/Median) Hospital stay^c (Range)	No. of complications	Success rate (%)
Pyeloplasty	(25)	7	13.0 (6–15)	Transperitoneal	184 (165–204)	1.2 (1.0–3.0)	1	100

Various outcomes for Pediatric Robotic Pyeloplasty. Outcomes delineated by *a*, *b*, and *c* are the most useful for comparison.

OUTCOMES

The continuing evolution of surgical therapies has had a profound effect on the management of UPJ obstruction. Open and endoscopic interventions are recently being challenged by long-term data that are emerging from laparoscopic pyeloplasty series.

Although controversy still goes on concerning which approach to choose, that is transperitoneal or retroperitoneal, arguments to advocate one approach over another are more theoretical than true evidence-based. We believe that surgeons who have started with laparoscopic nephrectomy using the retroperitoneal approach will be able to naturally extend the indications to retroperitoneal pyeloplasty without changing habits. Nevertheless, the longer time needed for the retroperitoneal approach is probably related to the limited working space, which makes suturing more difficult (20).

It is true that the golden standard of pediatric open renal surgery is the retroperitoneal approach and that minimal invasive surgery should follow the same rules (20). The major advantage of the retroperitoneoscopic approach is that it provides a direct route to the UPJ and thus allows access without interference from intra-abdominal structures. Furthermore, the complication of urine leakage would be better tolerated in the retroperitoneal space than in the intraperitoneal cavity. However, in our experience with the transperitoneal approach with stenting, the rate of urinary leakage from the anastomosis into the abdominal cavity has disappeared.

Laparoscopic pyeloplasty in children has been demonstrated to be feasible and to have satisfactory results (13,15,16,21). Although there are only a few published series on the long-term outcome to date, the short-term data suggest that outcomes are similar to those of open pyeloplasty in children (16,20).

When comparing the gold standard open approach to the laparoscopic approach (20), the mean operative time was significantly shorter in the open surgery group versus the laparoscopy group (96 minutes, range 50 to 150 minutes, vs. 219 minutes, range 140 to 310 minutes, $P < .0001$). On the other hand, the mean postoperative use of analgesics and hospital stay were less in the laparoscopy group. The major disadvantage of the laparoscopic approach is that it is clearly a technically challenging and lengthy surgical procedure because of the high proficiency required for intracorporeal suturing. Although automated devices that facilitate suturing (22) are available, accurate suture placement and unavailability of small size for pediatric application preclude their use (23). Development of novel alternatives to suturing, such as fibrin glue and laser welding may enhance the utilization of the laparoscopic approach; however, the results with these methods alone have not yet matched the success of conventional sutures in providing adequate tensile strength of the anastomosis (24). Thus, for surgeons interested in this approach, suturing experience through practice and training may be the only factor that would help in decreasing the operative times in pediatric series (17). In contrast, suturing using the robotic platform has been greatly facilitated and has significantly mitigated this disadvantage when compared with open pyeloplasty.

Complications

Bleeding—can be seen with access and intracorporeally

Wound infection—postoperative complication

Hernia at the port site and/or internal—postoperative complication. The authors close all trocar sites at the fascial level.

Thermal damage to tissues or organs—Ensure the instruments are always in the visual field.

Trocar or insufflation needle damage to viscera or vessels

Persistent leakage of urine—either from suture line or thermal injury to urinary organ

Stent migration—Ensure stent is completely in the bladder either by postoperative imaging or intraoperative verification with urethral catheter irrigation using methylene blue.

Reobstruction transient and persistent

UTI with stent in place

CONCLUSIONS

Transperitoneal and retroperitoneal approaches are reported to have comparable outcomes. In our experience, the retroperitoneal approach has been difficult in the following scenarios: (a) children under 15 kg with extremely large renal pelvis and (b) previous violation of the retroperitoneal space. For a relatively long obstructed UPJ segment associated with a hydronephrotic extrarenal pelvis, several flap pyeloplasty techniques such as a Culp–Deweerd spiral, Scardino–Prince vertical flap, and a dismembered tubularized renal pelvic wall flap described by Kaouk et al. (24) have been performed.

Reports on the retroperitoneal approach in laparoscopic pyeloplasty are less common despite wide use of this approach in laparoscopic nephrectomy. The level of difficulty of manipulation certainly increases in the retroperitoneal space. We believe that difficulty of manipulation in the retroperitoneal space can be overcome with improvement in operative skill, especially in ambidextrous suturing technique. This approach has some advantages. First, it can avoid dissemination of urine into the peritoneal cavity under retroperitoneoscopic procedures when the renal pelvis is transected. Second, it can minimize the risk of injury to intraperitoneal organs such as the colon and small bowel but with current experiences, this is still not established. Some actually speculate that with the transperitoneal approach, there is less risk to abdominal organs because they are always kept in the field of view.

The success rate of laparoscopic pyeloplasty is equal to that of conventional open pyeloplasty. Transperitoneal and retroperitoneal approaches are reported to have comparable outcomes (16). We believe that laparoscopic dismembered pyeloplasty for UPJ obstruction in infants is technically possible. We also believe the use of an indwelling stent is helpful but not mandatory.

CHAPTER 103 PEDIATRIC LAPAROSCOPIC NEPHRECTOMY AND PARTIAL NEPHRECTOMY

GLENN M. CANNON, JR. AND RICHARD S. LEE

Since the initial description of a laparoscopic heminephrectomy in a 14-year-old by Jordan and Winslow in 1993 (1), a large amount of literature has been devoted to laparoscopic renal ablative surgery in children. With its decreased length of stay, decreased postoperative opioid requirements, improved cosmesis, and equivalent operative times to open surgery, laparoscopic nephrectomy and partial nephrectomy have become widespread procedures in pediatric urology. In a cost analysis from the United Kingdom, the laparoscopic approach to nephrectomy in children was 54% less expensive than the open approach (2). Currently, robotic systems such as the da Vinci Surgical System (Intuitive Surgical, Sunnyvale, California) are being utilized for more complex reconstructive procedures such as partial nephrectomy. Future research will determine its utility as compared to conventional laparoscopy.

DIAGNOSIS

Children with prenatal or postnatal hydronephrosis and/or febrile urinary tract infection are often imaged with renal ultrasound, voiding cystourethrogram (VCUG), and possibly radionucleotide renal scanning. If there is no evidence of vesicoureteral reflux (VUR), nuclear renography is performed to determine if there is significant obstruction and/or salvageable function. If a clinically significant nonfunctioning renal moiety (e.g., <5% to 10% function by dimercaptosuccinic acid study) is identified, nephrectomy or partial nephrectomy may be considered. Further imaging is usually not warranted, unless there is a history of a continued day and night wetting and possible ureteral ectopia. In these instances, magnetic resonance imaging (MRI) urography may be beneficial (3). In cases of a renal mass, abdominal computed tomography (CT) or MRI is typically obtained to further delineate the mass. In all cases, particular attention should be paid to vascular anatomy, the presence and appearance of the contralateral kidney, the presence and appearance of the ipsilateral and contralateral adrenal glands, and any degree of lymphadenopathy.

INDICATIONS FOR SURGERY

Indications for laparoscopic nephrectomy or partial nephrectomy in children include nonfunctioning kidney, poorly or nonfunctioning upper or lower pole moieties associated with duplicated collecting systems, or renal mass. Typical causes include obstruction, reflux, or ureteral ectopia. Symptoms can possibly include pain, hypertension, infections, or stone formation. Laparoscopy can also be applied when bilateral nephrectomy is required of nonfunctioning kidneys causing hypertension, infections, or nephrotic syndrome prior to renal transplantation. Removal of potentially malignant renal masses has not typically been approached in a laparoscopic fashion in children.

ALTERNATIVE THERAPY

Open nephrectomy or partial nephrectomy is the alternative to a laparoscopic approach. Percutaneous renal ablative procedures such as cryogenic and radiofrequency ablation are not performed in children. An open procedure may be considered if the kidney is large or extensive intra-abdominal adhesions are present. Retroperitoneal laparoscopy can be considered if there is a history of previous abdominal surgery, and transperitoneal laparoscopy can be considered if there is a history of retroperitoneal open surgery.

SURGICAL TECHNIQUE

The following descriptions refer to laparoscopic partial nephrectomy in children. Specific mention is made when the steps of the procedure differ from the performance of a complete nephrectomy. Otherwise, the steps are identical. Although ultimately the surgical approach will be chosen by an individual surgeon’s comfort level and experience, Borzi and Yeung (4) proposed selecting an approach based on the specific type of procedure performed. Reporting an experience of 179 laparoscopic procedures, they recommended a posterior retroperitoneal approach for isolated renal excision without extended ureterectomy, a lateral retroperitoneal approach for complete ureterectomy or access to horseshoe and pelvic kidneys, and a transperitoneal approach when complete moiety excision with lower urinary reconstruction is planned.

Transperitoneal Approach

Preoperatively, patients receive a clear liquid diet for 24 hours and a rectal suppository the night before surgery. Depending on surgeon preference, cystoscopy is performed prior to the start of the partial nephrectomy. A ureteral stent can be placed in the nonfunctioning moiety to assist in identification if necessary. A bladder catheter and orogastric tube are placed.

The affected side is elevated by a 30-degree wedge, and the patient is carefully secured to the operating table. The table is rotated to flatten the patient’s abdomen. With the patient’s abdomen flat, transperitoneal port access is gained using either a Veress needle or with the modified Hasson technique. A camera port (12 mm) is placed at the umbilicus (Fig. 103.1). A second port (5 or 8 mm) is placed superior to the umbilicus in the midline approximately 10 cm from the umbilical port. A third working port (5 or 8 mm) is positioned at the anterior superior iliac spine laterally at a 45-degree offset and 10 cm from the umbilical port. If necessary, a fourth 5-mm port is placed. The fourth port is often helpful in right-sided cases to lift the liver edge and expose the upper pole of the kidney. The table is angled to raise the affected side into a 60-degree flank position. If the da Vinci Surgical System is utilized, the robot is positioned on the ipsilateral side of the patient and angled over the shoulder. The three robotic arms are then engaged to the laparoscopic ports. A 30-degree lens is used in the down position.

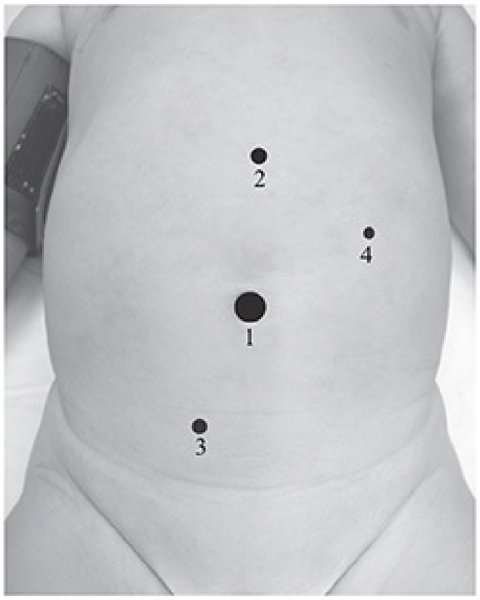

FIGURE 103.1 Port placement for a right-sided laparoscopic partial nephrectomy: camera port (*1*), right handed laparoscopic or robotic port (*2*), left handed laparoscopic or robotic port, if performed laparoscopically, a 10 or 12 mm port could be considered if larger laparoscopic instruments are needed for the procedure (*3*), assistant port (*4*).

The kidney is exposed by medial reflection of the colon. The ureter from the nonfunctioning moiety (or the single ureter for a complete nephrectomy) is identified and mobilized as distally as the iliac vessels. The nonfunctioning ureter is divided. If there is no VUR, the distal end can be left open. If there is VUR, the distal ureter is ligated with an absorbable stitch. The affected pole is manipulated by using the divided proximal ureter as a handle (Figs. 103.2 and 103.3).

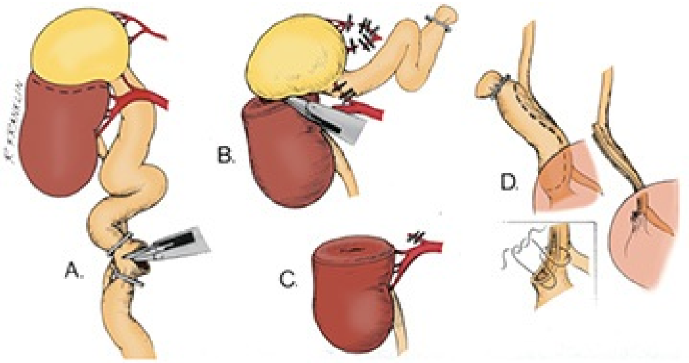

FIGURE 103.2 Laparoendoscopic right upper pole partial nephroureterectomy. **A:** The ureter is clipped and divided in the region of the midureter. **B and C:** The ureter has been dissected from beneath the main renal pedicle and the upper pole vasculature has been clipped. The hydronephrotic cap is dissected off with the parenchyma minimally divided. **D:** The ureter is left attached as the remaining wall of the ureter is dissected and ligated at the bladder wall.

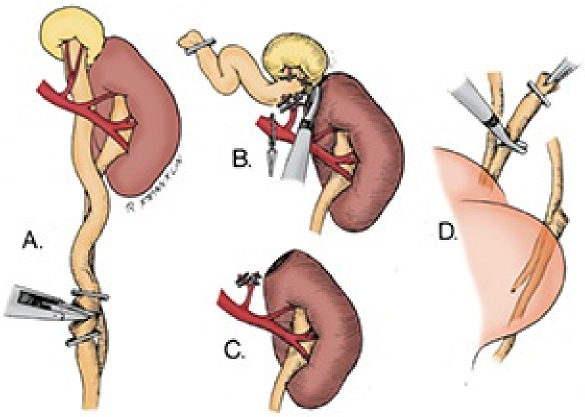

FIGURE 103.3 Laparoendoscopic left upper pole partial nephroureterectomy. **A:** The ureter is clipped and divided in the region of the midureter and dissected in a rostral direction. **B and C:** The upper pole segmental vessels are clipped and the cap of the kidney allowed to demarcate. The plane of amputation is marked, an endoscopic bulldog is applied to the major pedicle, and the upper pole cap is amputated. **D:** The ureter is dissected in a caudal direction to the point of the common vascularity and there amputated with the stump left open.

The proximal nonfunctioning ureter is mobilized and passed posterior to the main renal hilum for an upper pole nephrectomy. During this mobilization, the nonfunctioning ureter is dissected away from the remaining ureter by mobilizing the adventitia of the nonfunctioning ureter toward the remaining ureter. This maneuver is critical to preserve the blood supply of the remaining ureter.

The nonfunctioning ureter is mobilized to the kidney and the Gerota fascia is opened. The ureter is passed posterior to the main renal hilum for an upper pole nephrectomy. Suprahilar, cephalad traction on the ureter should provide access to the upper pole (nonfunctioning) hilum. If the blood supply is not clearly identified, laparoscopic bulldogs may be placed on the presumed upper pole vessels. A clear demarcation between the upper and lower pole should be visible. The upper pole vessels are clipped and divided. The renal pelvis of the nonfunctioning moiety is separated from the normal parenchyma using blunt dissection to better identify the demarcation between the functioning and nonfunctioning moiety. Large hydronephrotic moieties can be opened to help delineate the separation between the upper and lower pole. The nonfunctioning moiety is excised using electrocautery or the harmonic scalpel along the line of vascular demarcation (Fig. 103.4). Any collecting system injuries to the remaining pole should be closed with an absorbable suture. Perirenal fat is used as a bolster prior to closing the cut surface of the remaining moiety with 4-0 absorbable monofilament suture.

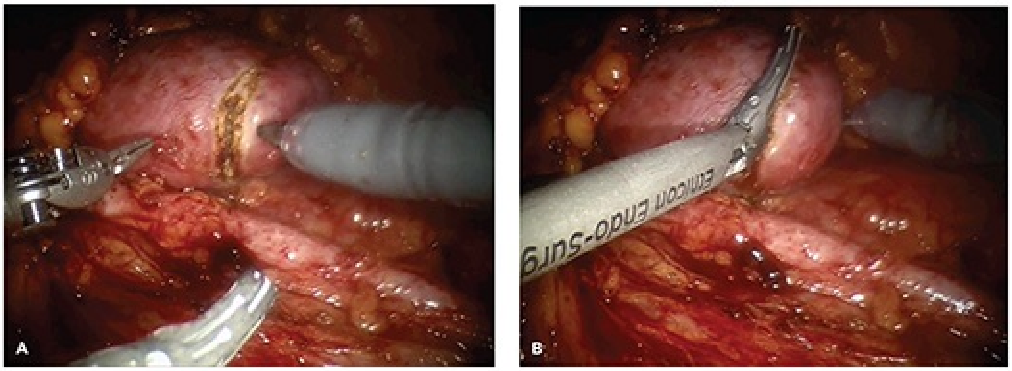

FIGURE 103.4 Transperitoneal view of the left lower pole demarcated by electrocautery prior to removal (A), with subsequent excision by harmonic scalpel (B).

If a complete nephrectomy is to be performed, after the ureter is divided and Gerota fascia opened, the renal vessels are dissected and divided using clips or an endovascular stapler. The kidney is mobilized and removed.

After inspection for hemostasis, a retroperitoneal drain is placed and the specimen is removed through the camera port. If a complete nephrectomy is performed, a drain is typically not placed. Local anesthetic is injected into the port sites. Most patients, if not all, do not require epidural analgesia. The bladder catheter is removed on the first or second postoperative day, depending on whether further bladder work is required. The drain is removed when there is minimal drainage. The patient is discharged when comfortable with diet and oral analgesics.

Retroperitoneal Approach

Retroperitoneal access to the kidney can be obtained by either a prone or a flank approach. The posterior prone retroperitoneal approach has been recommended for children with end-stage renal disease who may require immediate peritoneal dialysis (5). In the prone approach, initial retroperitoneal access is gained at the costovertebral angle using an open technique. Balloon inflation to 15 to 20 mm Hg of pressure is utilized to dissect and create the retroperitoneal space. Working ports are placed under direct vision inferior to the camera port and just above the iliac crest (Fig. 103.5). In this position, the kidney will move anterior by gravity, thereby exposing the hilar vessels. The psoas muscle is identified as a landmark. During nephrectomy, exposure and dissection of the hilum are performed first with subsequent identification and division of the ureter. In partial nephrectomy, minimal mobilization of the remaining vessels and moiety should be performed to prevent vasospasm of the remaining moiety. The affected vessels should be divided and the nonfunctioning moiety removed as in the transperitoneal approach. The ureter is used as a handle to manipulate and isolate the affected moiety. Collecting system injuries should be closed appropriately, and the edges of the remaining moiety may be sutured together for further hemostasis. A retroperitoneal drain is typically left in place.

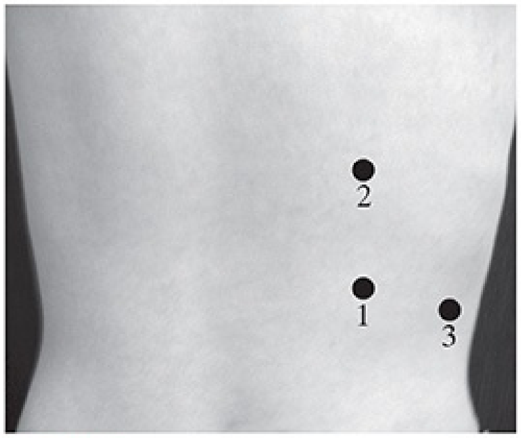

FIGURE 103.5 Port placement for right-sided prone retroperitoneal laparoscopic renal surgery: camera port (*1*), laparoscopic or robotic ports (*2*) and (*3*).

The flank approach is similar except that the working space is developed with the camera port just below the tip of the 12th rib. The working ports are placed along a transverse line with the camera medially and laterally after dissection of the peritoneum from the anterior abdominal wall. The remainder of the procedure is identical to that of the prone approach.

OUTCOMES

Janetschek et al. (6) presented the first series of pediatric laparoscopic heminephrectomy. In 12 cases, 7 upper renal poles were removed for ectopic refluxing megaureter and obstructive ureteroceles. Five lower poles were removed for reflux nephropathy. Their blood loss was minimal (10 to 30 mL), there were no complications, and mean operative time was 222 minutes. Horowitz et al. (7) later reported a series of 14 laparoscopic upper pole heminephrectomies with a mean operative time of 100 minutes.

To assess for potential benefits of laparoscopic renal ablative surgery over open procedures, Robinson et al. (8) retrospectively compared 22 consecutive partial nephrectomies of which 11 were performed laparoscopically and 11 performed open in a nonrandomized fashion. Although the mean operative time was significantly longer for the laparoscopic group (200 minutes versus 114 minutes), there was no difference in mean hospital stay. Patients in the laparoscopic group had a significantly lower opioid requirement than the open group. Piaggio et al. (9) compared intraperitoneal laparoscopic partial nephrectomy to an open retroperitoneal approach. They noted that length of hospitalization was shorter in the laparoscopic group and stated that the procedure is feasible even in infants under 6 months of age.

Success in laparoscopic partial nephrectomy has also been reported via a retroperitoneal approach. Castellan et al. (10) also reported their experience utilizing both transperitoneal and retroperitoneal heminephrectomy. Their overall complication rate was 10%, which included urine leak, pneumothorax, urinary tract infection, and hypertension. Lee et al. (11) performed an age-matched comparison of pediatric patients undergoing retroperitoneal laparoscopic partial nephrectomy to open surgery. Compared to open partial nephrectomy, the laparoscopic approach was eventually associated with equivalent operative times, significantly shorter length of stay, and less postoperative opioid requirements.

With the advent of robotic-assisted laparoscopic surgery (RALS), robotic-assisted laparoscopic partial nephrectomy (RALPN) has been performed and has demonstrated similar outcomes to open and standard laparoscopic surgical techniques (12,13).

COMPLICATIONS

The most severe complication that can occur during laparoscopic nephrectomy and partial nephrectomy is a major vascular injury. This is most likely to occur during trocar insertion or during the hilar dissection. Trocar injuries may be prevented by using an open Hasson approach. Meticulous attention must be paid during the hilar dissection. The vascular anatomy needs to be clearly defined prior to division of the renal vessels. When endovascular staplers are utilized, the surgeon must confirm that only the renal vessels are included within the stapler.

Other complications can include bowel injury, bleeding, infection, or urine leak resulting in urinoma formation. Bowel injuries can occur with inadvertent trocar placement or during dissection secondary to instrument handling or electrocautery misuse. Urine leaks are often discovered by elevated postoperative drain output. They are often managed with bladder decompression, with or without ureteral stent placement. Asymptomatic postoperative retroperitoneal fluid collections can be observed. Symptomatic retroperitoneal fluid collections may require percutaneous drainage and assessment for creatinine. A late complication that can occur is loss of function in the ipsilateral remaining moiety, eventually resulting in hypertension or, worse, loss of the moiety. If severe, this may require completion of a nephrectomy. This complication may be prevented with meticulous dissection and minimal mobilization of the hilum and kidney of the functioning moiety to prevent any intimal vascular injury or vasospasm.

As experience with laparoscopic nephrectomy and heminephroureterectomy increases, operative time and estimated blood loss can improve. Yucel et al. (14) retrospectively reviewed their experience with laparoscopic ablative renal surgery performed by one surgeon over a 6-year period. In the fourth year of their experience, they noted a statistically significant improvement in operative time for laparoscopic nephrectomy and in estimated blood loss for laparoscopic heminephroureterectomy. They concluded that their experience should continue to encourage pediatric urologists to perform laparoscopic renal surgery.

CHAPTER 104 UROGENITAL SINUS AND CLOACAL ANOMALIES

RICHARD C. RINK, JEFFREY A. LESLIE AND MARTIN KAEFER

Anomalies of the urogenital sinus occur on a spectrum ranging from a mild distal communication between the urethra and vagina to a very complex confluence between the urethra, vagina, and rectum. For this last-mentioned complex group, a distal common channel for all of these structures drains to a single perineal opening (Fig. 104.1A). The clinical presentation of this single opening results from persistence of the cloaca and is essentially a severe urogenital sinus abnormality with a high imperforate anus (Fig. 104.1B). In addition to a more bizarre and diverse internal anatomy, patients with cloacal anomalies have a high incidence of other serious midline congenital anomalies. Important elements of baseline evaluation and surgical management of urogenital sinus and cloacal anomalies are discussed in detail in this chapter.

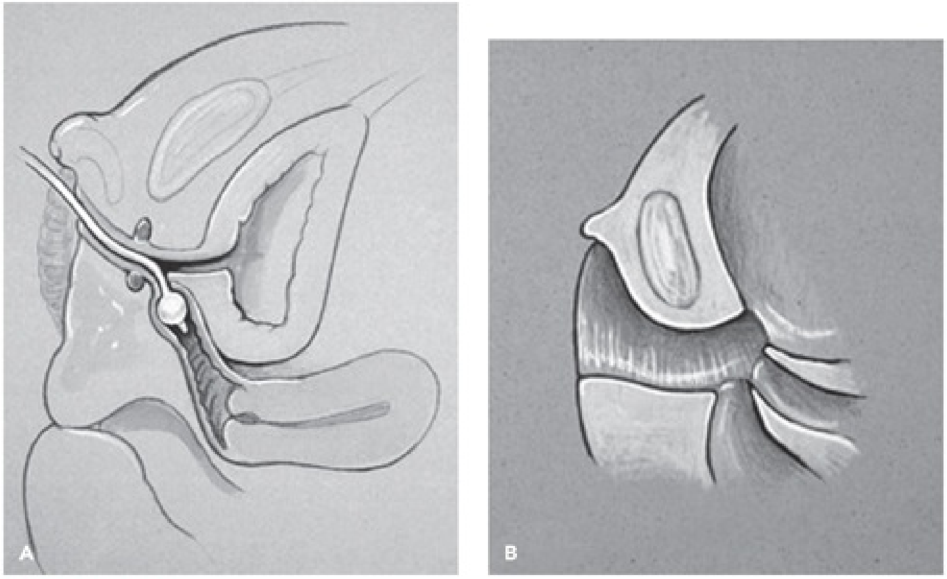

FIGURE 104.1 A: Urogenital sinus. The confluence of the vagina with the urethra is near the bladder neck and thus "high." A Fogarty catheter is in the vagina. B: Cloacal anomaly with the urethra, vagina, and rectum all exiting a single perineal opening. (From Indiana University School of Medicine, Office of Visual Media, with permission.)

Urogenital sinus abnormalities (no rectal involvement) in general occur in one of two forms: pure urogenital sinus anomalies and females with disorders of sexual development (DSD) conditions. The latter group is much more common. In these children, surgical management must address not only the urinary and vaginal communication but also the virilization of the clitoris and labia.

DIAGNOSIS

The majority of children with urogenital sinus abnormalities are detected at birth due to genital ambiguity. The initial evaluation in this group of children requires a team approach to rapidly identify the etiology and requires rapid chromosomal and endocrinologic studies. The history and physical examination are often helpful in establishing a correct diagnosis. Congenital adrenal hyperplasia (CAH) secondary to 21-hydroxylase deficiency is by far the most common etiology. Some children may be identified antenatally on ultrasound by noting a fluid-filled mass (distended vagina) posterior to the bladder and indeterminant genitalia. Persistence of the cloaca is suspected in utero when large fluid-filled pelvic structures are noted associated with bilateral hydroureteronephrosis, oligohydramnios, and ascites. A 46XX karyotype is found. Hydrocolpos due to retention of urine and secretions results in upper tract distention, and ascites occurs due to retrograde flow through the genital tract into the peritoneum. The rectum and bladder may also be filled with urine, giving rise to the other fluid-filled structures.

Prematurity and multiple congenital defects are common in children with cloacal anomalies. Initial evaluation of these children should therefore include medical stabilization and evaluation for midline abnormalities. Abdominal distention is common and may result in respiratory embarrassment. Cardiac, renal, and upper gastrointestinal anomalies and spinal dysraphism are frequently identified. Although these infants are uniformly female, ambiguity of the genitalia may occur and should be investigated. A single perineal opening is noted anteriorly, and the anus is absent. The perineum is in general flat with variable amounts of labial tissue mounded around the anterior orifice. Occasionally, a prominent phallic structure is found. The buttocks are often poorly developed, and the sacrum may be deficient on abdominal plain film.

Renal ultrasound reveals anomalies of number and fusion. Magnetic resonance imaging (MRI) clarifies the complex pelvic relationships, evaluates the structural quality of the sphincter complex, and defines the anatomy of the lumbosacral spine and distal spinal cord. A gender assignment committee is convened for all children with genital ambiguity. This committee includes an endocrinologist, geneticist, pediatric urologist, neonatologist, psychiatrist/psychologist, and the family. The child must be stabilized. Genitography to help determine the anatomy (i.e., length of common sinus, location of vaginal confluence, status of bladder, presence or absence of vesicoureteral reflux, or vaginal duplication) has routinely been used in urogenital sinus and cloacal anomalies. We have recently shown that the anatomy is delineated correctly in only 72% of CAH patients (1). Patients with cloacal anomalies have a communication between the urogenital tract and rectum, and vesicoureteral reflux is commonly identified. Endoscopy is imperative to understand this complex anatomy. Ultrasonography of the pelvis and kidneys is also of help to identify the uterus, ovaries, and any vaginal distention, or, in the case of cloacal anomalies, it may reveal hydronephrosis or increased echogenicity suggestive of renal dysplasia. The adrenal glands in CAH may be prominent with a cerebriform appearance (2). MRI of the pelvis is an excellent tool to determine pelvic anatomy and note the presence of lumbosacral spinal cord anomalies that may be present.

Pure urogenital sinus anomalies are in general not detected early because of normal external genitalia. These patients are usually found at puberty with hydrometrocolpos or difficulty with tampon insertion. Some children are identified earlier with incontinence and urinary tract infection (UTI) from urine pooling within the vagina. Those with pure urogenital sinus anomalies are also more likely to have other organ system abnormalities than those with a urogenital sinus associated with DSD.

INDICATIONS FOR SURGERY

It is very important for the reader to understand that there are many controversies associated with the care of children with genital ambiguity. The controversies primarily involve the role of surgical management including timing, types of repairs, outcomes—particularly sensory loss, and lack of patient consent. Ideal surgical timing for those with DSD is yet to be defined (3). Surgery for DSD generally involves clitoroplasty, labioplasty, and vaginoplasty. The timing of the surgery is the most controversial with proponents falling into one of four groups: (a) all components done in infancy, (b) clitoroplasty and labioplasty in infancy with delayed pubertal vaginoplasty, (c) all components done at puberty, and (d) no surgery unless the patient is of age to request it. There are advantages and disadvantages to each of these options. For CAH and cloacal anomalies, surgery is most often performed in infancy. We believe strongly that no family should be talked into surgery but should rather be given all advantages and disadvantages of the various options and support in their decision-making process. Creighton et al. (3) have noted that the idea of “doing nothing” can be a stressful concept for the parents. Clearly, gender assignment when the individual’s ultimate gender identity is unknown is a challenge and is at the core of this controversy (4). The family should also be given access to support groups such as the CARES Foundation, Accord Alliance, and MAGIC Foundation to aid in this complex decision.

For the purposes of this presentation, we will assume that the family and the gender assignment team agree to proceed with surgery. Although the majority in the United States elect surgery as an infant, it is imperative for the family to know that this “single stage surgery” may require secondary vaginal surgery at puberty most commonly due to introital or vaginal stenosis. This is usually a minor procedure. Even among proponents of early clitoroplasty, labioplasty, and vaginoplasty, it is understood that in the child with a very high, very small vagina, it may be more appropriate to postpone vaginoplasty until puberty. All techniques described herein are applicable to the infant or pubertal child. We are in agreement with others that these procedures are technically more challenging after the onset of puberty (5).

DECOMPRESSION THERAPY

While most of those with a urogenital sinus undergo reconstruction in the first few months, the complex nature of cloacal anomalies and their high incidence of other congenital defects may necessitate a delay in formal reconstruction while the child is stabilized. Certainly, temporary diversion of the gastrointestinal tract by colostomy is essential, and decompression of the urinary tract may be required. This may be done by clean intermittent catheterization, but if this is not adequate, a temporary cutaneous vesicostomy or vaginostomy may be needed. There has been concern historically that vaginostomy may tether the vagina to the abdominal wall making later vaginoplasty more difficult. However, this has more recently been challenged by Levitt and Pena (6,7), and vaginostomy has been valuable in some patients in our hands. In the current era of Malone antegrade continence enema (MACE appendicocecostomy) procedures to achieve fecal continence, nearly all will ultimately undergo complete reconstruction, including a rectal pull-through.

SURGICAL TECHNIQUE

All children with a very high vaginal confluence or a cloacal anomaly receive a polyethylene glycol electrolyte solution bowel preparation and prophylactic parenteral antibiotics preoperatively. Those with a low to midlevel confluence and most CAH patients receive only a preoperative enema and broad-spectrum antibiotics. CAH children must receive “stress dose” steroids prior to surgery.

Endoscopy is performed with the child in the lithotomy position. This is one of the most important steps in reconstruction, as it defines the level of vaginal confluence and allows identification of any other lower genitourinary pathology, such as vaginal duplication, ectopic ureter, and so forth. We believe that the distance of the vagina from the bladder neck is the most critical aspect and dictates the type of vaginoplasty. Endoscopy also allows placement of a Fogarty catheter into the vagina, which is left indwelling with the balloon inflated. Correct placement is confirmed by repeating endoscopy. The Fogarty balloon will aid in identification of the vagina during the reconstruction. A separate small Foley catheter is passed into the bladder.

Historically, urogenital sinus surgery has been performed with the child in the lithotomy position. While this position is acceptable, we have found it much easier to prepare the entire lower portion of the body circumferentially to allow access to the abdomen and perineum and to allow the child to be supine or prone (Fig. 104.2A and B). The supine portion of the procedure is done with the child "frog-legged," with the buttocks elevated on towels. This position dramatically improves visualization for the surgical assistants and does not hinder the surgeon. By far the most common group of patients with a urogenital sinus anomaly to require surgical reconstruction is the group with CAH, who have not only a urogenital sinus but also virilization of their external genitalia. This includes clitoral hypertrophy, absence of the labia minora, and anteriorly placed labia majora. Therefore, most patients will undergo clitoroplasty, labioplasty, and vaginoplasty.

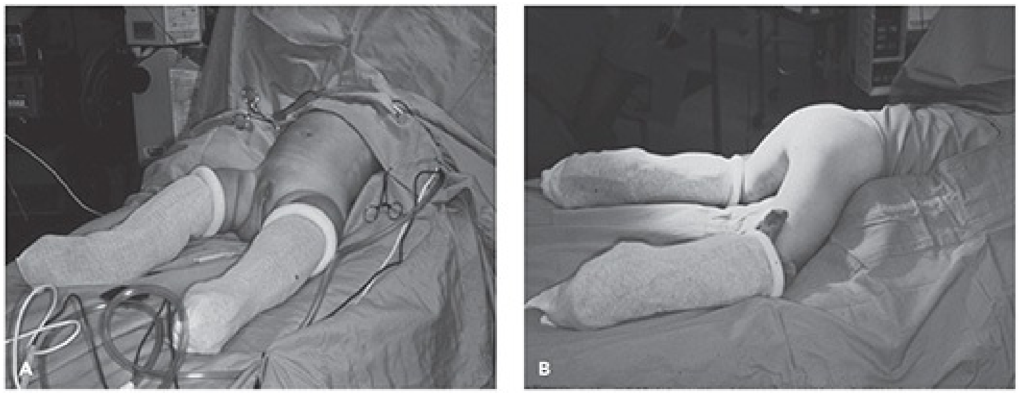

FIGURE 104.2 Total lower body preparation. A: Supine position allows access to perineum and abdomen. B: Child has been rotated prone, allowing access for a posterior sagittal approach.

Clitoroplasty

In cases of genital ambiguity, the operation begins with placement of a traction suture in the glans clitoris. Using a skin scribe, the proposed incisions are outlined as shown in Fig. 104.3. Historically, a very wide-based inverted U-shaped perineal flap has been created. Improved cosmesis occurs, however, if the flap has a narrower base similar to an omega (8), avoiding the appearance of a triangular introitus. After injecting 0.5% lidocaine with 1:200,000 epinephrine subcutaneously along the proposed suture lines, the clitoroplasty is begun. The initial incision is carried out dorsally at the junction of the inner preputial surface with the outer clitoral skin. This preserves the inner preputial skin for a clitoral hood and maximizes sexual sensitivity. The entire clitoris is degloved by creating a plane between the Buck fascia and the dartos circumferentially. Ventrally, the incision is carried around the urogenital sinus meatus. The rounded apex of the perineal flap should extend to near the meatus. In situations where the urogenital sinus meatus is at the base of the clitoris, parallel incisions on either side of the urogenital sinus plate will allow its preservation for later use in the reconstruction.

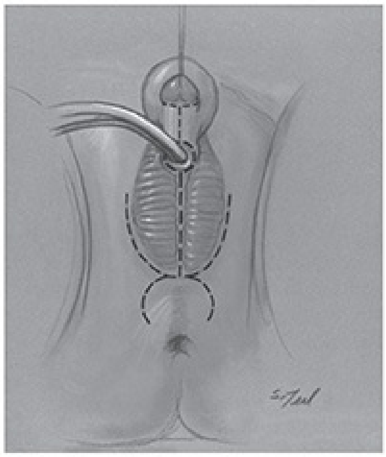

FIGURE 104.3 Proposed initial incisions. Notice the omega-shaped perineal flap. The meatus is encircled. (From Indiana University School of Medicine, Office of Visual Media, with permission.)

The perineal flap is elevated with its underlying subcutaneous and adipose tissue to expose the urogenital sinus. Dorsally, the suspensory ligament is divided and the bifurcation of the corporal bodies is exposed ventrally. With the entire clitoris now exposed, a tourniquet is placed at its base. A vertical ventral midline incision is made along the entire length of each corporal body to the glans (9) (Fig. 104.4A). The erectile tissue is exposed and excised, with care taken not to injure the Buck fascia, the tunica albuginea, the neurovascular bundle, or glans. This is performed bilaterally from the glans to the level of the bifurcation (Fig. 104.4B). The proximal end of each corporal body is oversewn with 5-0 polyglycolic acid sutures to prevent bleeding. With the Buck fascia folded, the glans is now secured to the corporal stumps with 5-0 polydioxanone sutures. We had previously sutured the glans to the pubis but found that this technique prevents appropriate concealment of the glans. At times, the glans is quite large, but one should resist aggressive glans reduction. If any reduction is done, it should only occur on the ventral aspect of the glans to prevent loss of sensation (10).

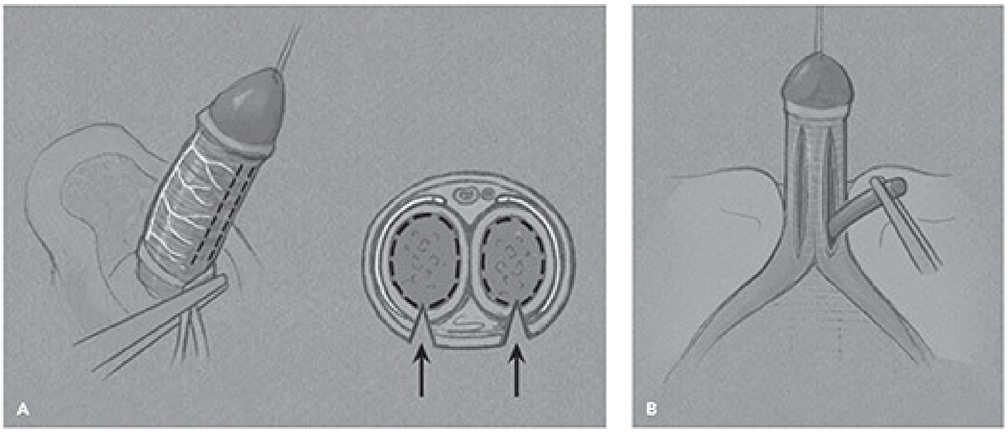

FIGURE 104.4 Clitoroplasty. **A:** The longitudinal incisions must be ventrally placed to avoid injury to the neurovascular supply. **B:** The erectile tissue is removed. There is no excision of any of the tunic, and the neurovascular pedicles are never manipulated. (From Indiana University School of Medicine, Office of Visual Media, with permission.)

Vaginoplasty

The most complex component of reconstruction of the urogenital sinus is the vaginoplasty. While multiple techniques of vaginal reconstruction have been described, they all fall in general into four types: (a) cut-back vaginoplasty, (b) flap vaginoplasty, (c) pull-through vaginoplasty, and (d) vaginal replacement. The type of vaginoplasty is determined by the location of the confluence between the vagina and the common urogenital sinus.

The *cut-back vaginoplasty* is applicable only for minor labial fusion and we believe is contraindicated for any true urogenital sinus anomaly. In this procedure, the sinus is opened with a midline vertical incision that is then closed transversely in a Heineke-Mikulicz fashion. Although we believe there is a high risk of inadequate opening of the narrow distal vagina with the cutback technique and therefore of historical significance only, some have recently reported it to be useful in low confluence (<1 cm) Prader I and II patients (11).

Low Vaginal Confluence

For the low confluence, a *flap vaginoplasty* is performed. This procedure leaves the vagina in the same anatomic location but opens the sinus to provide a larger common opening for the urethra and vagina (9). It is contraindicated in patients with a high vaginal confluence. The previously elevated perineal flap must be long enough to allow a tension-free anastomosis to the normal-caliber proximal vagina. Redundancy of the flap, however, will create a lip of tissue at the introitus. The exposed ventral aspect of the sinus is opened in the midline, and the incision is carried through the narrowed distal one-third of the vagina into the normal-caliber proximal vagina. It is very important to open into the normal-caliber vagina to prevent later vaginal stenosis. It is also noteworthy that the flap vaginoplasty does not change the vaginal location or confluence but merely exposes the vagina by widely opening the introitus (9). Because the anterior and lateral aspects of the vagina are untouched, stenosis is less common. This is overwhelmingly the most common procedure for urogenital sinus anomalies and has the least risks but does have the drawbacks of the posterior wall of the vagina being skin and often results in a hypospadic urethra.

High Vaginal Confluence

If the vaginal confluence is near the bladder neck, a flap vaginoplasty is contraindicated, as it will result in severe female hypospadias with urine pooling. Deep spatulation of the sinus and posterior vagina may permanently open and injure the sphincteric mechanism. Therefore, a *pull-through vaginoplasty*, which allows a complete separation of the vagina from the sinus, has been recommended (12). The sinus is closed in layers to create a urethra, and the vagina is brought to the perineum. In this technically demanding procedure, the vagina is completely separated from the sinus. The dissection of the anterior wall of the vagina from the urethra and bladder neck is the most difficult part of the procedure, and if not done with care and excellent exposure, it may result in injury to the urethra or sphincteric mechanism. The initial portion of this procedure is identical to the flap vaginoplasty. It is important to expose the entire posterior wall of the vagina by dividing the bulbospongiosus muscle and sweeping the rectum posteriorly. The sinus is opened in the midline until the Fogarty balloon is exposed in the vagina. At this time, we have found it most helpful to rotate the patient to the prone position and elevate the posterior wall of the vagina with a malleable retractor, providing excellent exposure of the anterior wall of the vagina and its confluence with the urethra (13). Stay sutures on the vagina are very helpful. With the vagina separated from the urethra and sinus, the opened sinus is closed in layers over a catheter, allowing the sinus to become the urethra. Unfortunately, “pull-through” is at times a misnomer: Even following complete circumferential vaginal mobilization, the vagina may not reach the perineum. In these situations, the perineal flap will create the distal posterior vaginal wall and the anterior wall has historically been created by preputial or labial flaps. Passerini-Glazel (14) has also incorporated the mobilized sinus with the clitoral skin to create the anterior wall. This later procedure remains popular today. In the very high vagina where exposure is often limited, it may be helpful to split the anterior wall of the rectum as described by Dòmini et al. (15) (ASTRA technique). In extreme situations, bowel interposition may be required to create the distal vagina. A Penrose drain is left in the vagina, and the Foley remains in the urethra.

Labioplasty

Having completed the clitoroplasty and vaginoplasty, only the labial reconstruction remains. The phallic skin is unfurled and divided in the midline longitudinally (similar to Byars flaps), stopping short of the base to allow creation of a clitoral hood (Fig. 104.5A). We secure the split clitoral skin to the preserved preputial skin to create a clitoral hood. It is helpful cosmetically to plicate the clitoral skin in the midline prior to its anastomoses to the inner surface of prepuce (16). These skin flaps are now sutured in place inferiorly along either side of the vagina to create labia minora. The anteriorly displaced labia majora are mobilized posteriorly by making lateral incisions in a Y-V fashion (Fig. 104.5B). The mobilized labia majora are now sutured to the labia minora and to the apex of the perineal flap. This step moves the labia posteriorly to their normal location on either side of the vagina (9).

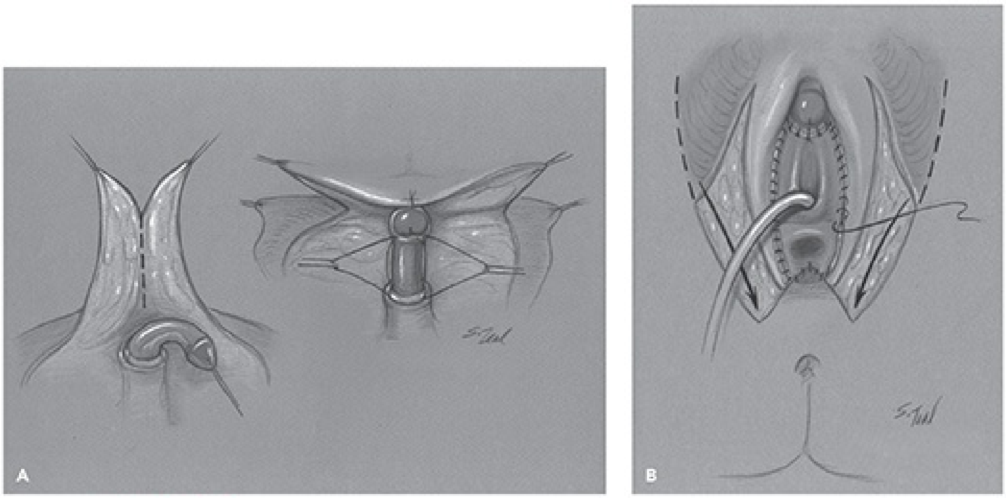

FIGURE 104.5 **A:** The phallic skin is divided in the midline and used to create labia minora. The incision should stop well short of the base to allow creation of a clitoral hood. **B:** Y-V plasty of the labia majora moves the labia inferiorly to place the urethra and vagina between the labia in a more normal location. (From Indiana University School of Medicine, Office of Visual Media, with permission.)

Cloacal Anomalies

Surgical management of children with cloacal anomalies occurs in several important steps, but the formal reconstruction is best performed in a single stage. The rectal pull-through should never be done in isolation without the vaginoplasty. Neonates require early diverting colostomy. Hendren (17) prefers a divided transverse colostomy to leave adequate distal colonic length and leaves the left colic blood supply intact for subsequent rectal pull-through. A long distal colonic segment, however, can allow persistent retention of urine in the mucus fistula and result in refractory hyperchloremic metabolic acidosis. A divided colostomy in the descending colon just after the colon takes off from its retroperitoneal attachment is now recommended by Levitt and Peña (6). Preliminary mapping of the anorectal sphincter complex provides prognostic information for future rectal pull-through.

Decompression of the genitourinary tract is performed during endoscopic investigation of the cloacal anatomy. Inspissated mucus and meconium debris are drained. Because the bladder neck and vagina are often closely related, the vagina passively retains voided urine. If vaginal voiding is a problem, intermittent catheterization of the common channel will allow decompression, with the catheter most likely entering the vagina rather than the bladder. Poor emptying is suspected in children with persistence of hydronephrosis postnatally. Alternatively, if the common channel is narrow and more urethral-like, it can be opened distally to facilitate voiding. If the previously described measures fail, cutaneous vesicostomy or cutaneous vaginostomy will allow free drainage.

Severe anomalies of other organ systems should be corrected early. Other urinary tract abnormalities that may compromise long-term renal function should be addressed. Colonization of the urinary tract is common, but symptomatic infections mandate aggressive therapy. Assuming that all other congenital issues have been satisfactorily addressed, formal repair of the cloaca with the Peña posterior sagittal anorectovaginourethroplasty (PSARVUP) is planned for 6 to 12 months of age (18). This demanding procedure should be completed in a single stage, capitalizing on the virgin tissue planes for both anorectal and urogenital reconstruction.

The initial preparations for repair of the persistent cloaca are similar to those described above for the high-confluence urogenital sinus. After a circumferential lower body preparation and endoscopic placement of Fogarty catheters in the vagina(s) and rectum and a Foley catheter in the bladder, the patient is placed prone on the chest and pelvic rolls. The sphincter complex is stimulated, and the optimal positions for the anus, perineal body, vagina, and urethra are marked. The perineum is incised in the midline from the tip of the coccyx to the posterior margin of the single perineal orifice. The sphincteric muscles are split in the midline and tagged to facilitate subsequent reconstruction. The rectal communication is sharply dissected off the common channel, and the distal colon is mobilized for pull-through. Occasionally, abdominal exploration is required to achieve adequate rectal mobilization. At this time, the entire urogenital system is circumferentially mobilized toward the perineum by the Peña technique of *total urogenital mobilization* (19). Even if this maneuver cannot bring the vagina to the perineum, it does improve exposure to the confluence for completion of a pull-through vaginoplasty. Duplicate vaginas are often encountered and are combined by division of the vertical septum. Vaginal agenesis or atresia requires bowel interposition for vaginoplasty, and again, this is best performed at the time of rectal pull-through and urethroplasty.

Total and Partial Urogenital Mobilization

Total urogenital mobilization (TUM), described by Peña in 1997 (19), entails complete circumferential dissection of the intact urogenital sinus, urethra, and vagina from the pubis (Fig. 104.6A). This was originally proposed for cloacal anomalies but has since been often applied to those with a urogenital sinus only. TUM allows the midlevel vagina to be moved to the perineum easily, thus avoiding a *pull-through* vaginoplasty, and while the high-confluence vagina may still require a *pull-through* vaginoplasty, the separation of the vagina from the urinary tract is much more easily performed.

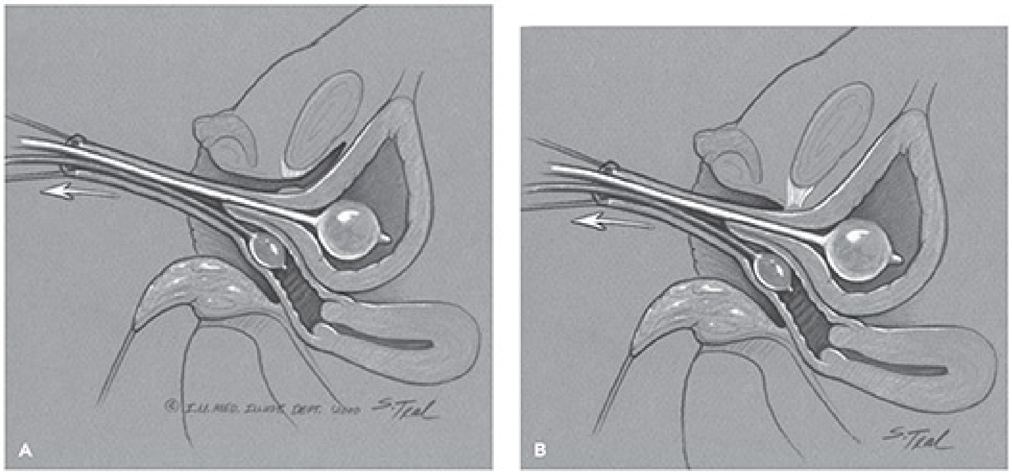

FIGURE 104.6 **A:** Total urogenital mobilization. Complete circumferential mobilization of the intact sinus with the dissection well above the pubis. **B:** Partial urogenital mobilization. The anterior dissection ceases at the pubourethral ligament. *Arrows* indicate direction of tissue mobilization. (From Indiana University School of Medicine, Office of Visual Media, with permission.)

The initial incisions are similar to those described previously, but the urogenital sinus is mobilized intact off the corporal bodies and is carried out between their bifurcation to the pubourethral ligament. At this time, the dissection is continued posteriorly in the midline, separating the rectum from the posterior wall of the vagina. The Fogarty balloon within the vagina is palpated, and an incision is made into the vaginal wall posteriorly near the confluence. If the vagina reaches the perineum, no further dissection is performed and instead partial urogenital mobilization is used (20). In Peña's original description, the mobilized sinus was amputated, but Rink et al. (21) have shown that this is important tissue to save for the reconstruction. If the vagina does not reach the perineum, then the sinus is mobilized between the corporal bifurcation and off the pubis (TUM). When these avascular attachments from the pubis are divided, the sinus moves toward the perineum. If the sinus is near the perineum, we still believe a flap vaginoplasty should be performed to prevent vaginal stenosis. The redundant sinus is then split ventrally to create a mucosa-lined vestibule (Fig. 104.7A and B) (21,22). Recently, we described splitting the sinus laterally to create a posterior vaginal wall (Fig. 104.8) (23). This is also a form of *flap vaginoplasty*, but the posterior flap is native urogenital tissue rather than perineal skin. If the vagina is high following the TUM, then the vagina is separated from the sinus as described previously for a pull-through vaginoplasty. This vaginal separation is again more easily achieved by placing the patient prone over chest rolls. The mobilized sinus is split dorsally, and the opened sinus is rotated to create an anterior vaginal wall (Fig. 104.9).

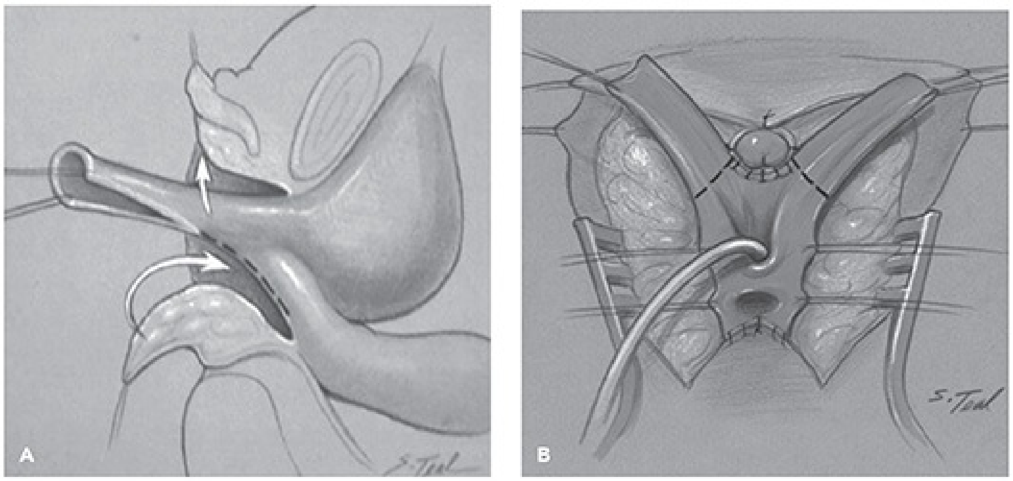

FIGURE 104.7 Low confluence with flap vaginoplasty. A: The mobilized sinus is opened on the ventral side. B: The opened sinus provides a mucosa-lined vestibule. *Arrows* indicate direction of tissue placement. (From Indiana University School of Medicine, Office of Visual Media, with permission.)

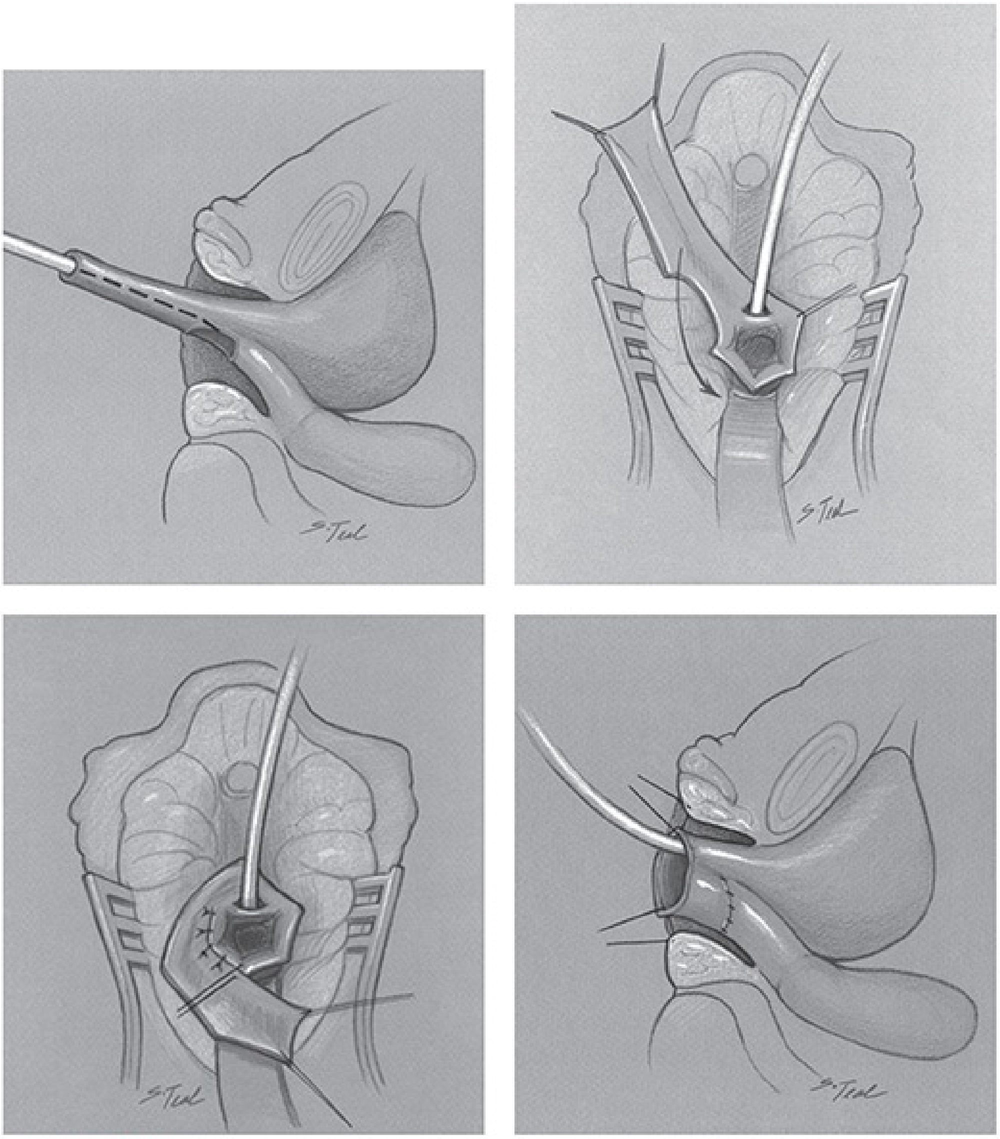

FIGURE 104.8 The mobilized sinus is split laterally to allow rotation of the flap to create a posterior vaginal wall. (From Indiana University School of Medicine, Office of Visual Media, with permission.)

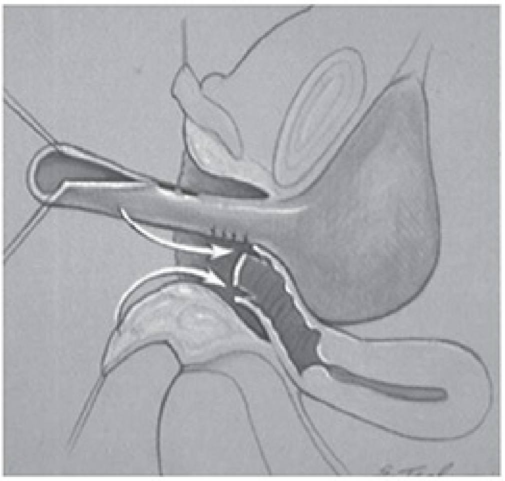

FIGURE 104.9 The sinus is opened dorsally for a pull-through vaginoplasty and rotated to create an anterior vaginal wall. *Arrows* indicate direction of tissue placement. (From Indiana University School of Medicine, Office of Visual Media, with permission.)

Due to concerns for potential sphincteric injury from aggressive retropubic dissection, Rink et al. (20) described *partial urogenital mobilization* (PUM). In the PUM, the dissection anteriorly ceases at the pubourethral ligament (Fig. 104.6B). We believe this procedure is less risky yet still allows use of the mobilized tissue for improved cosmesis and function as described previously for the TUM.

This concern for incontinence or sphincteric injury with TUM has been challenged (24,25). To date, no incontinence has been noted with TUM. In the majority of urogenital sinus anomalies, PUM is adequate to exteriorize the vagina when combined with a flap vaginoplasty.

OUTCOMES

This is a time of widespread evaluation of all aspects of feminizing genitoplasty. There is little agreement on any component, including the timing of the procedure or even the necessity of some aspects, such as clitoroplasty. While virtually all surgeons believe they achieve excellent cosmetic results, blinded studies have questioned this. Unfortunately, there are few data available on long-term results from current surgical techniques. There is debate about both the psychological aspects of having genital surgery and the psychological aspects of not having the surgery and growing up with genital ambiguity. Clitoroplasty is controversial, as no one knows if it is a clinical problem to have an enlarged clitoris, and there remains a concern that even modern techniques may alter sensation. Certainly secondary clitoral surgery has very high risks. Risks of decreased temperature and vibratory sensitivity have been described with concerning frequency (26). Vaginal stenosis following vaginoplasty requiring secondary vaginoplasty has been reported in 30% to 90%. Although we believe current techniques will improve the results, long-term studies are needed. Should the parents make the decision about early surgery, or should it be postponed until the patient can decide? If the latter, then what are the social implications of growing up with ambiguous genitalia? Virtually all agree that the vagina must be exposed to allow egress of menstrual fluid, but when this should be done remains controversial. Surprisingly, there is little evidence that a urogenital sinus effects menstrual flow. We have encountered adult patients without surgery who have no problems with their menstrual flow. Early TUM results are promising, and incontinence does not seem to be a problem in children who are otherwise neuroanatomically normal. The procedure is technically easier. The results now 15 years after the original description of TUM have not shown incontinence to be a problem (24). True long-term results and potential for stress incontinence remain unknown. Early PUM results are similarly promising with no incontinence and excellent cosmetic results. All neurologically normal children older than 2 years who have undergone PUM in our hands are dry and voiding. These issues are complex and will only be solved by long-term prospective multi-institutional studies. We believe that virtually all CAH patients can be treated with a PUM technique, avoiding the more aggressive TUM.

From an anatomic and cosmetic standpoint, surgical reconstruction of cloacal anomalies is now satisfactory in the majority of cases. Unfortunately, the functional success of the urinary and rectal elements of the reconstruction also depends upon sacral nerve function and the quality and innervation of the sphincteric complexes. The bladder neck and intrinsic sphincter may be inherently deficient with a high confluence. No natural plane exists between the bladder neck or trigone and the vagina, and therefore, the continence mechanism may be further compromised as the vagina is dissected off the bladder neck. The external sphincter may also be congenitally deficient or may be injured during reconstruction. Due to abnormal sacral nerve function, these patients may require intermittent catheterization or further reconstruction, such as outlet resistance enhancement or augmentation cystoplasty, to achieve continence (27).

Outcomes of vaginoplasty in cloacal anomalies are as reported with the high-confluence urogenital sinus. TUM appears to reduce the incidence of stenosis and the need for a pull-through procedure, although long-term pubertal follow-up is pending. Introital revision may be required at puberty after vaginoplasty in infancy.

One of the most important issues in functional outcome after repair of a persistent cloaca is the long-term preservation of renal function. Many of these children have congenital renal dysplasia related to vesicoureteral reflux and/or in utero infravesical urinary tract obstruction. Persistent postnatal hydronephrosis should be aggressively addressed with diversion if necessary. Chronic renal failure may occur even in the fortunate subset of patients who achieve a normal nadir creatinine in infancy (28). This is usually due to abnormal lower urinary tract dynamics. Therefore, even after apparently successful lower urinary tract reconstruction, these patients require urodynamic evaluation and vigilant monitoring to prevent upper urinary tract deterioration due to silent bladder dysfunction.

CHAPTER 105 ■ SURGERY TO CORRECT AMBIGUOUS GENITALIA (46XX DISORDER OF SEXUAL DEVELOPMENT)

ANTHONY J. CASALE

Ambiguous genitalia and *intersex* are historical terms used to describe a congenital condition where the appearance of the genitalia is neither classically male nor female. Modern nomenclature has been proposed to replace the old, and this group of disorders is now described as disorders of sexual development (DSD). The condition affects both external genitalia (phallus, labia, scrotum, and introitus) and internal reproductive structures (vagina, urethra, urogenital sinus). In these cases, there is usually a conflict between the genetic sex, gonadal sex, and apparent gender as based on genital appearance. The genital appearance may be gender neutral and give little indication of the genetic or gonadal sex. On the other hand, the genitalia may have an appearance more consistent with the opposite gender, as with females with severely virilized congenital adrenal hyperplasia (CAH). When patients with these conflicts reach adulthood, they face significant hurdles in both reproduction and sexual activity.

The historical goal of surgery for ambiguous genitalia has been to provide the child with genitalia that have the appearance of and are functional as either male or female gender and that are consistent with the genetic and gonadal sex when possible. *Feminizing genitoplasty* is the term used to describe a series of surgical procedures designed to create classic female genitalia from a truly ambiguous genital state. This surgery has usually been applied to female patients with partially masculinized genitalia, and in those cases, surgery brings the genetic, gonadal, and genital sex back into alignment. Rarely, this surgery has been used to reassign the gender of genetic and gonadal male patients with what was felt to be inadequate phallic tissue to the female gender. It is this later group of patients who have had more difficulties with gender dissatisfaction and their experience has brought the principle of gender assignment under question. This chapter will discuss the technical aspects of feminizing genitoplasty.

Society dictates that the appearance of the infant’s genitals and therefore its apparent gender is the subject of great and urgent interest for the immediate and extended family and friends, making ambiguous genitalia a cause of intense concern and confusion for all. It is this powerful interest that has driven physicians and families to treat the condition as an emergency, even though there are often no immediate health risks. The historical approach to this issue has been to assign gender based on several factors, including the potential for reproduction, the technical limits of surgical reconstruction (i.e., our limited ability to create a male phallus without adequate corpora), and the belief that gender was determined by genital appearance and role assignment in childhood. The validity of this approach has recently been questioned and is the subject of widespread study at this time. At present, intrauterine and postpartum androgen exposure of the central nervous system seems to be the dominant factor in determining gender identity. Exactly how to reliably measure the gender of the brain remains an unsolved question.

Genital ambiguity is a result of an abnormality in sexual determination resulting from a defect in genetic, gonadal, or genital tissue differentiation and has been classified historically into four categories: female pseudohermaphrodite (now called 46XX DSD), male pseudohermaphrodite (46XY DSD), mixed gonadal dysgenesis (sex chromosome DSD), and true hermaphrodite (ovotesticular DSD). Female genital reconstruction, also called feminizing genitoplasty, is restricted to female pseudohermaphrodite (46XX DSD), mixed gonadal dysgenesis (sex chromosome DSD), and true hermaphrodite (ovotesticular DSD) individuals who have the potential to have normal female sexual function. CAH is a form of 46XX DSD and is by far the most common condition causing ambiguous genitalia. CAH is responsible for over 70% of cases of ambiguous genitalia and the vast majority of patients treated with feminizing genitoplasty.

Candidates for feminizing genitoplasty have two distinct problems: (a) the fusion of their internal reproductive system with the urinary tract as a urogenital (UG) sinus with a single external orifice and (b) the virilization of the external genitalia, with fused labioscrotal folds and clitoral enlargement. The internal anatomy can cause problems by pooling of urine within the vagina and uterus and inadequate vaginal drainage for secretions and menses. There is no adequate external vaginal orifice for sexual intercourse. Infants with a UG sinus may present with urinary infection or an abdominal mass from a poorly drained vagina or uterus. Today, many present on prenatal ultrasound screening that reveals a dilated bladder, vagina, or upper urinary tract. The external genitalia are a concern primarily for sexual function and the potential psychological damage that may result from gender ambiguity.

There have been great advances in the surgical technique of feminizing genitoplasty over the past half century, resulting in more normal appearance and sexual function. Despite apparently successful surgery, some adult patients have expressed profound dissatisfaction with their childhood genital reconstruction and gender. Because of this concern, more long-term outcome studies that include all patients with these rare conditions must be undertaken in order to understand the most appropriate management of these complex patients. The challenge of these studies is to make them comprehensive in surveying medical, sexual, and psychological health.

The first task for the physician faced with a child with intersex is to correctly diagnose the underlying condition responsible for the appearance of the genitalia. A team including a pediatric urologist, pediatric endocrinologist, neonatologist, and either pediatric psychologist or psychiatrist provides the best approach for this complex process.

The first step in diagnosis is a thorough physical examination. The initial caregivers in the nursery are usually alerted to the possibility of gender ambiguity if the phallus is small or curved and if the labioscrotal folds are partially fused (Fig. 105.1). The pediatric urologist should then document the length and diameter of the phallus and the position and number of external perineal openings, including the position of any potential UG orifices as well as the rectum. The state of fusion of the labioscrotal folds and their location are important, as is the presence or absence of palpable gonads. The presence of a palpable gonad almost always is consistent with male gender. Hyperpigmentation of the labioscrotal skin is common in cases of CAH. The blood pressure should be measured carefully because of the threat of hypertension with CAH.

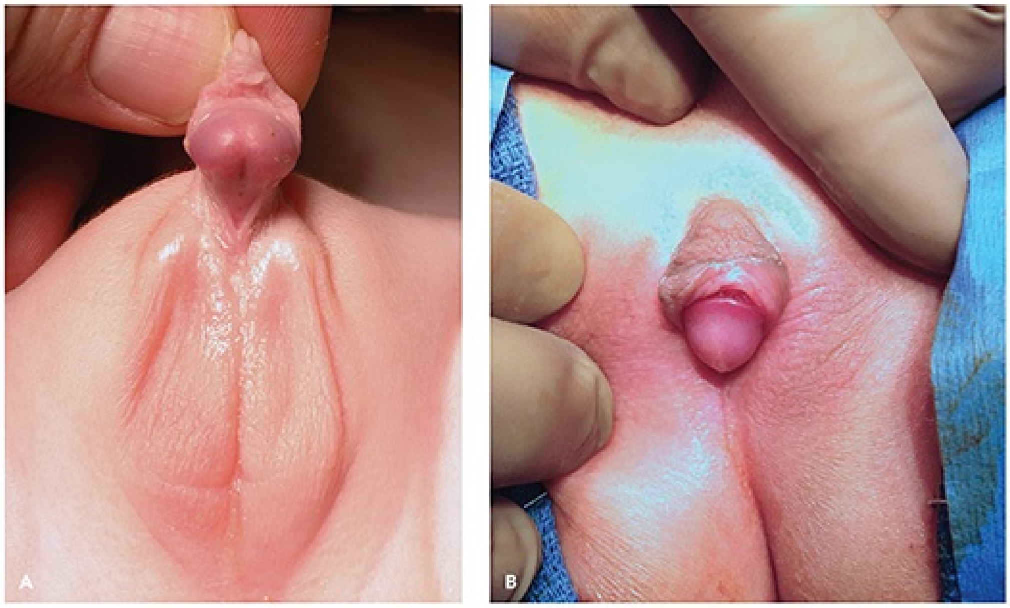

FIGURE 105.1 A and B: These intersex female patients demonstrate labial/scrotal fusion and a hypertrophied phallus with a distal UG sinus opening.

Chromosomal studies should be sent immediately. In the immediate newborn period, the presence of functioning testicular tissue can be determined by measuring serum testosterone, which is elevated in the first few days of life. CAH is diagnosed by finding elevated plasma levels of 17-hydroxyprogesterone and androstenedione and urine levels of pregnanetriol and 17-ketosteroids. CAH can be a life-threatening condition because adrenal insufficiency commonly causes salt wasting leading to hyponatremia and hyperkalemia and could result in lethargy, vomiting, and eventual hypotension.

Imaging studies of the infant should include a pelvic ultrasound looking for the presence of a uterus and retrograde injection of contrast into the UG sinus (genitogram) to identify the presence of a vagina and uterus. The uterus can usually be identified on pelvic ultrasound of the newborn as a 1-cm solid midline mass just posterior to the bladder (Fig. 105.2). The uterus can often be identified on a genitogram with a cervical impression outlined by the contrast in the vagina.

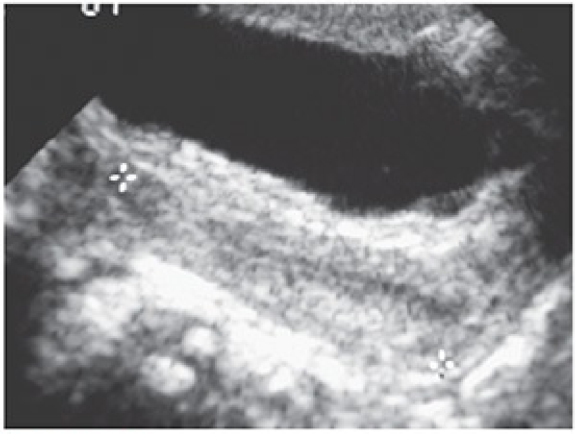

FIGURE 105.2 Pelvic ultrasound demonstrates the uterus in the midline position posterior to the urinary bladder.

During the initial investigation, the family is advised to delay naming the child and reporting the child's gender to others until the gender is established and to state only that the child had some developmental problems that need to be investigated. It is during this period that the gender assignment team should carefully educate and counsel the family about the nature of their child's problem and the limitations and potential inherent in the exact condition. The family should be prepared to face the options of therapy, including reconstructive surgery, so that when the diagnosis is clear, they can make an informed decision. This is a difficult and often painful process for both family and team, and it is critical that every option be explored and discussed with the family and that this counseling is documented in the medical record.

There are actually two decisions to be made by the parents: the gender that they will raise the child and whether to have reconstructive surgery. Gender decisions have always been considered urgent, while surgical reconstruction decisions may be made later as long as there is not a health concern because of inadequate drainage of urine. The medical team must explain the surgical options, including advantages, risks, and potential complications of delaying surgery, performing the external genital reconstruction (clitoroplasty), and performing the internal genital reconstruction (UG sinus repair).

TIMING OF SURGERY

Once the decision for feminizing genitoplasty has been made, the timing of the procedure is of some importance. In cases of CAH, glucocorticoid and mineralocorticoid replacement therapy will diminish androgen production by the adrenal and lead to partial reversal of the clitoral hypertrophy. For this reason, the external genital surgery should be delayed until at least 6 months of age. In some cases, hormone replacement therapy decreases the size of the clitoris so that surgery on this structure is not necessary. Since most complaints about childhood genital surgery involve dissatisfaction with clitoral reconstruction, most surgeons have currently limited this surgery to the most extreme cases of enlargement and with the family’s clear support. Some surgeons have refused to perform clitoral reconstructive surgery altogether. The decision about clitoral reconstruction is the most difficult issue to face in the care of these children and must be considered carefully by the family and medical team.

Some surgeons prefer to delay reconstruction of the internal structures until adolescence if the child does not have problems with urine retention and urinary tract infections because historically, patients who had reconstruction early in life might require a secondary procedure at adolescence to correct vaginal stenosis. On the other hand, those children who have early reconstruction need only dilations or simple revisions of the vagina at adolescence, in contrast to the child who delays the major reconstruction until later in life. We prefer to do a complete reconstruction at 6 months of age and explain to the family that a second minor procedure may be needed later.

PREOPERATIVE EVALUATION

Each child suspected to have ambiguous genitalia should have a complete anatomic, endocrine, and genetic evaluation. A karyotype is necessary not only to determine the correct genetic sex but also to look for other chromosomal errors that may be present. A complete endocrine evaluation should focus on potential gonadal function as well as concerns related to the endocrinopathy of CAH.

A comprehensive definition of the anatomy is imperative in planning for and accomplishing the reconstruction. The upper urinary tract should be imaged with ultrasound and, if the kidneys are not normal, a diuretic (Lasix) renal scan. The lower urinary tract should be imaged with a retrograde genitogram (Fig. 105.3). This is performed by placing a catheter in the most distal portion of the UG sinus and injecting contrast while imaging from the anterior, lateral, and oblique perspectives. This gives the surgeon important information about the length of the UG sinus, the point of confluence of the vagina and urethra, and their relative lengths and position within the pelvis. The level of this confluence, either high (UG sinus over 3 cm) or low (UG sinus <3 cm), ultimately determines the surgical approach. Further imaging of the pelvic organs may be necessary in complex cases and can be done with magnetic resonance imaging or computerized tomographic scanning with good visualization.

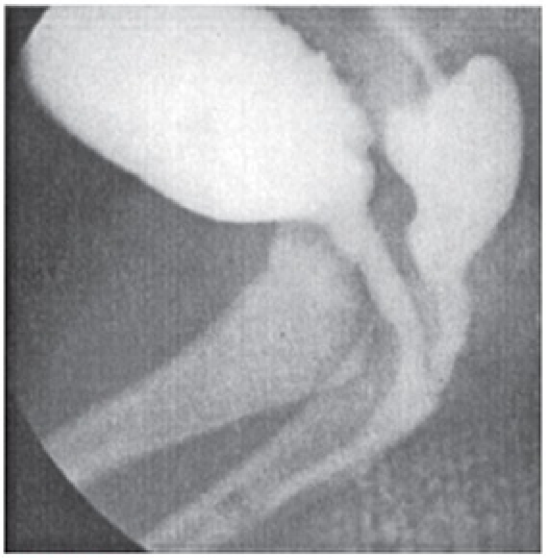

FIGURE 105.3 Genitogram demonstrates confluence of the urethra anteriorly and vagina posteriorly. Note cervical impression at the apex of the vagina and contrast within the cervix.

Finally, an examination under anesthesia is needed, including cystoscopy and vaginoscopy. It is often easier to measure the length of the UG sinus and determine the height of the confluence with the scope than with imaging. The length of the UG sinus can be measured by placing the tip of the scope at the point of confluence and marking the scope at the level of the external meatus. When the scope is withdrawn, the length of the UG sinus is estimated by measuring the distance from the mark on the barrel to the tip of the scope. These measurements of the UG sinus, vagina, and urethra, along with the position of the confluence of all three, are important in order to plan what techniques may be necessary for repair.

SURGICAL POSITIONING

Most of the surgery for ambiguous genitalia can be performed in the lithotomy position. The lithotomy position is ideal for the clitoroplasty and reconstruction of the labia and introitus. The lithotomy position, however, does not always provide adequate exposure of the higher forms of UG sinus. Hendren and Atala (1), Peña (2), and Rink and Adams (3) have demonstrated the superior exposure provided by the posterior prone approach to the pelvic organs. We follow Hendren's recommendations to prepare the patient circumferentially while applying sterile wrapping to the lower legs to allow the patient to be turned from the lithotomy to the prone position as necessary during the operation. It is wise to have all positioning options available for this challenging surgery. Surgery usually begins in the lithotomy position and the clitoroplasty is done first, followed by the vaginoplasty, and finally the labioplasty.

SURGICAL TECHNIQUE

Repair of the External Genitalia

Clitoroplasty

Once the decision has been made to surgically reconstruct the clitoris, the goal of clitoroplasty is to reduce the size of the enlarged clitoris to one that is within the range of normal for females. Modern clitoroplasty developed after Mollard et al. (4) realized that the erectile tissue of the corpora was primarily responsible for the large size of the organ and that it caused problems during sexual engorgement. The glans clitoris must be preserved for sensation, but the corpora should be shortened. Mollard mobilized the neurovascular bundle that supplied the glans and excised the corpora from the level of their union at the pubis to the distal tip. He then sewed the glans back to the stumps of the corpora cavernosa, resulting in a functional clitoris that could become engorged to an appropriate size and was sensate. The dissection of the neurovascular bundle is somewhat difficult and can potentially lead to compromise of the nerves or infarction, so we prefer a variant of the Mollard procedure that was described by Gonzalez and Fernandes (5).

A circumferential incision is made on the clitoris just proximal to the coronal sulcus, and the clitoris is degloved from skin and subcutaneous tissue. The urethral plate and rudimentary corpus spongiosum may be divided distally and dissected with the subcutaneous tissue or just mobilized from the corpora cavernosa while leaving it attached both proximally and distally. We prefer to divide the urethral plate from the glans during this dissection. Incisions are made in the tunica albuginea of the corpora at the 2 and 10 o'clock positions using needle-point electrocautery. These incisions are extended and joined across the ventral aspect of the corpora at the subcoronal level distally and 0.5 cm above the pubis proximally (Fig. 105.4). The dorsal tunica albuginea (including the enclosed neurovascular bundle) is dissected from the erectile tissue and remaining tunica of the corpora. The erectile tissue bodies and their ventral and lateral fascia can be dissected from the dorsal fascia and excised. A 4-0 polyglycolic acid suture can be used to ligate each corporal body at its base. The rim of fascia on the glans can be sewn to the fascia on the stumps of the corpora with 4-0 suture to reseat the glans and stabilize it. The dorsal fascia, which contains the neurovascular bundle, is allowed to fold under the skin cranial to the glans. The urethral plate, which was previously separated from the glans, can now be shortened and partially split in the midline to flatten the introitus and to shorten the distance from the vagina to the clitoris (Fig. 105.5).

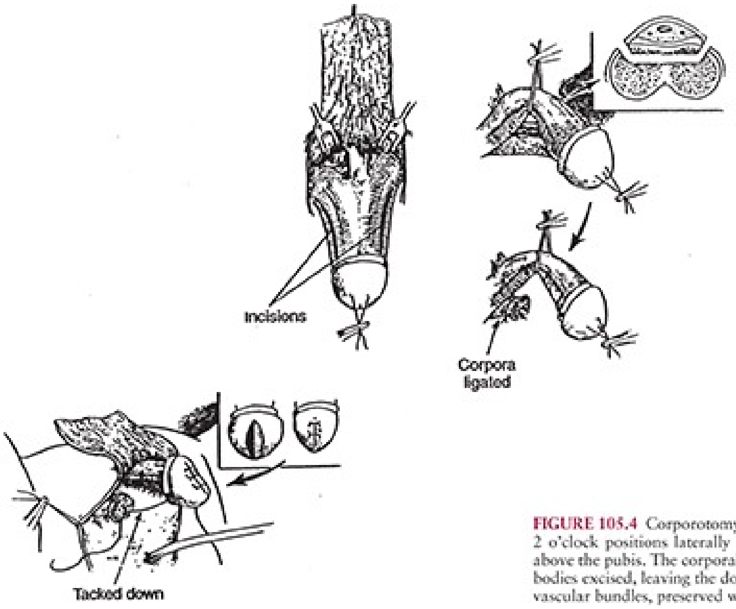

FIGURE 105.4 Corporotomy incisions are extended from the 10 and 2 o'clock positions laterally from just below the corona to 0.5 cm above the pubis. The corporal bodies are ligated at their base and the bodies excised, leaving the dorsal strip of fascia, including the neurovascular bundles, preserved with the glans.

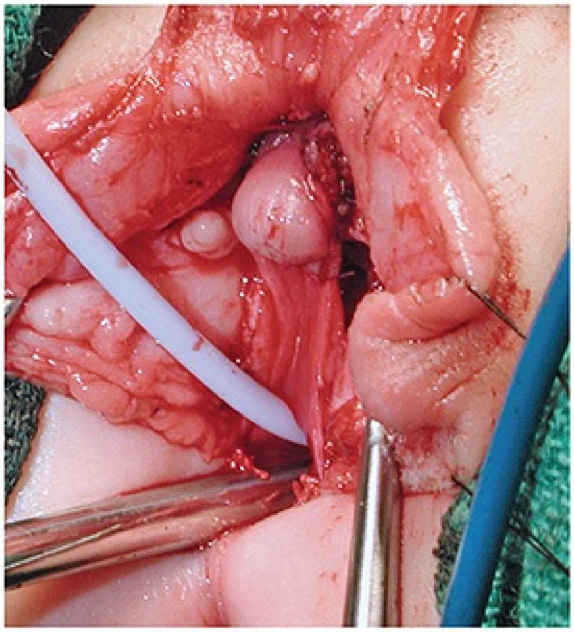

FIGURE 105.5 The urethral plate is used to shorten the distance between the clitoris and the vagina, producing a more normal introitus.

The glans clitoris is often quite large, and several procedures have been described to reduce its size. We have preferred not to decrease the overall size of the glans but instead to conceal some of the dorsal glans with the glans hood. A small patch of the dorsal glans epithelium at the base can be excised, leaving the erectile tissue intact, and the glans hood can be sewn to this area and allowed to fold over the remainder of the glans. This leaves the glans with its full erectile capability, leaves it accessible, and covers it appropriately with a skin hood.

Labioplasty

The goal of labioplasty is to create a normal-appearing and normal-functioning female perineum and introitus. The shaft skin and dorsal prepuce of the clitoris can be utilized to form the labia minora and to fashion a clitoral hood. The original skin incision had degloved the clitoris and left all skin based on the dorsal pedicle. This skin can then be split in the midline for approximately two-thirds of its length (Fig. 105.6). At the proximal end of the incision, a transverse incision is made and curved proximally at each end for a few millimeters to develop a flap that is used for the clitoral hood. The two long sides of the shaft skin are folded to form long, thin, vertical two-sided flaps that will form the labia minora. The horizontal central flap is folded under itself to form a two-sided hood for the clitoris. The clitoral hood is sewn to the base of the dorsal aspect of the clitoris and around each side to the approximate 3 and 9 o’clock positions. Each of the three flaps is sewn into shape using 5-0 absorbable suture.

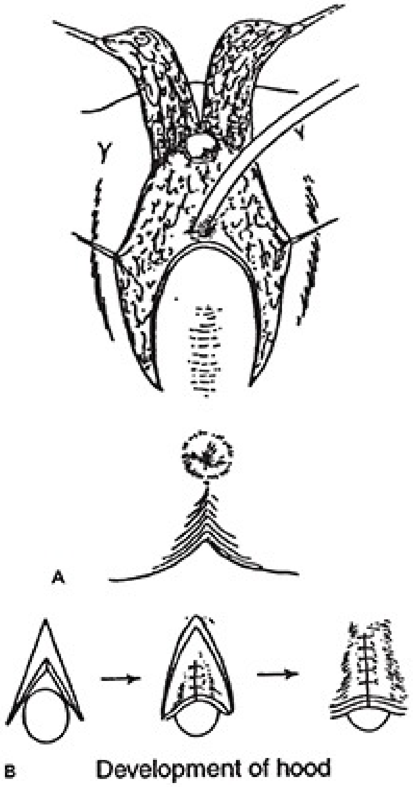

FIGURE 105.6 **A:** The clitoral shaft skin is mobilized and partially split in the midline. **B:** The skin is then folded down toward the vagina. The dorsal aspect of the skin is folded on itself to form a two sided dorsal hood over the clitoris and the ventral skin is sewn together side to side and then sewn to the vagina and labial scrotal skin to form labia minoria.

The labia minora are created with the two lateral strips of shaft skin. They are dissected on their pedicles to allow them to extend to the vagina or midperineum (Fig. 105.7). They are then sewn to the lateral aspect of the urethral plate, which now lies in the midline between vagina and clitoris. A three-way stitch is used to fasten the labia minora to the introitus and to narrow their base so that they maintain their character and their base does not spread and flatten. The labioscrotal folds are then sewn to the labia minora to form the labia majora. All sutures are absorbable 4-0 and 5-0, and while some suture lines can be created using a running 5-0 suture, any point of potential tension, such as at corners, should be fixed with an interrupted 4-0 skin suture.

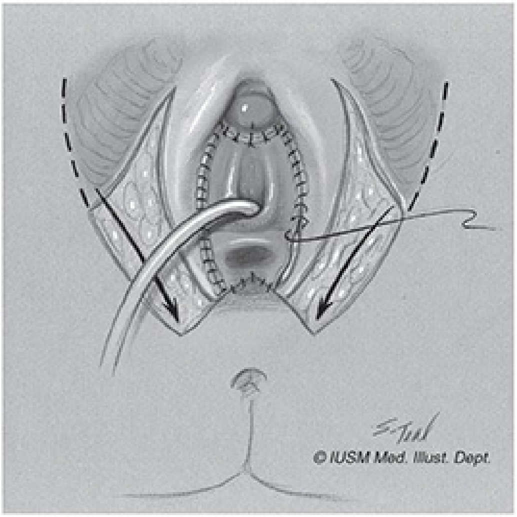

FIGURE 105.7 The dorsal preputial skin flaps are mobilized laterally and advanced toward the vagina (*arrows*). There, they are sewn to the lateral edge of the urethral plate as a labial flap. The labioscrotal folds are then sewn to the lateral edge of the labia minora to form labia majora.

Repair of the Urogenital Sinus

Low-Confluence Urogenital Sinus

The goal of UG sinus reconstruction is to create separate functional openings for the urinary and genital tracts. The low-confluence UG sinus has a long urethra and vagina that join near the perineal surface, resulting in a short common channel or sinus (Fig. 105.8). There are two good options for managing these anomalies. John Lattimer introduced the posterior flap vaginoplasty in 1964, and it is still a useful technique (6).

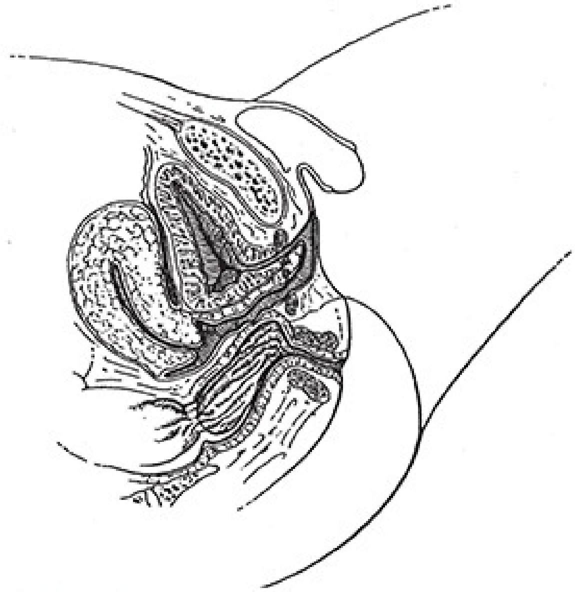

FIGURE 105.8 This illustration demonstrates a low-confluence UG sinus with a short common UG sinus channel draining the urinary bladder and vagina.

A U-shaped incision is made in the perineum with the open end facing caudally and the proximal point at the orifice of the UG sinus. This incision isolates a posteriorly based skin flap (Fig. 105.9). This flap was originally designed to be wide-based but it needs to be no wider than half of the circumference of the proposed vagina (a 1- to 1.5-cm flap in infants). The excellent blood supply of the tissue allows a narrower flap, which results in a more normally functional and cosmetic introitus.

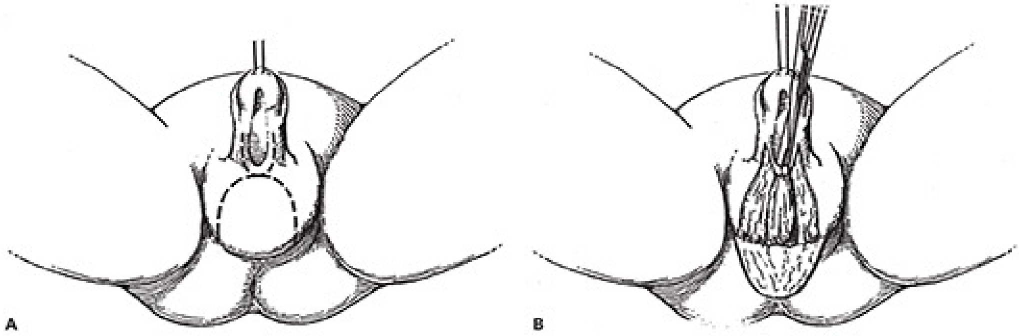

FIGURE 105.9 A: Inverted U incision. B: Posterior-based perineal skin flap used to widen and change the angle of the poster wall of the vagina.

Once the skin flap is isolated, it is mobilized from the deeper tissue and folded back to expose the caudal wall of the UG sinus (Fig. 105.10). A fine-tipped hemostat can be placed in the orifice and the sinus split using electrocautery in the midline to the level that exposes the confluence of the sinus vagina and urethra. The vagina is split as deep as the apex of the posterior skin flap will reach. With a catheter in the urethra, the posterior skin flap is sewn in position starting at the apex and using interrupted absorbable 4-0 sutures. This advancement of the flap into the sinus and vagina both widens the introitus and the vagina and reorients the vagina into a more vertical position, improving passive drainage (Fig. 105.11).

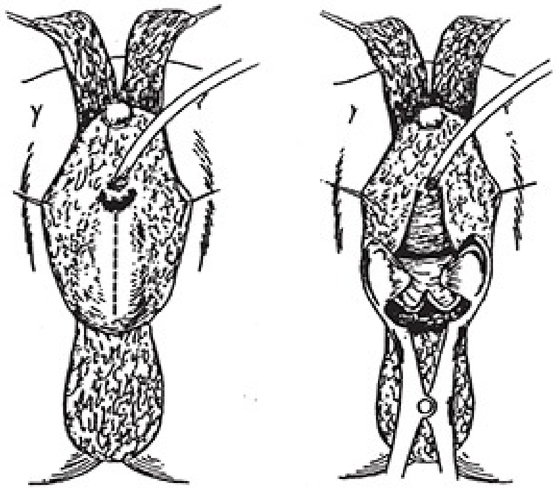

FIGURE 105.10 The caudal portion of the UG sinus is exposed by deflecting the perineal skin flap inferiorly. The sinus can then be mobilized intact or split in the midline ventrally to the level of the vagina in a very low confluence case.

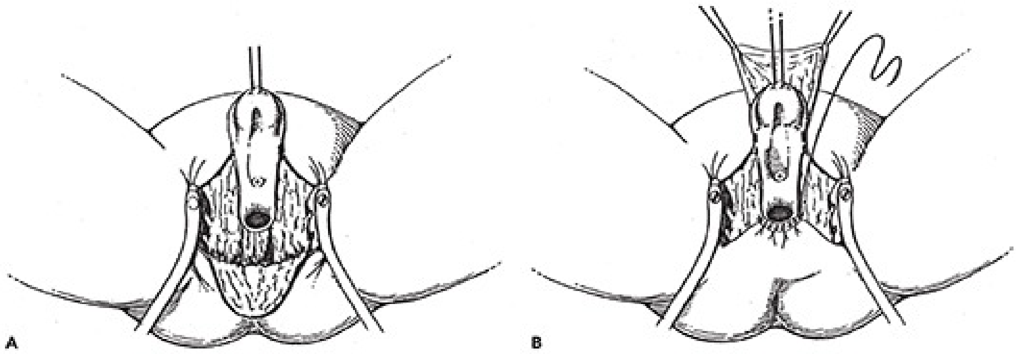

FIGURE 105.11 A: The posterior vaginal wall can be split in the ventral midline. B: The perineal skin flap advanced to form the posterior wall of the vagina tow widen it and make the introitus more vertical.

The other option for the low UG sinus is a limited total urogenital mobilization (TUM) technique as described originally by Peña (2). This is a relatively simple technique and is initiated by a circumferential incision around the UG sinus orifice (Fig. 105.12). This dissection is continued around the sinus while providing constant traction on the sinus with multiple stay sutures. The entire sinus vagina and urethra can then be mobilized caudally, delivering the confluence of the urethra, vagina, and sinus to the level of the perineal skin (Fig. 105.13). Peña (2) originally described this technique for use in cloacal reconstruction and stressed that the dissection must extend high in the pelvis, but this is not always necessary in the low-confluence UG sinus. The dissection can be considered complete when the confluence is at the level of the perineum.

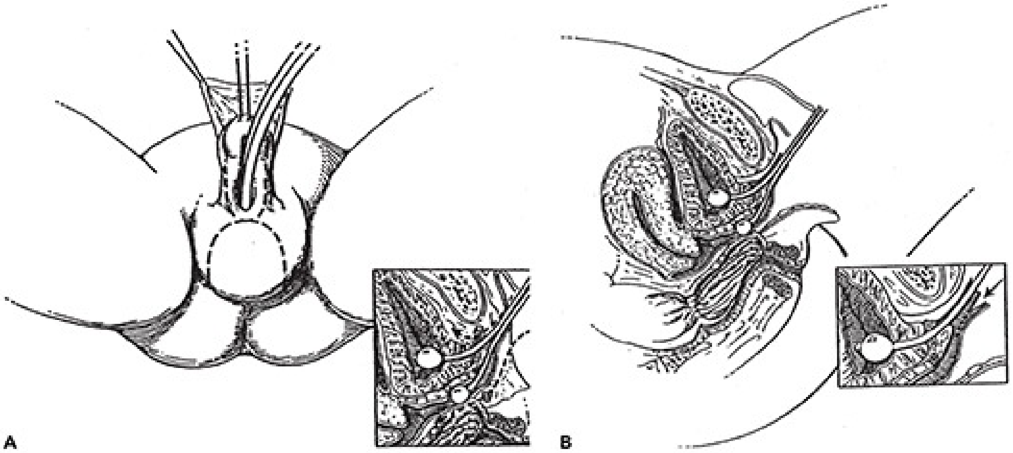

FIGURE 105.12 A: Total urogenital sinus mobilization (TUM) for the UG sinus begins by circumferential dissection around the common channel. With cranial dissection, the entire sinus can be mobilized and delivered to the level of the perineal skin. *Inset*, Fogerty baloon catheters are helpful in guiding dissection. B: If the vagina reaches the perineum easily, the excess sinus can be amputated. *Inset*, if the vagina is narrow, it can be split in the midline posteriorly and the posterior perineal skin flap inserted as part of the posterior vaginal wall.

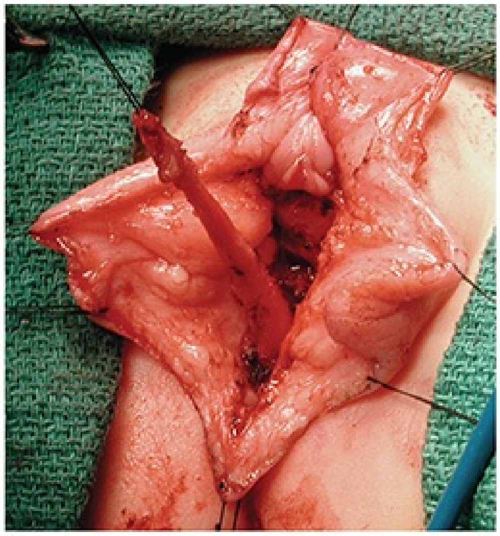

FIGURE 105.13 Total UG sinus mobilization for the high UG sinus requires a more extensive circumferential cranial dissection that takes down all the attachments to the pubic bone.

If the vagina and urethra reach the appropriate level and are wide enough to be functional, then the distal UG sinus can be amputated and discarded (Fig. 105.14). If the vagina is too narrow, the posterior wall of the vagina can be split and a posteriorly based perineal skin flap can be inserted to widen it.

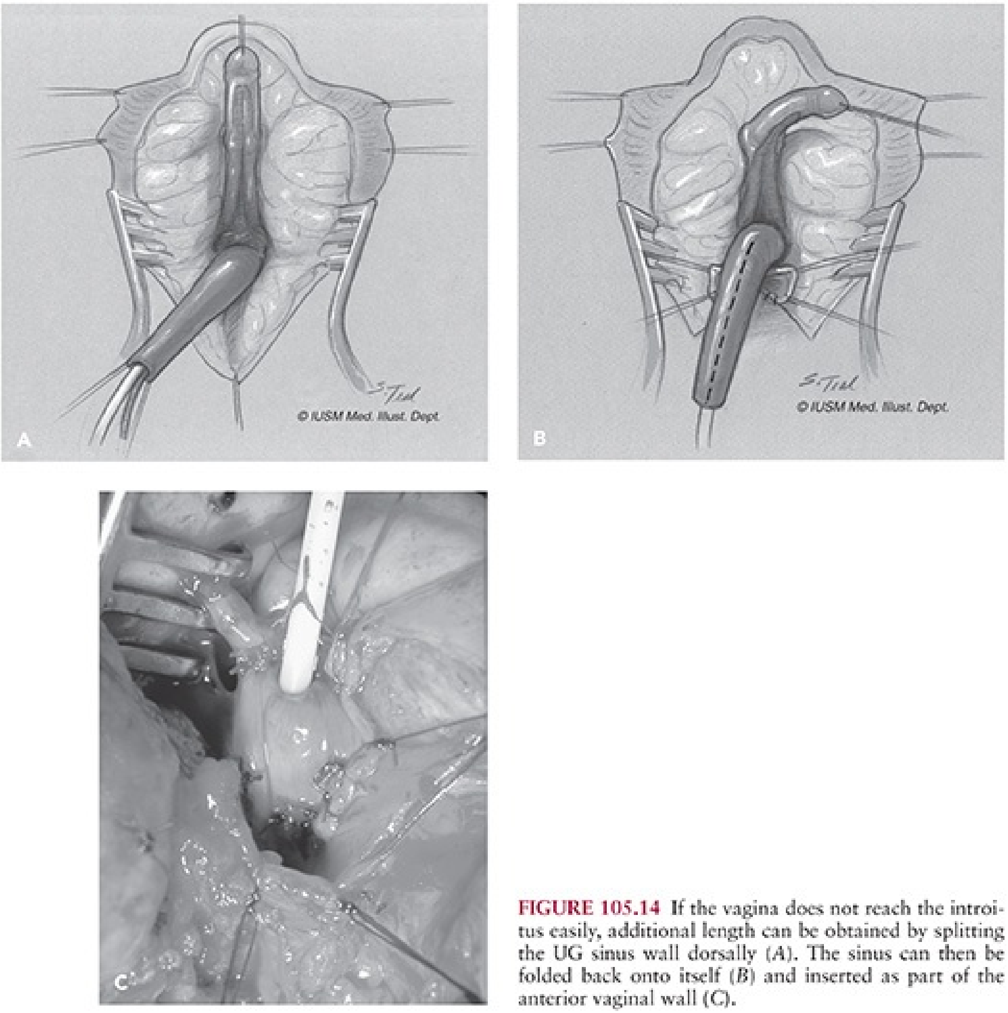

FIGURE 105.14 If the vagina does not reach the introitus easily, additional length can be obtained by splitting the UG sinus wall dorsally (*A*). The sinus can then be folded back onto itself (*B*) and inserted as part of the anterior vaginal wall (*C*).

High-Confluence Urogenital Sinus

The high-confluence UG sinus with a short urethra and vagina and a long common UG sinus channel is much more of a challenge to reconstruct because of the position of the confluence high within the pelvis and the relative lack of suitable tissue for reconstruction. In this condition, the urethra and vagina are short and tethered far from the introitus by soft tissue attachments within the pelvis.

Early attempts to repair these children were made using techniques that were more suitable for low-confluence variants, and this fact may explain many of the poor surgical results now apparent in older patients. The posterior flap repair, which was very useful for less severe cases, did not provide enough length to reach the high confluence and left the child with a short, hypospadiac urethra, and inadequate tissue to reconstruct the vagina to the introitus. Hendren pioneered the dissection separating the bladder and vagina, allowing the vagina to be advanced toward the perineum. This dissection between the urinary and genital tract is very difficult and can result in vesicovaginal fistula and bladder dysfunction. Even with the vagina completely dissected from the posterior bladder, it often would not reach the perineum, and the gap was bridged with complex skin flaps that were sometimes less than ideal.

Peña’s (2) TUM procedure is a perineal-based approach that is based on circumferential dissection of the UG sinus, vagina, and urethra and advancement of these structures toward the perineal surface. This approach leaves the child with a urethra of normal length by lowering the bladder and vagina in the pelvis. The TUM also lowers the proximal vagina and uterus in the pelvis, allowing the vagina to be reconstructed with less outside tissue. The TUM has become an important tool in the reconstruction of children with UG sinus, particularly those with a high confluence (7).

The initial circumferential dissection around the UG sinus is performed just as with the lower confluence variant. Multiple stay sutures are placed and the dissection can be performed in the lithotomy position. Unlike the lower confluence UG sinus, those who have a high confluence need much more extensive dissection to allow the vagina to come close enough to the perineum for satisfactory reconstruction. The dissection usually must reach the level of the pubis both anterior and posterior to the UG sinus.

If the vagina and urethra reach the appropriate level and are wide enough to be functional, then the distal UG sinus can be amputated and discarded (see Fig. 105.14). This is usually not the case, however, and the distal vagina is usually too narrow. In this case, the vagina can be divided from the sinus, dissected away from the urethra and bladder, and split in the midline dorsally. The mobilized sinus can also then be split in the midline dorsally and the sinus can be folded back on itself ventrally and advanced into the vagina as a flap to widen the vagina (8). If the vagina is still too narrow, the posterior vaginal wall can be split as well and a posteriorly based perineal skin flap can be inserted (see Fig. 105.11). The TUM has allowed UG sinus reconstruction and minimized the need to perform the difficult dissection between bladder and vagina.

We prefer to approach the child with high UG sinus as an individual who may need various techniques for successful repair. The options are TUM, mobilization of the vagina from the urethra/bladder, and various flaps to augment the vagina from either the UG sinus tissue or perineal skin. The less severe cases may need only TUM and a posterior skin flap, while the most severe cases need all techniques in order to have a successful outcome.

Dressing and drains are strictly up to the surgeon and the difficulty of the procedure. A simple genitoplasty may need only antibiotic ointment or, at most, overnight catheter drainage. More complex procedures always merit catheter drainage of the bladder, and complex vaginoplasties may be aided with a vaginal Penrose drain or in some cases a pressure dressing of fluffed gauze and elastic tape crisscrossing the perineum. Some surgeons believe in keeping these patients in bed and relatively immobile for 48 hours, but we often allow them to move about at will and to be held by their mother immediately after surgery.

OUTCOMES

Complications

The most common complication of genitoplasty is bleeding, both immediate and delayed. The tissue is very vascular and the use of injected dilute epinephrine during the procedure may be helpful. Late bleeding may originate from the corpora cavernosa or vaginal wall and can usually be controlled with pressure dressing. Pressure dressing must be carefully applied since it is possible to cause vascular compromise of the glans clitoris in the immediate postsurgical period.

The neurovascular pedicle of the glans clitoris can be injured during the original dissection. This potential injury is minimized by leaving the entire dorsal fascia, including the bundles, intact during and after dissection. Infections in the urine or wound are also possible but uncommon. It is not unusual to find a small dehiscence of the wound at the posterior apex of the labial incisions due to tension from movement. These heal without surgical intervention. They can be bathed normally and dressed with antibiotic ointment. The skin stress in this area is the prime reason to close with longer lasting absorbable sutures.

Results

At this time, surgical results are consistently good in terms of appearance and potential for function.

There are, however, few long-term outcome data for feminizing genitoplasty, and the studies that have been done are, by necessity, evaluating the surgical technique that was in fashion 25 years ago. The techniques have improved, and while we can see superior cosmetic and functional results in young children and adolescents treated more recently, we still need to observe and evaluate these patients as they mature (9–11).

The question of gender assignment is one of great importance and intense study at this time. While it is necessary to learn from our patients, we must learn from all of them and not focus on only those who have been dissatisfied with their treatment. We now know that gender identity is much more complex than to be dependent on genital appearance and gender roles. While we must continuously re-evaluate our management of these difficult problems, we should not lose faith in the ability of surgery to create UG structures that can function normally and have an appearance consistent with the classic norm of the human body. Feminizing genitoplasty, like all surgery, has demonstrated that the most difficult question remains the choice of the correct procedure for the proper patient.

CHAPTER 106 CIRCUMCISION, CONCEALED PENIS, AND SCROTAL ABNORMALITIES

IRENE M. MCALEER AND GEORGE W. KAPLAN

Currently, about 1.2 million newborn boys and an unknown number of males beyond the newborn period in the United States are circumcised annually, probably making circumcision the most commonly performed surgical procedure on boys or men (1,2). It is estimated that 58% of hospitalized newborn males in the United States will be circumcised (3). The incidence of circumcision in the United States is highest in whites (88%) and less frequent in African Americans

(73%) and Hispanics (42%) (2). The frequency of newborn circumcision is much lower in other countries, such as Canada (35%) and Australia (10%), and is generally much less than 8% in Europe and most parts of Asia (1).

DIAGNOSIS

No diagnostic studies are needed preoperatively. Comorbidities, such as excessive prematurity, inherited or transient bleeding disorders associated with infancy, and congenital abnormalities of the skin such as epidermolysis bullosa and of the penis such as exstrophy, hypospadias, penoscrotal webbing, concealed penis (megaprepuce), or micropenis, would all mitigate against circumcision, particularly routine newborn circumcision (Fig. 106.1).

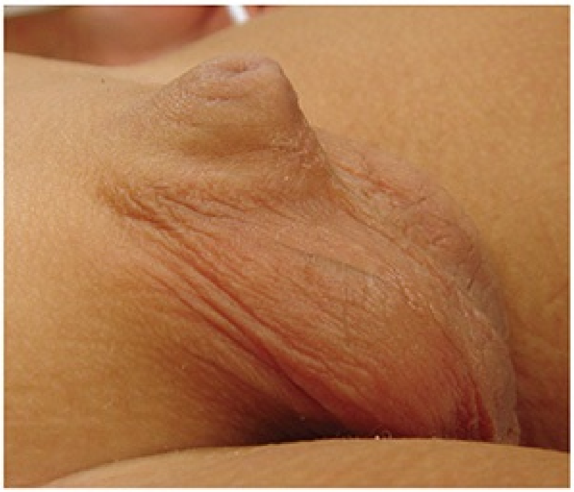

FIGURE 106.1 Webbed penis with paucity of shaft skin.

INDICATIONS FOR SURGERY

Circumcision is often performed in the neonatal period, infancy, or childhood for cultural or religious reasons and is also performed after the newborn period, when phimosis, paraphimosis, balanoposthitis, or sexually transmitted diseases are more prevalent. Medical benefits to the boy circumcised in infancy include reduced urinary infections in infancy (3,4), decreased incidence of sexually transmitted disease (2,5,6), and marked reduction in the incidence of penile carcinoma (7), but these benefits must also be weighed against the risks of the procedure: bleeding, infection, and poor outcome (8).

The American Academy of Pediatrics (AAP) in 1999 (9) concluded that there were benefits from neonatal circumcision, but the benefits gained did not warrant universal routine circumcision. Conversely, there are some opponents who feel that neonatal circumcision is never warranted (10). The AAP updated their review and recommendations concerning male circumcision in 2012. After an extensive 5-year review, the task force concluded that circumcision is a well-tolerated procedure with infrequent complications when performed by trained professionals under sterile conditions using appropriate pain management. Further, they found that the benefits of circumcision for preventive health outweighed risks associated with the procedure (11).

There is now fair evidence from studies in Africa that circumcision is protective against heterosexually acquired HIV infections in men. The average efficacy of reducing the risk of acquiring HIV in these studies was about 60% (3). The inner preputial skin in the uncircumcised man has more Langerhans cells than does the glans, outer preputial skin, or penile shaft skin. Langerhans cells have densely concentrated CD4 receptors used by HIV to bind to these receptors and enter the body. The retraction and telescoping of the inner preputial skin during intercourse facilitates HIV entry into the body (2,6). Male circumcision is also protective against syphilis, chancroid, and human papilloma virus (HPV) infections with a 30% to 40% reduction in risk of HPV infection in circumcised men compared to uncircumcised men (3).

Because circumcision is so common, there are a number of misguided ideas and practices that have evolved in American medical practice leading to some circumcisions being done for reasons that are not completely medically sound. At birth, the prepuce, in over 90% of infants, is fused to the glans and is not retractable. As studied by Gairdner in 1949 (12), the foreskin progressively retracts on its own with age, so that many preschool boys will have nonretractable foreskins that will spontaneously become retractable at some time before puberty. Oster et al. (13) found that only 1% of 17-year-olds will not have retractable foreskins. It is not necessary for parents or physicians to retract the prepuce as retractability occurs with penile growth, erection, and smegma formation; the smegma that forms will generally spontaneously be discharged from under the prepuce and does not need to be removed. Balanoposthitis is not a mandatory indication for circumcision in children as the prepuce in that area of the penis after such an episode will generally be separated from the glans and, once separated, should not produce recurrences of balanoposthitis. Occasional episodes of balanoposthitis should not be confused with the pathologic condition of balanitis xerotica obliterans (BXO). Forcible retraction of the prepuce causes the child pain and can produce paraphimosis or a dense cicatrix and perhaps subsequent BXO (Fig. 106.2).

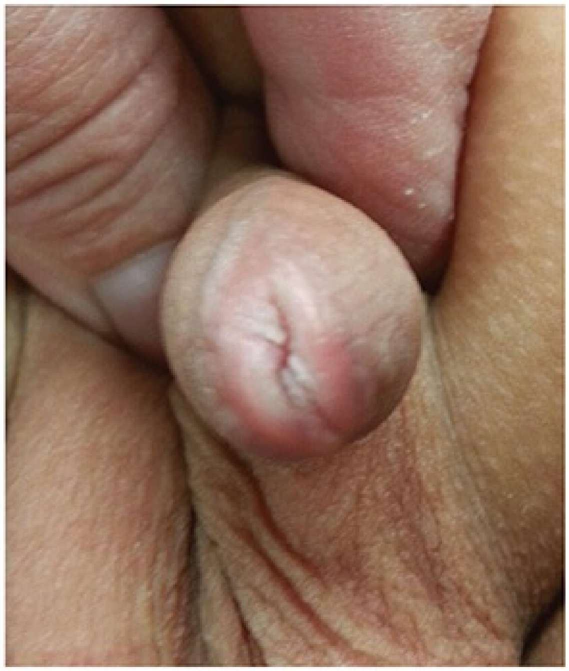

FIGURE 106.2 Photo of pathologic phimosis due to BXO.

Phimosis becomes pathologic when the opening of the foreskin develops a tight cicatrix often caused by BXO. According to Shankar and Rickwood (14), BXO represents the one absolute indication for circumcision. BXO is a chronic dermatologic condition of the prepuce and glans, analogous to lichen sclerosus et atrophicus, that can also involve the meatus and the anterior urethra, especially if the glans is extensively involved (15).

Most of the series of BXO in children have found that most of the patients affected are older boys, whose ages range from 5 to 15 years old (14–17). Previously, it was thought that the incidence of BXO was relatively rare in boys (range from 0.6% to 6%) (14,17), but recent reviews have shown that the BXO occurs more frequently in boys than previously reported. One recent study found BXO in a child who was only 2.5 years old, significantly younger than most reported cases (17). Circumcision alone is thought to be curative of BXO in 96% of cases, but it is concerning that in more obese boys, especially those with prominent pubic fat, more severe disease is prevalent and recurrent (17).

ALTERNATIVE THERAPY

Observation, intermittent medical treatment for balanoposthitis, and dorsal slit are common alternatives to circumcision. Recently, the use of topical steroid creams, typically 0.1% triamcinolone or 0.05% betamethasone cream (18–20), applied to the preputial opening for about 4 to 8 weeks has successfully treated phimosis and obviates the need for circumcision in 85% to 87% of boys reported to be using the steroid preparations.

Paraphimosis occurs when the prepuce with a tight preputial orifice becomes trapped behind the glans penis when retracted with resultant swelling of the glans that prevents its reduction. If untreated, paraphimosis can lead to infection, significant penile edema, pain, and, occasionally, loss of penile tissue. The edema can often be reduced by injecting hyaluronidase into the edematous tissue, thereby allowing for easier reduction of the paraphimosis. Alternatively, multiple punctures of the edematous prepuce with a hypodermic needle (after a penile block or analgesia is given) can relieve the edema, especially if manual pressure is applied after the punctures are made (21). Many health care providers are hesitant to inject anything or make multiple punctures into a swollen and painful penis, so another easy and effective treatment to reduce the paraphimotic edema is to place granulated sugar over the swollen penile tissue, producing an osmotic gradient that pulls the fluid out of the edematous prepuce (Fig. 106.3). Application of ice or application of a temporary pressure dressing can also be used to reduce swelling. Paraphimosis is then reduced by grasping the penis between the second and third fingers of both hands and pulling the shaft skin distally while simultaneously applying pressure to the glans with both thumbs. If this maneuver is unsuccessful, a dorsal slit is necessary to open the phimotic constriction ring. Circumcision can be performed after the inflammation and edema have resolved but should not be attempted at the time that the acute paraphimosis is present.

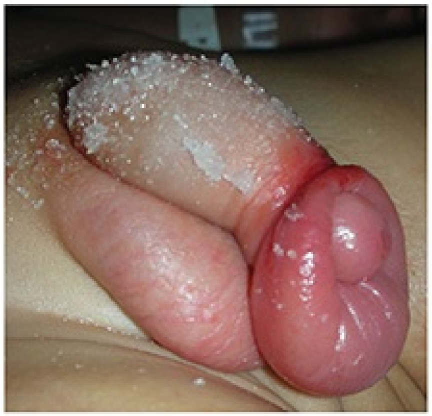

FIGURE 106.3 Photo of paraphimosis with topical granulated sugar.

Another alternative to a circumcision for pathologic phimosis is to perform a preputioplasty as either a triple incision procedure or a Y-V plasty on the dorsal surface of the prepuce. The triple incision involves three longitudinal incisions across the stenotic preputial ring down to the inner preputial layer with subsequent transverse closure of the three skin defects using absorbable suture which allows enlargement of the phimotic ring. The Y-V plasty can be performed by retracting the preputial skin to the corona (taking down the glanular adhesions to the prepuce), marking a “Y” incision from the inner preputial skin on the dorsum, incising the inner preputial skin on the marked “Y,” and advancing and closing the inner skin as a “V” using absorbable sutures to enlarge the phimotic ring. Both of these methods allow the patient to remain uncircumcised, if this is preferred, but both methods may form scar bands requiring an eventual formal circumcision (21).

SURGICAL TECHNIQUE

The goal of a circumcision is to remove an adequate amount of the prepuce such that the glans is exposed and balanoposthitis, phimosis, BXO, and paraphimosis are prevented. Too much or too little skin should not be removed, as the former can tether the penis and on occasion produce chordee, while the latter may produce continued risks of phimosis or paraphimosis.

All circumcisions should take place with an anesthetic: During the newborn period, local anesthesia with 1% lidocaine is generally used with or without topical anesthesia (EMLA 2.5% to 2.5% lidocaine–prilocaine). EMLA should be used cautiously in newborns, especially premature infants, as methemoglobinemia can occur. Other potential side effects from EMLA use include erythema, edema, or blister formation, and are more common in low birth weight infants who should probably have penile nerve blocks used instead (3). In older children and adolescents, general anesthesia is usually used. In adults and some adolescents, local anesthesia will often suffice. The penis is cleaned and draped and the foreskin retracted by taking down all the adhesions between the glans and the inner preputial skin. If a dense phimotic band prevents preputial retraction, a dorsal slit may be performed by placing one blade of a straight clamp inside the preputial opening in the dorsal midline (ensuring that the blade is not within the urethral meatus itself) and then placing the other blade on the outer skin. The clamp is closed and left in place for a few minutes, crushing the tissue and producing temporary hemostasis; the crushed area is then incised with scissors. Stretching the preputial opening gently with the hemostat clamp makes visualizing the urethral meatus easier and the dorsal slit may then be safely performed. Marking the coronal ridge (as seen through the shaft skin) in ink helps identify where to place the circumferential incision about the shaft skin. In the adult or older child, the proposed line of incision in the inner preputial sac is marked with ink about 3 to 4 mm below the coronal sulcus.

A common method of excising the prepuce, called a “sleeve technique,” is performed by incising the two previously marked lines of incision circumferentially about the penis and dividing the tissue between the layers. Hemostasis is secured generally with judicious use of either bipolar or monopolar cautery, although vessels can also be individually ligated. The skin and the inner preputial epithelium are then coapted with fine absorbable sutures (Fig. 106.4).

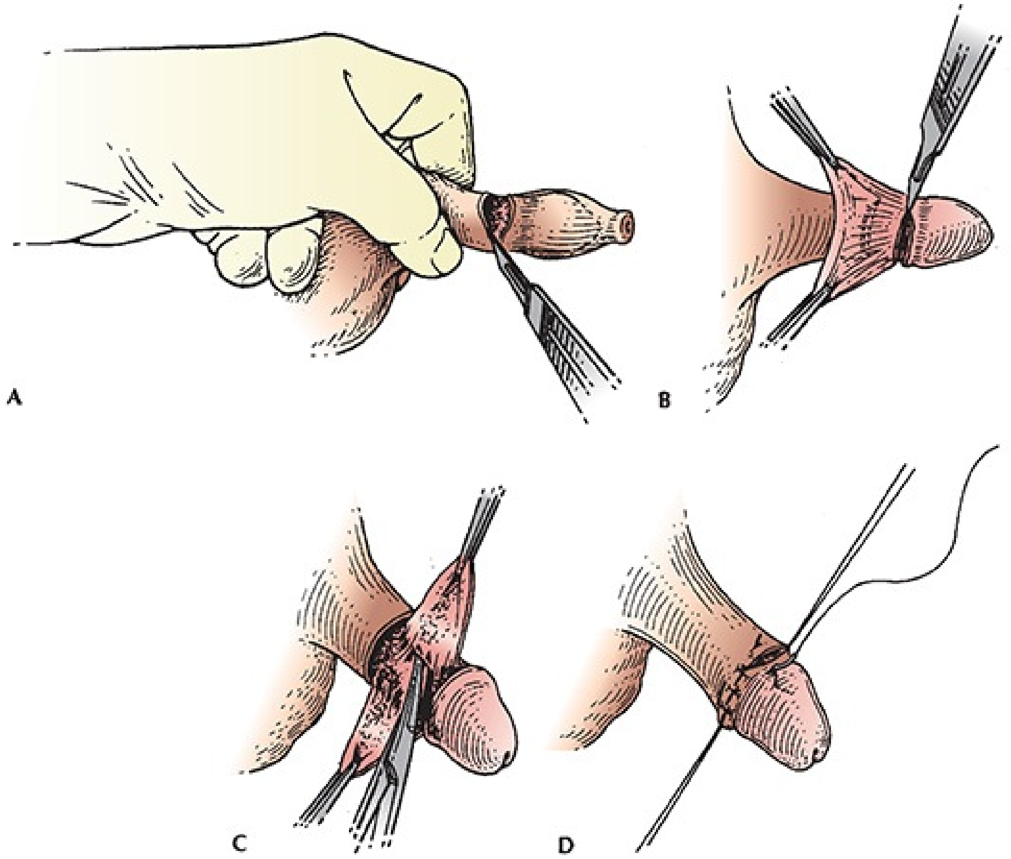

FIGURE 106.4 A: An incision is made on the shaft. B: A second incision is made below the coronal sulcus. C: Removing the excessive preputial skin. D: The wound edges are coapted and sutured together.

Alternatively, another circumcision method involves putting the prepuce on stretch after applying a hemostat to the dorsal and ventral aspects of the preputial orifice. The area of the shaft skin previously marked as overlying the coronal ridge is pulled forward beyond the tip of the glans and a straight clamp is applied, taking care to ensure that the glans is not included in the clamp. The prepuce distal to the clamp is amputated with a knife, the clamp is removed, hemostasis is secured, and the skin edges are coapted. It is especially important in this method to take down all preputial adhesions first or excess inner preputial skin may be left behind that may cause a tightening of the excess skin on the penile shaft, similar to paraphimosis in an uncircumcised male.

With the advent of synthetic tissue adhesives such as Dermabond (2-octyl cyanoacrylate, Ethicon), circumcisions can be performed quickly and safely with good cosmetic results in most children with minimal surgical time, few if any sutures required, and minimal tissue handling, thereby decreasing postsurgical swelling and possibly postsurgical pain (22) (Fig. 106.5).

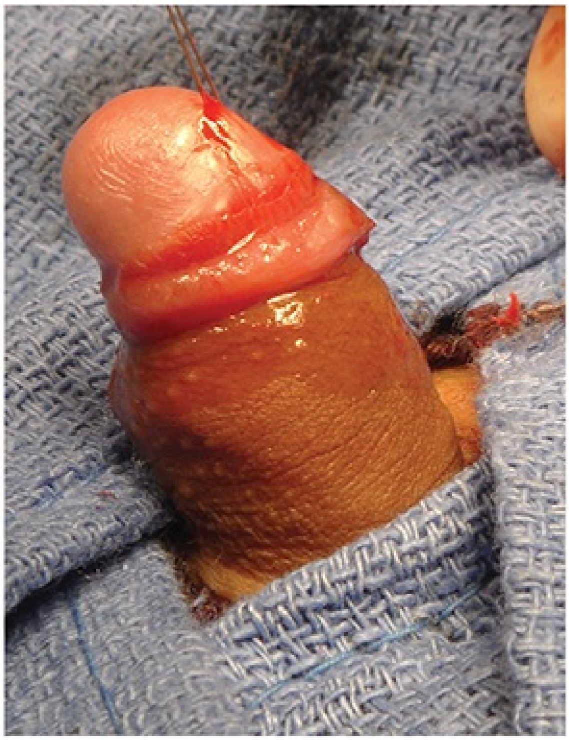

FIGURE 106.5 Photo of circumcision using 2-octyl-cyanoacrylate (Dermabond).

Neonatal Circumcision

In newborns, circumcisions performed without anesthesia previously were common. However, local anesthesia using an agent such as lidocaine or bupivacaine as a dorsal penile block or, more importantly, a ring block at the base of the penis can alleviate most of the pain experienced by the newborn at the time of the circumcision. The anesthetic dose must be adjusted for the weight of the patient.

In newborns, circumcision is in general accomplished using some type of device. The common devices in use in the United States are the Gomco clamp, the Plastibell, and the Mogen clamp. The methodology for the Gomco clamp and Plastibell is similar. After local anesthesia has been provided and the skin cleansed, the area of the coronal ridge is marked as previously described, followed by a dorsal slit being performed. Marking the outer shaft skin at the coronal ridge helps ensure that too much shaft skin is not removed during the circumcision. The Gomco device has three parts—a bell of variable size that fits over the glans, a plate, and a screw that completes the assembly. After the dorsal slit is performed and all the adhesions are released, the bell is then placed over the glans; a safety pin placed through the distal corners of the previously incised prepuce that keeps the edges aligned may be helpful. Then, the plate is placed over the glans, the shaft skin is pulled up until the marked area can be seen emerging from the hole in the plate, and then the screw is placed and tightened. The device is left in situ for several minutes and the prepuce distal to the plate is then excised with a knife. Electrocautery must never be applied to the Gomco device, as this has resulted in total necrosis of the penis. The device is then removed, reversing the order in which it was applied. By loosening the screw, the plate can be disengaged from the bell and removed. The cut skin edges of the penis are then gently teased over the edge of the bell to ultimately remove the bell and complete the circumcision; rarely are sutures needed for hemostasis for this type of clamp circumcision (Fig. 106.6).

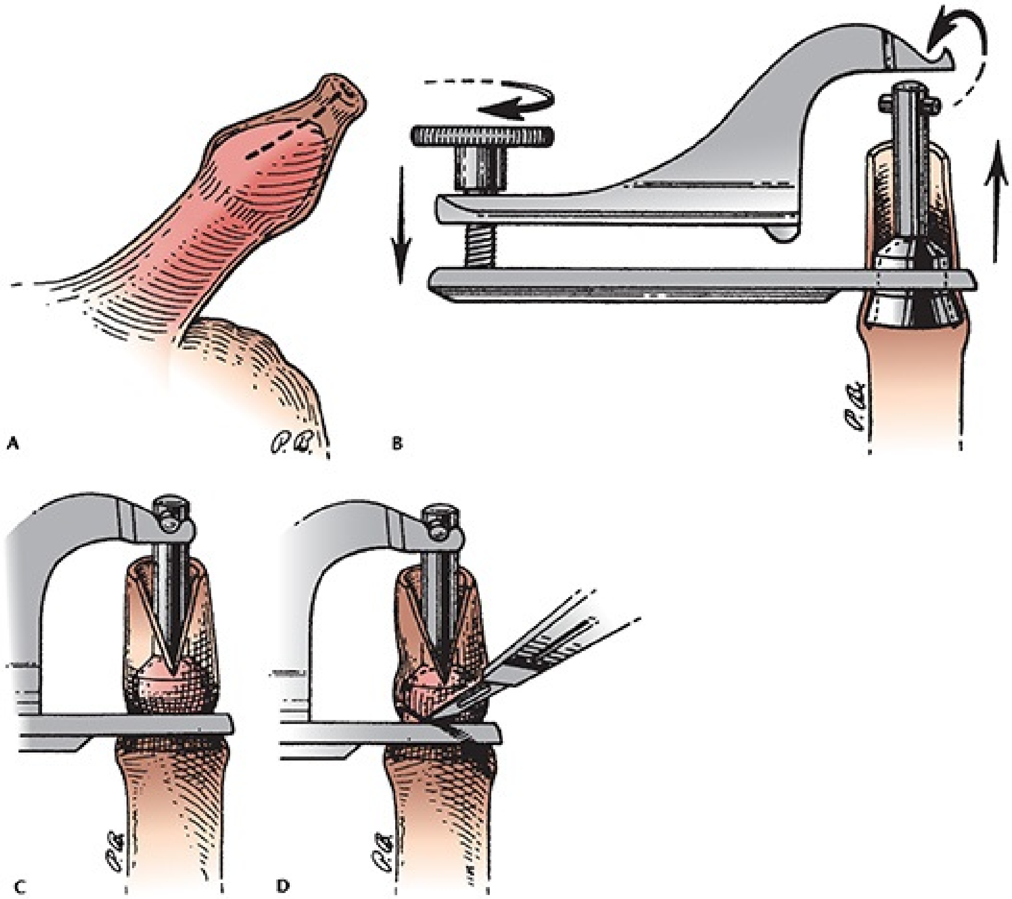

FIGURE 106.6 Gomco circumcision. A: Line of incision for dorsal slit. B and C: Application of the device. D: Excision of the prepuce.

The Plastibell follows the same principles as the Gomco device. After the bell is applied, a heavy string is tied over a groove at the base of the bell at the level of the previously marked area on the shaft. The distal prepuce is then excised. The stem distal to the bell is snapped off, leaving a plastic ring under the inner preputial epithelium. In roughly 1 week, the skin distal to the ligature sloughs and the ring comes off spontaneously (Fig. 106.7).

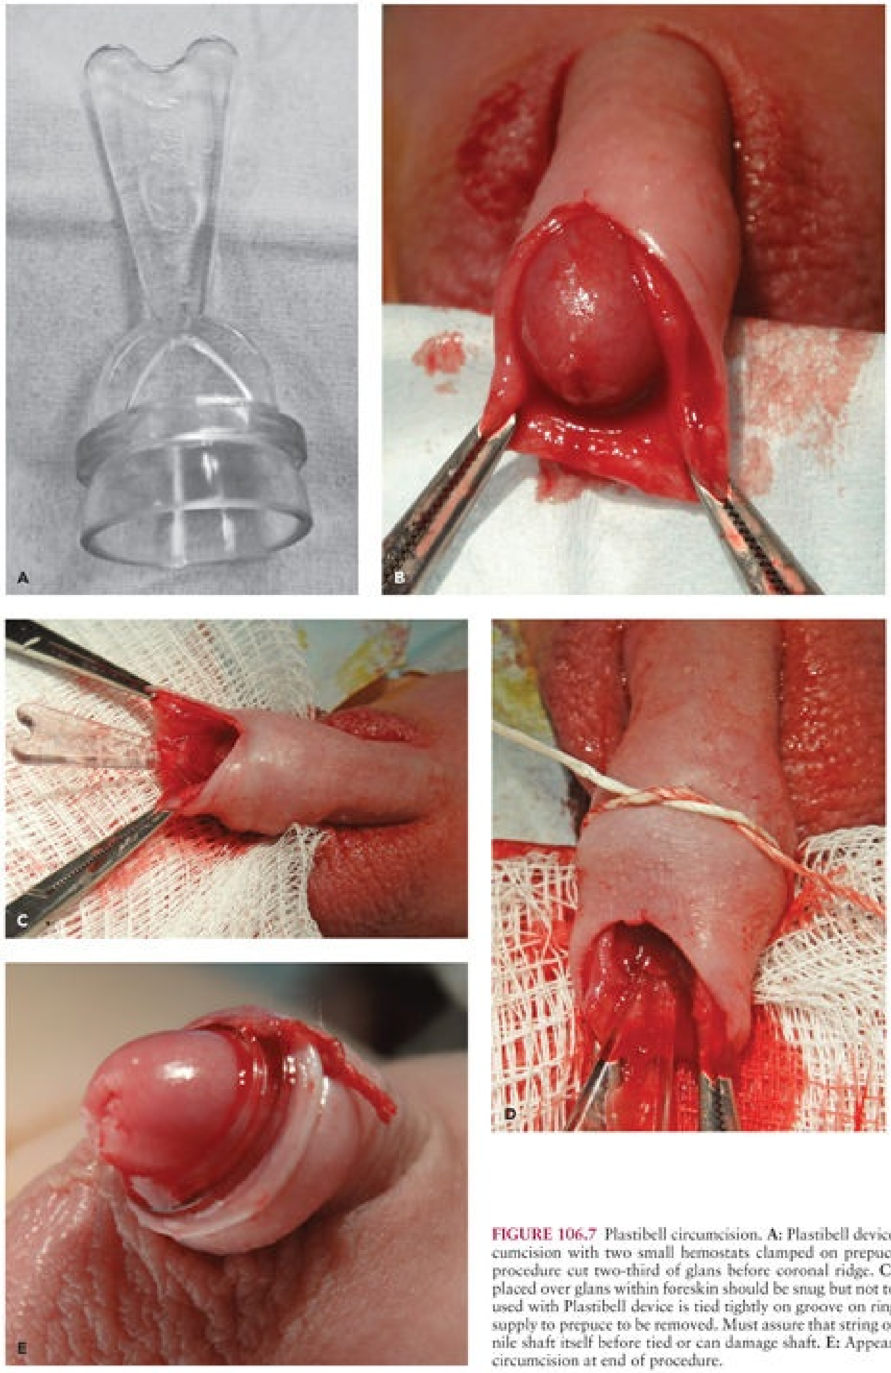

FIGURE 106.7 Plastibell circumcision. A: Plastibell device. B: Plastibell circumcision with two small hemostats clamped on prepuce after dorsal slit procedure cut two-third of glans before coronal ridge. C: Plastibell device placed over glans within foreskin should be snug but not too tight. D: String used with Plastibell device is tied tightly on groove on ring to cut off blood supply to prepuce to be removed. Must assure that string on ring and not penile shaft itself before tied or can damage shaft. E: Appearance of Plastibell circumcision at end of procedure.

The Mogen clamp is a clothespin-like device, and the methodology of its application is akin to the older open surgical method described previously. After the skin is cleansed and the area of the coronal ridge as seen through the shaft skin is marked with ink, the adhesions between the glans and the inner prepuce should then be lysed with a blunt probe. It is usually not necessary to perform a dorsal slit when using the Mogen clamp. The prepuce is pulled distally and the clamp applied, taking care to ensure that the glans is not included in the clamp. The clamp is closed and left in situ for a few moments. The prepuce distal to the clamp is excised and the clamp is removed. This type of clamp device is the easiest to use by those first performing neonatal clamp circumcisions, but it is the one most likely to have associated complications, typically partial or complete amputation of the glans if the glans is inadvertently enclosed in the clamp and cut when the tissue in the clamp is incised (23) (Fig. 106.8).

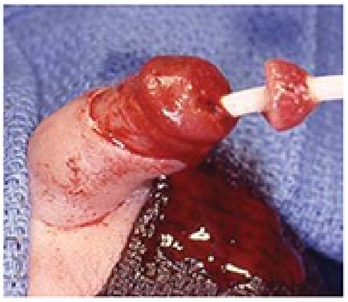

FIGURE 106.8 Traumatic amputation of portion of glans from Mogen clamp circumcision.

TIMING OF GENITAL SURGERY

Timing of the surgical repair of urogenital anomalies with a general or local anesthetic is important with regard to feasibility of the surgery, safety of the surgery to the patient, and the psychological impact of the anomaly and surgery. Penile surgery and repair of concealed penis or scrotal conditions can be scheduled at a time that is appropriate for the infant and convenient for parents and physicians, as these conditions or anomalies do not generally cause any functional detriment to the patient, with the exception of megaprepuce that may cause infections or voiding difficulties if not corrected. Technically, from the surgeon’s point of view, outpatient surgical correction with a general anesthetic may contemplated as early as the child’s fourth to sixth month, age adjusted for prematurity. Neonatal circumcision done with a local anesthetic may be performed in an office or nursery setting once the patient is clinically healthy, feeding well, and not known to have any bleeding or other problems that would preclude a circumcision in infancy.

Psychological aspects of surgery create a relative upper age time limit (24). The child’s anxiety concerning hospitalization, gender identity, separation from their parents and guardians, and subsequent sexual development generally increase with age as the child passes the age of 1 year. If genital surgery is performed before the child is 18 months of age, the patient will generally not remember the surgery nor associate the experience with any abnormality of his penis or scrotum. Therefore, optimal surgical timing for these patients is from generally best between 6 and 18 months. Parents need to determine what time during this window is best for their child and them. Most of these surgical repairs can usually be performed on an outpatient basis. Rarely will an overnight hospitalization be required. It is also easier for parents to care postoperatively for a boy who is younger and probably not ambulatory.

OUTCOMES

Complications

Occasionally, complications do occur, but most are minor and rarely portend a bad result. Bleeding is the most frequent complication and occurs in approximately 0.1% of cases. Most episodes of bleeding are minor and respond to pressure alone. Some require cautery or suture for control, particularly in the area of the frenulum. Most infections are minor and superficial, manifested by redness and occasionally purulence at the circumcision site that usually responds to local wound care. A common complication of neonatal circumcision is meatal stenosis, probably produced by a chemical meatitis from ammoniacal urine exposure on the tip of the penis while the patient is still wearing diapers. Serious complications, fortunately, are rare but include recurrent phimosis, wound separation, major tissue loss, concealed penis, skin bridges between the shaft and the glans, inclusion cysts, urethrocutaneous fistula, and loss of some of the glans or all of the penis as an extremely rare occurrence.

Necrotizing fasciitis, also termed as *Fournier syndrome* or *gangrene*, has occurred in infants and young children after circumcision as well as after other injuries and secondary infections to the perineum (25,26). Several cases of necrotizing fasciitis after newborn circumcision have been reported with at least two of the patients' having a circumcision using a Plastibell device (25). It is imperative that infants who develop edema and erythema of the scrotum and lower abdomen be evaluated and treated aggressively surgically and medically to prevent more serious sequelae of the process. The patient may or may not have a fever on initial presentation. Infection after newborn circumcision is not very common, but it is more common where a Plastibell device is used as compared to the other clamp devices that are used (Fig. 106.9).

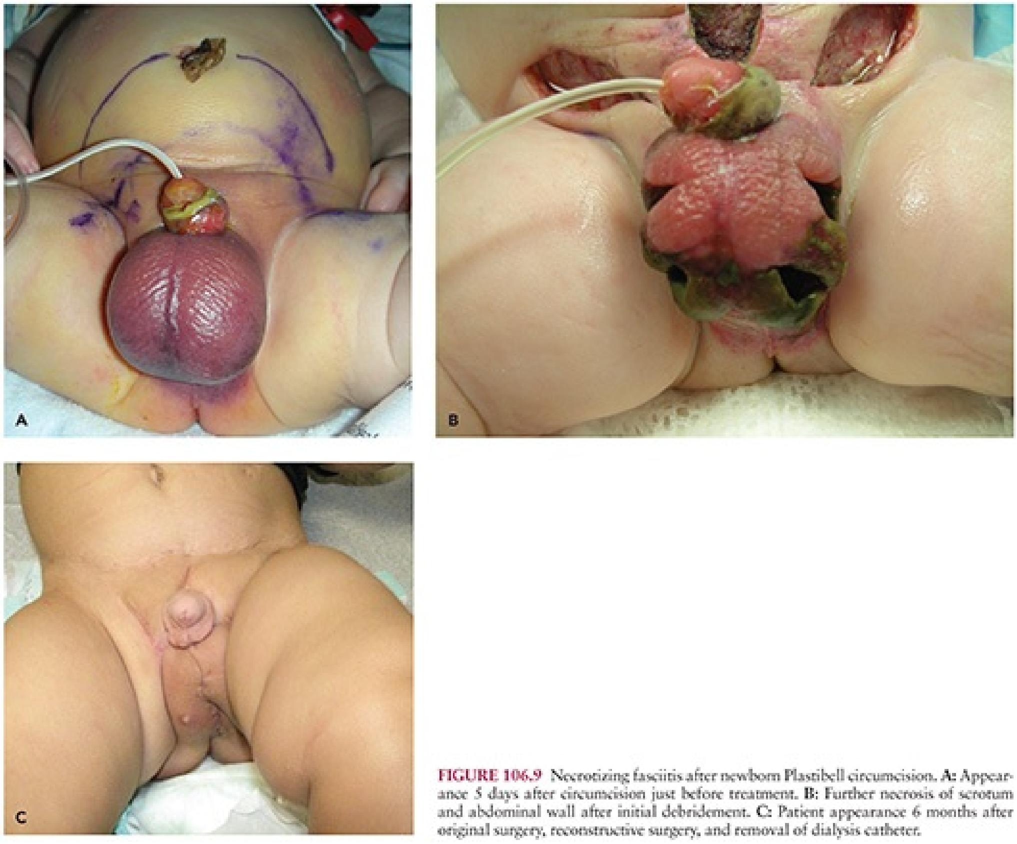

FIGURE 106.9 Necrotizing fasciitis after newborn Plastibell circumcision. **A:** Appearance 5 days after circumcision just before treatment. **B:** Further necrosis of scrotum and abdominal wall after initial debridement. **C:** Patient appearance 6 months after original surgery, reconstructive surgery, and removal of dialysis catheter.

Results

A circumcision should remove a sufficient amount of the prepuce so that the glans is exposed, significantly reducing the risk of developing phimosis, paraphimosis, BXO, or balanoposthitis.

CONCEALED PENIS (MEGAPREPUCE)

Congenital megaprepuce or concealed penis is a relatively recently described condition where the inner prepuce is excessively redundant and accompanied by a relative paucity of outer penile shaft skin with scrotalization of the penile shaft. Since its initial description in 1994 (27), it has been found more frequently. These children should *not* have a typical newborn circumcision performed as that will primarily remove penile shaft skin, not address the excessive inner preputial skin, and result in a more concealed or buried penis with resultant loss of penile shaft skin necessary for a normal circumcised penis appearance. The etiology of this condition is not well defined but described as either failure of the urethral folds and scrotal folds to separate, failure of the penis to develop its normal attachments to the pubic region, or infolding of the prepuce causing outlet obstruction and dilation of the inner prepuce (28,29).

Since the first reports of this condition, many authors have described their preferred surgical corrective procedure (28–31). All authors agree that this condition does require surgical repair because the inner prepuce will continue to dilate and produce increasing urine pooling in the redundant sac surrounding the penis causing urinary tract infections, treatment-resistant perineal rashes, and incomplete voiding necessitating manual drainage of the urine from the preputial sac by the child’s caregivers (Fig. 106.10).

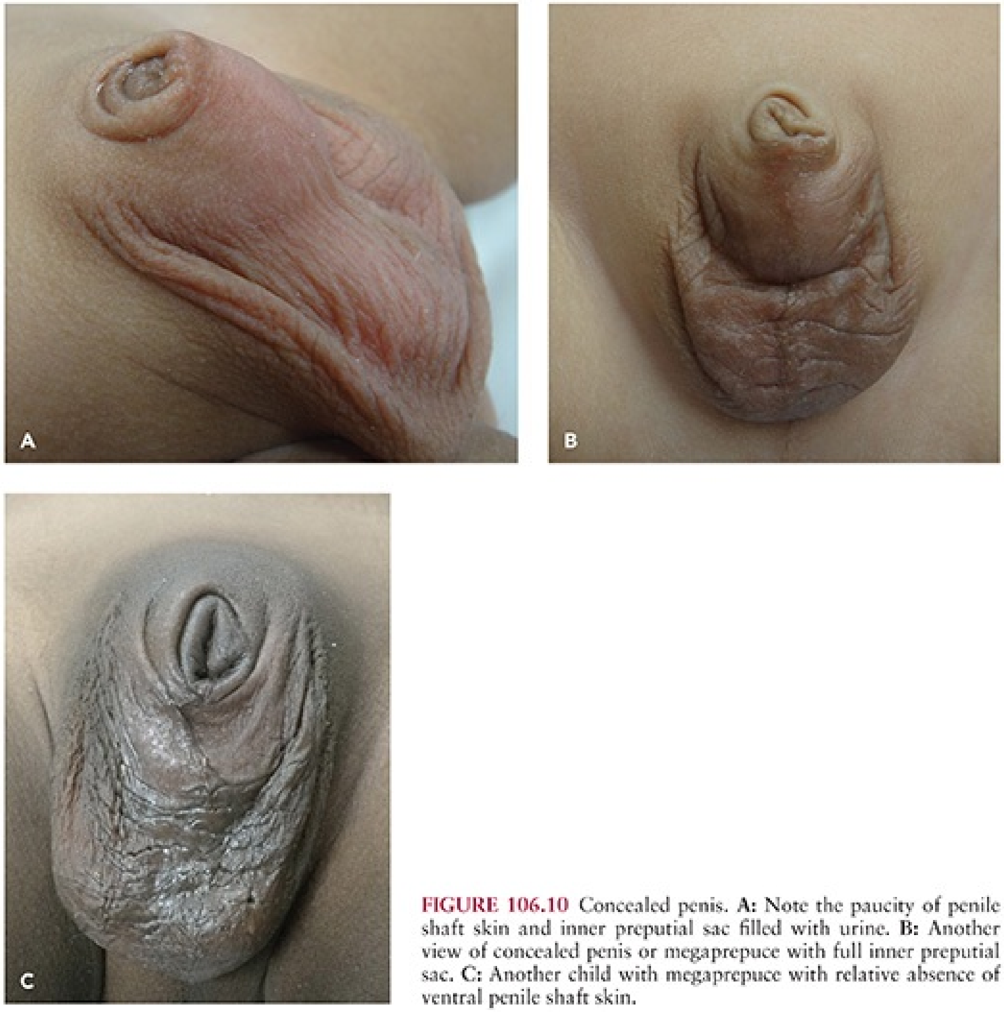

FIGURE 106.10 Concealed penis. **A:** Note the paucity of penile shaft skin and inner preputial sac filled with urine. **B:** Another view of concealed penis or megaprepuce with full inner preputial sac. **C:** Another child with megaprepuce with relative absence of ventral penile shaft skin.

All of the procedures try to use the redundant inner preputial skin because it provides good coverage of the shaft, relieves the inner preputial reservoir of urine, and provides a cosmetically acceptable circumcision appearance.

Two preferred methods use this inner preputial skin differently: one as primary coverage of the penile shaft (30,31) and the other as accessory coverage, if needed (28,29).

Repairs using the inner skin as primary coverage start with circumferentially elliptically incising the skin at the preputial penile shaft skin junction (31) or excising the preputial phimotic ring itself (30). The inner preputial skin is then unfurled and attached to the previously cut skin edge, which is located at the penoscrotal junction after the incision or excision of the phimotic band is made. The excess inner skin is reduced and removed to allow adequate coverage of the shaft itself. The scrotum in this technique drops down to its normal location at the base of the penile shaft after the initial stage of the procedure. Absorbable sutures are used for the repair. A temporary urethral tube may be left to drain the bladder but generally is not necessary. A pressure dressing can also be used as is used with hypospadias surgery to reduce postsurgical edema at the discretion of the performing surgeon but is not necessary.

Alternatively, the inner preputial skin can be used as additional skin coverage and not primary coverage. In these techniques, the initial incision originates on the scrotum itself, generally at the location where the outer bulge of the ballooned megaprepuce meets the scrotum. The skin is incised down to the penoscrotal junction and the inner preputial skin is then unfurled or degloved from this ventral scrotal incision. The inner preputial skin is then incised to form a coronal cuff as left on a routine circumcision. These approaches differ in that the penile shaft coverage here is from the penoscrotal skin giving thicker skin coverage typical to normal penile shaft skin than the thinner inner preputial skin. The excess inner preputial skin may be used to fill in any ventral skin deficit that may occur, but the dorsal skin coverage is more consistent to the penile shaft skin that is seen after routine circumcision. The scrotal skin flaps are then rotated to meet in the midline using absorbable sutures to create a normal penoscrotal junction appearance. The dressing placed may be a pressure dressing or not as preferred by the operating surgeon. Bladder drainage may be used but is also not necessary for this technique (Fig. 106.11).

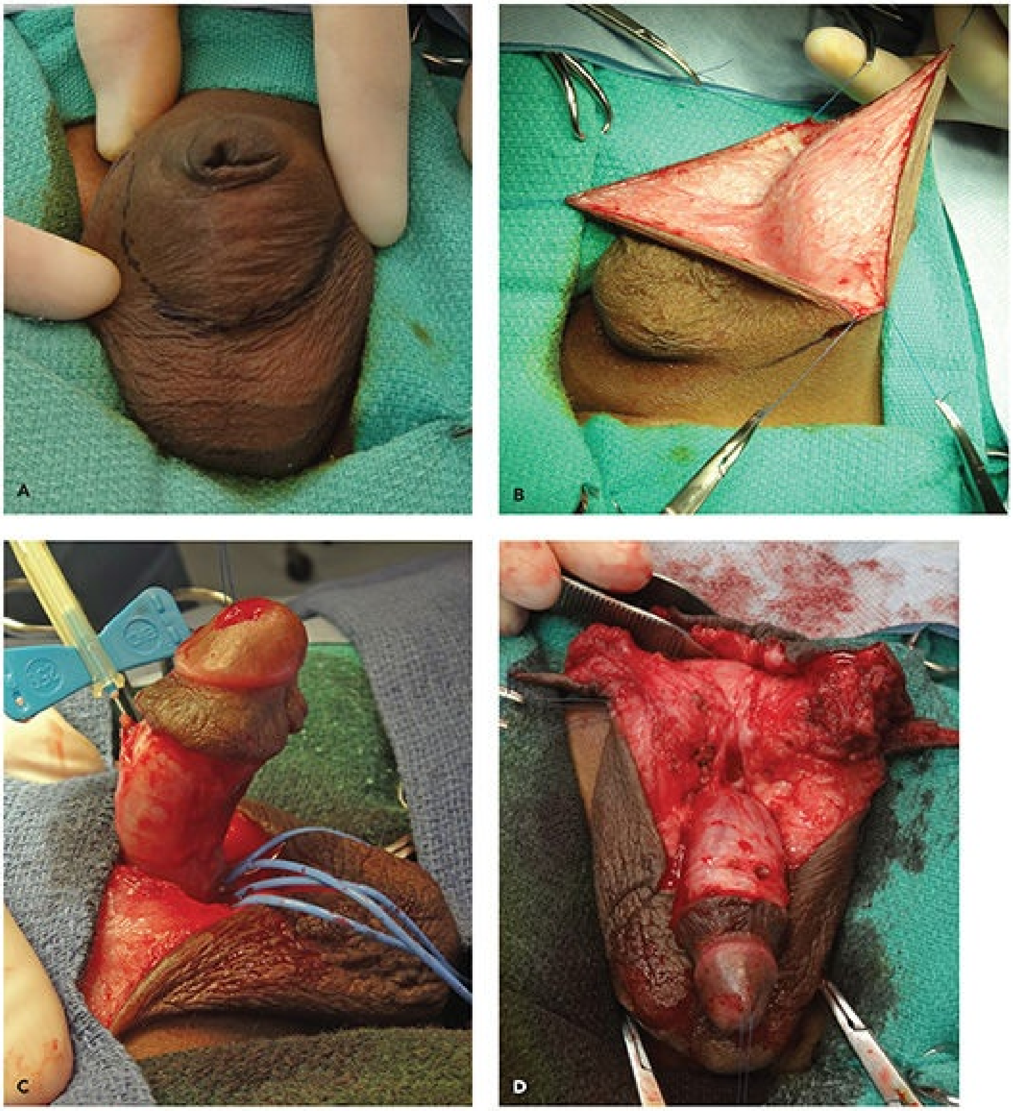

FIGURE 106.11 Concealed penis repair. **A:** Initial step is to mark the extent of the inner preputial sac on scrotum. **B:** Penoscrotal mark is incised, and penis is degloved from ventral incisional area. **C:** Artificial erection shows mild ventral chordee which was corrected. Scrotal flaps will be rotated medially to place scrotum in normal position. **D:** Inner preputial skin and shaft skin rotated on superior to the penile shaft and will be rotated to cover the dorsal shaft. Residual inner preputial skin will be used to cover areas on the ventral shaft requiring skin coverage. (*continued*)

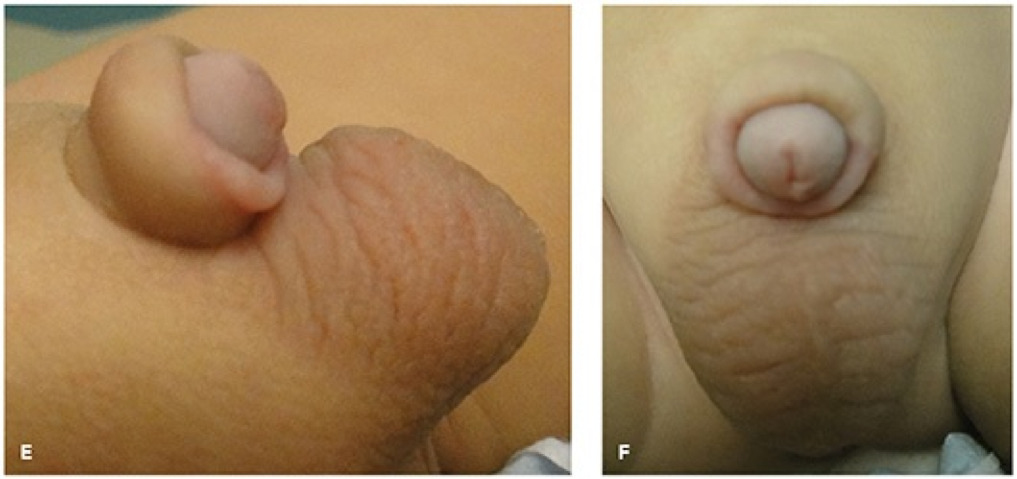

FIGURE 106.11 *(continued)* **E:** Postsurgical results on a different patient 6 months after megaprepuce repair. **F:** Postsurgical results on same patient as previously 6 months after repair.

It may be reasonable to perform an artificial erection to evaluate for possible chordee because there has been an association of ventral chordee with megaprepuce in some patients (Fig. 106.12).

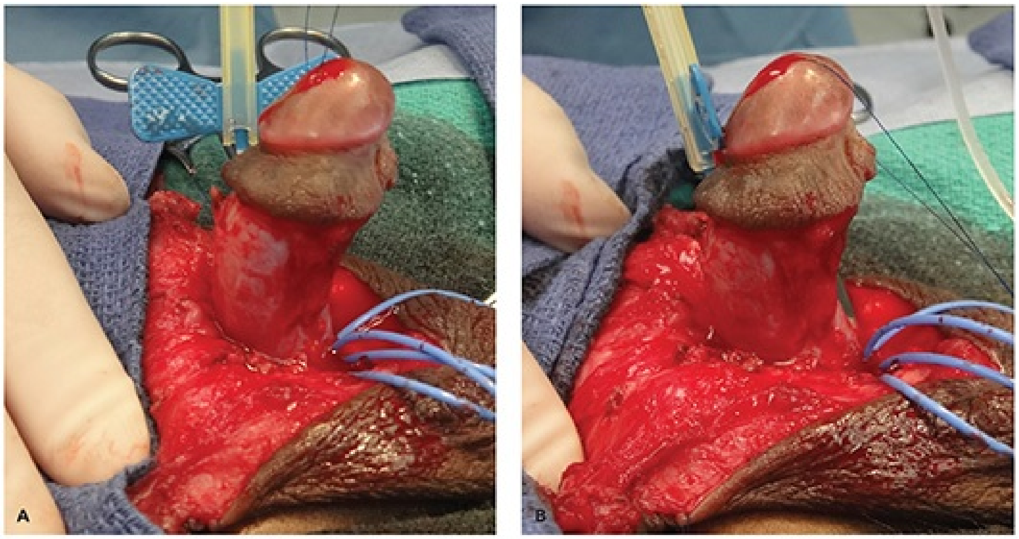

FIGURE 106.12 Chordee associated with concealed penis. **A:** Ventral chordee found with artificial erection test after inner preputial skin degloved. **B:** Penis straightened with dorsal plication before finishing the scrotoplasty and penile shaft skin coverage.

All sutures used in any of these techniques are absorbable, at the preference of the operating surgeon, similar to those used for circumcision and scrotal surgeries.

Outcomes

Complications

Reported complications have been few. Rarely, scar tissue may form at the penoscrotal junction causing some tethering of the penis with healing. Those techniques using the inner prepuce at complete shaft skin coverage may have some redundancy but generally do not need reoperation. Bleeding and infection complications, although not reported in these series, would be similar to expected occurrence with routine circumcision.

Results

Concealed penis or megaprepuce is a relatively new indication for surgical repair. Resolution of the inner preputial sac occurs with all procedures described. Cosmetic results vary with the technique used but are generally acceptable with any technique used. The only difference is the shaft skin coverage with the initial scrotal approach tends to be thicker shaft skin as seen with a typical circumcision as compared to the shaft coverage when using the thinner inner preputial skin alone. Penile curvature may be present in some children who should have this evaluated and treated if found.

CONGENITAL ANOMALIES OF THE SCROTUM

Isolated congenital anomalies of the scrotum, including inclusion cysts, the bifid or hypoplastic scrotum, penoscrotal transposition, and webbed penis, scrotal ectopia, agenesis, or accessory scrotum, are uncommon. Generally, these anomalies are associated with other genitourinary abnormalities such as penoscrotal transposition and bifid scrotum with hypospadias, bifid scrotum and scrotal ectopia seen with exstrophy, scrotalization of the penile shaft skin in megaprepuce, and scrotal hypoplasia associated with cryptorchidism. Isolated scrotal anomalies are sometimes associated with other congenital malformations, such as hemangiomata, cardiac, cerebrovascular, ocular, and sternal defects (32). Children presenting with these isolated scrotal conditions (scrotal agenesis, hemiscrotal agenesis, ectopic or accessory scrota) should be evaluated for nongenital-associated congenital conditions. When scrotal anomalies occur in conjunction with other genital abnormalities, the scrotum can generally be surgically repaired, with excellent results, at the same time of surgical correction of the associated genital condition (Fig. 106.13). Neonatal circumcision must not be performed in boys with genital anomalies because the prepuce may be required for reconstruction of the penis and scrotum, especially if there is scrotal agenesis or megaprepuce. The prepuce is an excellent tissue graft source where scrotal or penile skin would otherwise be insufficient to correct these genital conditions. Megaprepuce or concealed penis, as previously described, combines abnormal scrotal and preputial development. Surgical repair of this condition involves combining penile as well as scrotal surgical techniques (28–30,33).

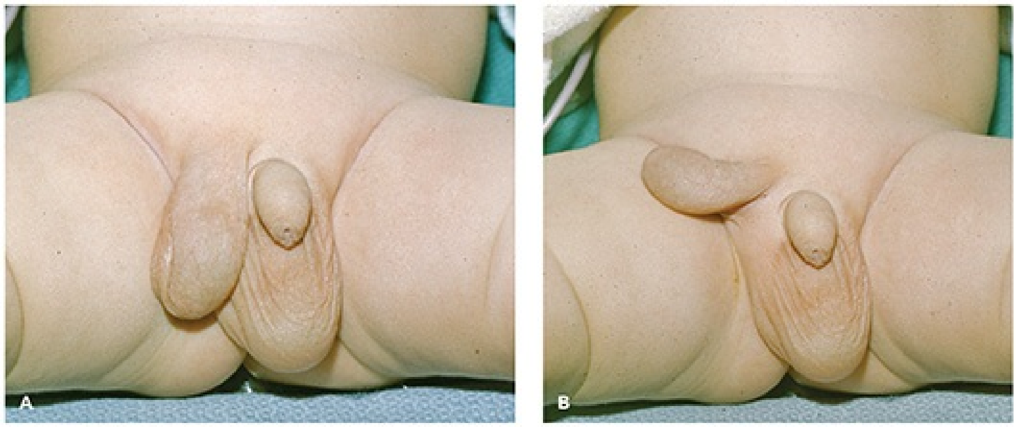

FIGURE 106.13 Ectopic scrotum. **A:** Young boy with ectopic right scrotum with testis in sac before correction. **B:** Another view of ectopic scrotum in same patient.

Diagnosis

The diagnosis of scrotal congenital anomalies is made by physical examination. Because it is rare for these anomalies to occur alone, the patient should be appropriately evaluated for associated anomalies, both genital and systemic. The physician should examine the scrotum for its relative position to the penis, rectum, and median raphe. The scrotal appearance should be examined with attention to symmetry and the general anatomy of the patient to find the associated conditions (bladder exstrophy, hypospadias, cryptorchidism, cardiac, hemangiomata cerebrovascular, ocular, and other linked findings). Specifically, the testes, penis, urethra, and rectum should be inspected to ensure that they are normal.

Indications for Surgery

Timing of the surgical repair of urogenital anomalies is important with regard to feasibility of the surgery, safety of the surgery to the patient, and the psychological impact of the anomaly and surgery. The use of optical magnification and fine absorbable sutures applies to scrotal procedures as well as penile surgeries with optical magnification not always required for some simpler scrotal procedures.

The use of tissue expanders for progressive skin dilatation, as in the cases of hypoplastic or absent scrotum, has offered a viable alternative to myocutaneous flaps, which often result in a poor cosmetic result in the pediatric population. Again, prophylactic antibiotics are seldom necessary in uncomplicated cases with the prepubertal child that do not involve instrumentation of the urinary tract.

Alternative Therapy

There are no alternatives to surgical correction for these congenital anomalies. However, nontreatment is an option, or reconstructive surgery can be delayed until the boy can participate in the decision to proceed. The psychological advantage of earlier surgery would need to be weighed against the importance of allowing the youngster to be involved in the decision-making process.

Surgical Technique

Bifid Scrotum

Isolated bifid scrotum is rare. Most patients who present with a bifid scrotum will have associated hypospadias and chordee. When it occurs in isolation, the corpus spongiosum appears to be continuous with a prominent median raphe of the scrotum, a fibrous band that separates and divides the scrotum into two individual parts. Surgical reapproximation of the two hemiscrota can be achieved after dissection and excision of this midline band. The underlying urethra must be preserved and allowed to fall away from the dense band. Mobilization of each hemiscrotum is required to the extent that each hemiscrotum can be elevated and moved medially to the midline. Closure is accomplished using two layers. Deep absorbable sutures allow fixation and reconstruction of the midline. Surgical fixation of the testes is rarely necessary unless there is associated cryptorchidism. Fine absorbable sutures should be used to close the skin. In general, interrupted simple sutures are used, but a running subcuticular closure or horizontal or vertical mattress sutures may also be used at the preference of the surgeon.

Penoscrotal Transposition

Various degrees of penoscrotal transposition exist, ranging from the complete form (34,35), in which the scrotum is actually anterior and cephalad to the base of the penis, to incomplete forms, in which the penis emerges from the center of the scrotum, and milder forms, in which only the superior edges of the scrotum lie anterior to the penis. As with other anomalies of scrotal formation, there may be some associated congenital anomalies such as imperforate anus, chromosomal, vertebral, and central nervous system anomalies (36). For correction of the anomaly, the two hemiscrota are mobilized, swept inferiorly and medially, mimicking the normal embryologic migration of the labioscrotal folds, and sutured together. It may be necessary to transpose the penis cephalad to the scrotum. This can be achieved by using a skin bridge (Fig. 106.14) or by dividing the abnormal scrotum in its midline cephalad and caudal to the phallus and swinging both halves below the penis (Fig. 106.15) or using a scrotal mobilization technique as in megaprepuce repair (28–30,33). Some authors suggest leaving a segment of skin intact cephalad to the penis to avoid jeopardizing the vascularity and lymphatic drainage of the penile shaft skin. Other authors advocate the creation of a suprapubic buttonhole through which the penis can be delivered (37–39). For less severe cases of penoscrotal transposition, the wedge of ectopic scrotal skin is removed and the resultant defect closed, thereby eliminating the problem (40). This approach is most appropriate when there is incomplete mild penoscrotal transposition. The penoscrotal angle can be recreated by anchoring sutures applied to the underlying fascia and corresponding skin but is not always necessary, especially if the scrotal repair is primarily ventrally performed (28–30,33). Fixation of the penopubic angle can also be performed in a similar fashion. The anchoring sutures may have the additional benefit of stabilizing penile length (33,41).

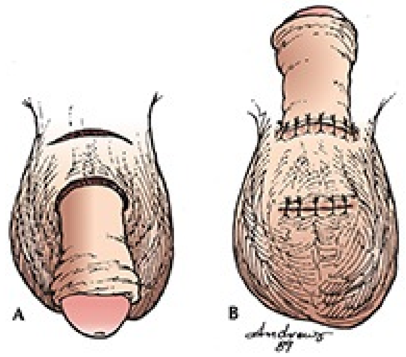

FIGURE 106.14 **A:** In the moderately severe case of penoscrotal transposition, the phallus is circumscribed and freed of supporting tissue. An incision is made cephalad to the base of the phallus. **B:** The penis can then be brought back through the new opening and the skin sutured about it. The original opening is then sewn closed.

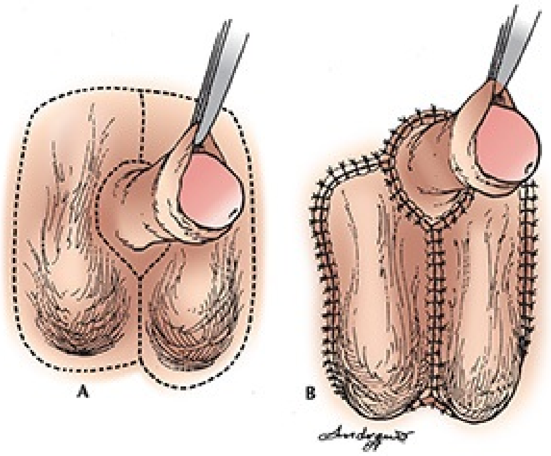

FIGURE 106.15 **A:** In the more severe case of penoscrotal transposition, each hemiscrotum is circumscribed. **B:** Once each side is freed to rotate caudally and medially, the two portions are sewn together. Some authors suggest leaving a bridge of skin cephalad to decrease the possibility of a vascular insult.

Scrotal Hypoplasia

Scrotal hypoplasia is generally only seen in boys with cryptorchidism. A small tight muscular scrotum where both testes are descended is not hypoplastic and does not require any surgical intervention. Surgical intervention is not needed for the hypoplastic scrotum with or without associated cryptorchidism. Orchiopexy can easily be performed in this group without tissue expanders or testosterone treatments prior to surgery. There may be a limited role for androgen stimulation in testis prosthesis placement in a hypoplastic scrotum using either testosterone enanthate, 2 mg per kg intramuscularly, or testosterone cypionate, Depo-Testosterone, 25 mg intramuscularly once a month for up to 3 months, as is done for complex hypospadias repair as a similar treatment plan to help with scrotal development prior to prosthesis placement. This short-term testosterone program will induce scrotal development and enlargement in addition to increasing penile length and glans circumference (42). This allows easier surgical placement of prosthesis in the poorly developed scrotum at the time of surgery. The hormonal treatment effects are temporary so the proposed surgical procedure should be done shortly after finishing the testosterone course to get the benefits of the scrotal enlargement. In severe cases of scrotal hypoplasia or the rare case of congenital scrotal agenesis, tissue expanders may be used as another alternative where there is inadequate space for the testis or prosthesis. The preoperative use of testosterone in patients with scrotal hypoplasia is rarely indicated, however, and should only be used if the placement of a testicular prosthesis is contemplated and the scrotum is extremely hypoplastic and may not accept the prosthetic when placed. The expanders can be used to progressively dilate the scrotum to an adequate size.

Placement of a testicular prosthesis before puberty is not routinely advocated because these children will outgrow an initial small-sized prosthesis and need to have the smaller prosthesis changed out to a larger size at a later date. However, in patients with bilateral anorchia, either due to perinatal testis torsion of both testes or both testes never forming, it may be reasonable to place appropriately sized testis prostheses in this group at a young age. Families are devastated by the absence of both testes in their child, especially with the long-term ramifications that their child will need lifelong hormone supplementation and is infertile from birth. Having prostheses placed alleviates some of this devastation, as the child will look “normal” to the family by having a full scrotum. Additionally, these prostheses will act as tissue expanders for when larger prostheses are placed in adolescence.

Scrotal Ectopia and Accessory Scrotum

Although less common than either scrotal transposition or a bifid scrotum and usually associated with cloacal exstrophy, scrotal ectopia on occasion is found in the otherwise normal child (43). Ectopia is generally thought to be due to the abnormal migration of the labioscrotal folds during embryologic development, whereas accessory scrotum may be due to intervening tissue disrupting the normal migration of the folds. These children need to be evaluated for other congenital conditions because they frequently will have associated ipsilateral renal agenesis or dysplasia. There may also be an association with imperforate anus (44). The ectopic scrotal tissue can be found on the inner aspect of the thigh or caudal and inferior to the external inguinal ring (Fig. 106.5). Often, the ipsilateral testis can be found within the ectopic tissue as an undescended testis. Correction is accomplished by relocating the ectopic tissue, by way of a flap or graft, or by utilizing the normally positioned contralateral hemiscrotum as a reservoir for both gonads and discarding the ectopic tissue, depending on the size and location of the ectopic scrotum (16). Again, rarely does treatment of scrotal ectopic require tissue expanders or androgen hormone pretreatment. If needed, a short course of testosterone injections (testosterone enanthate 2 mg per kg intramuscularly or Depo-Testosterone [testosterone cypionate] 25 mg intramuscularly for three doses given monthly) may increase the size of the truly hypoplastic ectopic scrotum, or primary stretching of the ectopic tissue may allow the scrotal tissue to be expanded for orchiopexy and reconstruction of the scrotum itself.

Accessory scrotal tissue, generally found in the perineum, is also a rare condition. In distinction with scrotal ectopia, these accessory folds are not associated with cryptorchidism, ipsilateral renal agenesis, or abnormal scrotal median raphe anatomy. These folds may be part of the popliteal pterygium syndrome (45). There may be an underlying lipoma. Surgical excision of the accessory scrotal tissue and lipoma is usually all that is required (Fig. 106.16A–C). Generally, these rare accessory scrotal sacs are removed due to abnormal cosmesis and due to irritation and inflammation of the sac in an abnormal perineal position (44).

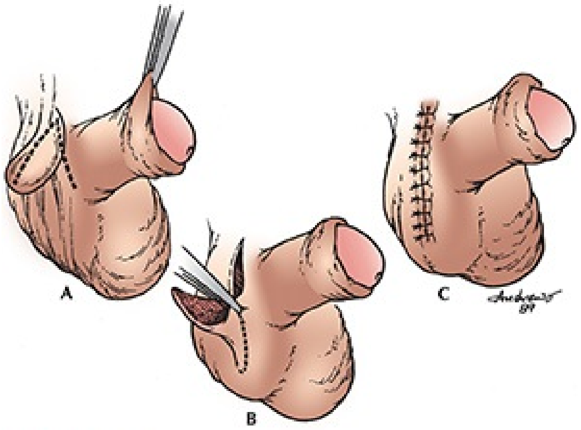

FIGURE 106.16 **A and B:** In the case of mild scrotal ectopia, a wedge of ectopic scrotal skin is excised. **C:** The defect is then closed, thereby eliminating the ectopic scrotal skin.

Scrotal or Hemiscrotal Agenesis

Scrotal agenesis is an extremely rare condition with only six cases being reported in recent literature (32). These boys are missing the entire scrotal tissue mass from the base of the penis to the anus. All patients have a male karyotype (46). Testes are generally present but in either an undescended or ectopic location. The penis and other external androgen-dependent structures are typically normal. Testis location may be palpable in the inguinal or ectopic positions, or the testes may be nonpalpable and intra-abdominal in location.

Scrotal agenesis has been associated with other congenital anomalies, specifically, facial anomalies, developmental delay, nystagmus, and cardiac defects. Importantly, as the patient presents with an elongated male phenotypic phallus, it is imperative to ascertain that some disorder of sexual differentiation is not present, given the male phenotypic appearance with an absent scrotum. A karyotype must be performed, and the child must be evaluated for congenital adrenal hyperplasia. Determination of the cause of scrotal agenesis rests on possible localized 5-alpha reductase deficiency or receptor deficiency or malformation. Alternatively, there may just be failure of the labioscrotal folds to form.

Hemiscrotal agenesis is an even rarer phenomenon, with only two cases reported to date (32,47). These boys may also need to be evaluated for possible congenital adrenal hyperplasia. Interestingly, these boys have what appears to be a normally developed hemiscrotum with a normal median raphe. Both testes, in the cases reported, were descended in the normal scrotal sac and in the normal location of the side without a scrotal sac. These patients may also have some associated congenital conditions, including ocular, cardiac, cerebrovascular, hemangiomata, and sternal defects, whereas one of the reported patients had no such associated conditions.

Surgical construction of scrotal sacs in scrotal agenesis may be done by various techniques, but the most common and most anatomically based requires using the preputial skin as a replacement for the scrotal skin. These children *must not* be circumcised. The initial surgery involves incising the inner prepuce circumferentially near the coronal ridge and then unfolding the prepuce and degloving the penis, so that a long tube of skin is created. This tube is then split ventrally along the midline down to the perineal raphe region. Buttonholing the dorsal flap surface allows the previously distally located preputial skin to be rotated as flap over the glans and into the perineum as a scrotal sac.

Generally, tissue expanders or testis prostheses are placed in the newly created scrotal sacs and delayed orchiopexies are planned for several months after the first procedure (46,47).

Hemiscrotal agenesis typically does not require such extensive reconstructive procedures as does complete scrotal agenesis. Orchiopexy of the ipsilateral testis with hemiscrotal agenesis may be performed by placing it in the developed hemiscrotum. Alternatively, a similar hemiscrotal construction may be contemplated as is described for complete scrotal agenesis but is rarely needed (32,48).

Webbed Penis

In boys with a webbed penis, scrotal skin is tethered to the ventrum of the penile shaft. This tethering produces a web of skin stretching from the penis to the scrotal base (Fig. 106.17A). The webbed penis causes no problem during childhood unless there is significant tethering of the penis from a scrotal web that is located high on the penile shaft. This can causes difficulties with toilet training and with transitioning to standing to void in some boys due to the tethering high on the shaft. Also because the scrotal skin is hair-bearing, future intercourse could be difficult or uncomfortable with the scrotal webbed skin on the shaft of the penis (Fig. 106.17B and C). Therefore, a webbed penis is usually corrected during infancy or prior to the child being ambulatory. A modified circumcision can often correct minor webbed defects. The circumcision incision can be brought more distally than normal on the ventrum to repair short defects, thereby preserving all penile shaft skin possible in that location. After the inner preputial skin is excised, the additional length on the ventrum allows the scrotum to fall away from the glans and penis. Inner preputial skin can also be unrolled, if necessary to help drop the scrotal web further down to the normal penoscrotal junction area, if the web is very distal on the shaft. If necessary, skin from the dorsum can be mobilized and swept ventrally to provide additional shaft skin. A second type of repair can be performed by incising the web transversely and closing it longitudinally, thereby separating the penis from the median raphe of the scrotum. Care should be taken not to make this mobilization too limited as a cicatrix may occur after the Heineke-Mikulicz closure. Circumcision is usually performed at the same time because it facilitates the approximation of the skin (Fig. 106.18).

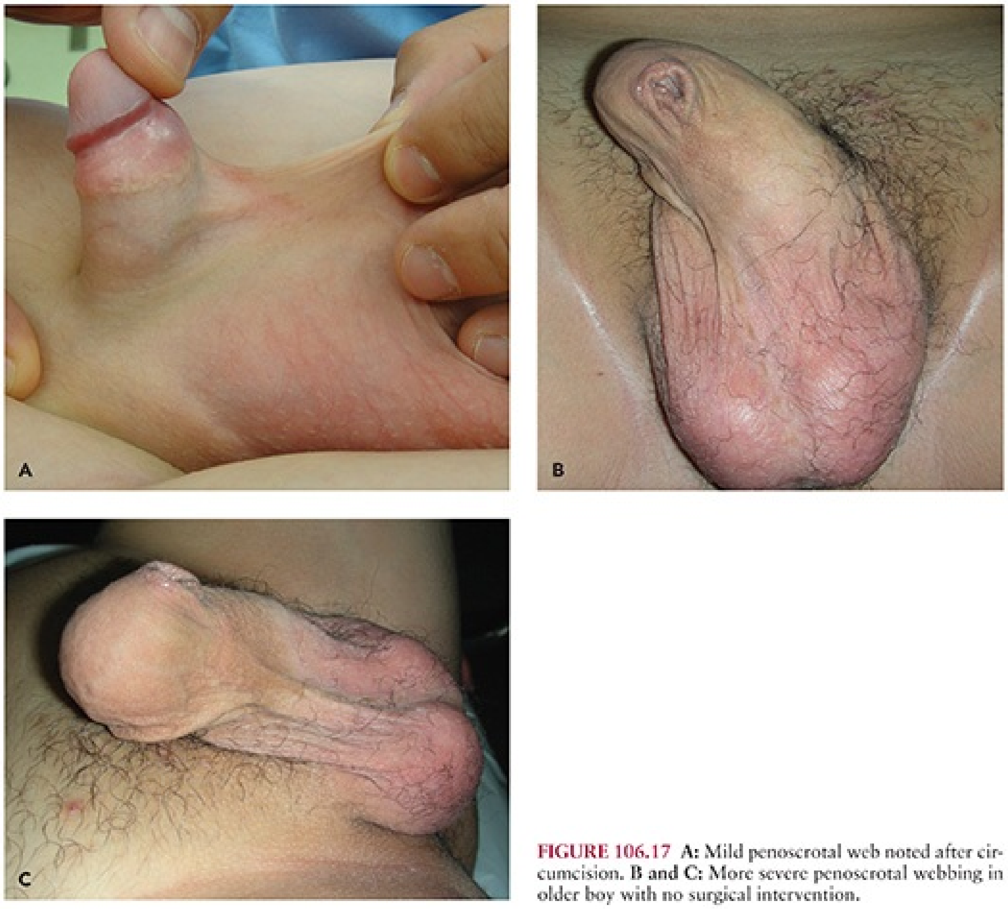

FIGURE 106.17 **A:** Mild penoscrotal web noted after circumcision. **B and C:** More severe penoscrotal webbing in older boy with no surgical intervention.

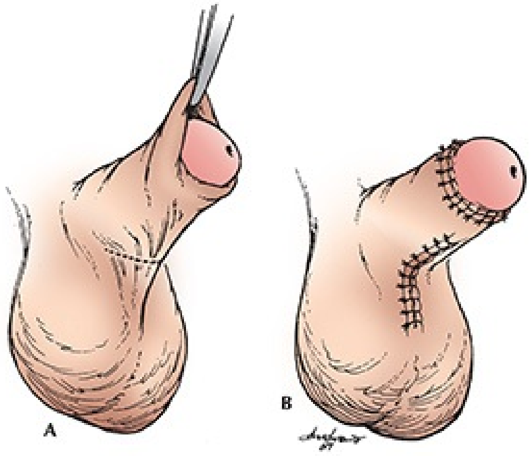

FIGURE 106.18 In the moderately webbed penis, the defect can be repaired by transversely incising the web (**A**) and closing it longitudinally (**B**). As in the mild cases, a modified circumcision incision with preservation of all the ventral skin can be helpful in recovering the penile shaft.

In more severe cases of webbed penis, a U-shaped incision is made about the phallus (49). This releases the penis from the dependent scrotum. Flaps are developed to allow ventral closure of the penis with fine absorbable sutures. The scrotum is closed in a side-to-side manner (Fig. 106.19). In a manner similar to cases of penoscrotal transposition, the penoscrotal angle can be recreated by the placement of anchoring sutures securing the skin to the underlying fascia, although rarely is this needed.

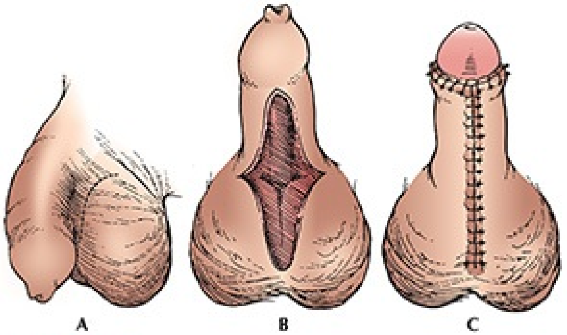

FIGURE 106.19 **A:** In a severely webbed penis, an incision is made between the penis and scrotum. **B:** Skin flaps are elevated in all directions so that the surgical defect can be closed. **C:** A two-layer closure is used to stabilize and approximate the skin and underlying tissues.

Scrotal Inclusion Cysts

Midline scrotal inclusion cysts are uncommon but benign and dermatoid in origin and can be managed by local excision (49). They may occur anywhere in the midline from the external urethral meatus to the anus. They occur as an aberration of the normal embryologic development of the male genital fusion of the urethral folds enveloping the urethral groove. However, care must be taken not to confuse these cysts, especially those situated near the anus, with a sinus associated with an imperforate anus or anal fistula. A fistula from imperforate anus can rarely track anteriorly to the penoscrotal junction. All of these cysts can be found ventrally as is the commonly found urethral meatal cyst. All are located in the median raphe, and these cysts can be multiple (Fig. 106.20). Most inclusion cysts are found because of cosmetic disfigurement, but these cysts can get infected or have calculus formation making it reasonable to consider excision of the inclusion tracts with care to evaluate anal components prior to surgical excision (49,50).

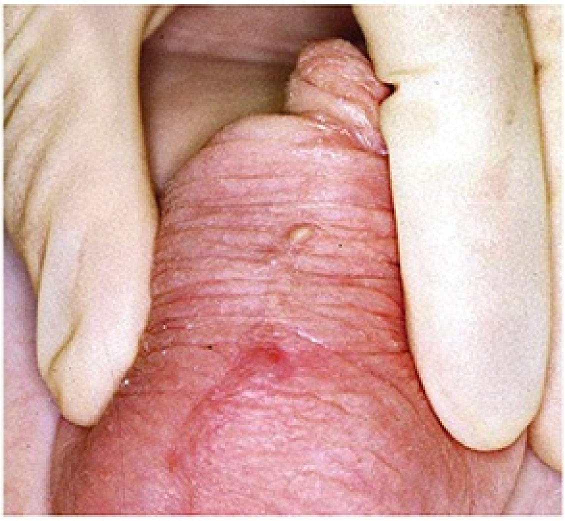

FIGURE 106.20 Median raphe scrotal inclusion cysts.

Outcomes

Complications

Complications from these surgeries are in general uncommon. Superficial infections can be treated with antibiotics.

Results

The cosmetic results of this surgery are usually excellent. It is imperative, however, in many of these rare conditions that the child *not* be circumcised as a newborn because the preputial skin may be invaluable for scrotal construction techniques. The infant's primary physician or medical provider must be alerted to have the baby evaluated by the pediatric urologist or surgeon prior to contemplating a neonatal circumcision because they are for possible penile abnormalities such as hypospadias, chordee, or penile torsion.

CHAPTER 107 AUGMENTATION CYSTOPLASTY IN CHILDREN

NORA G. LEE AND HANS G. POHL

Dedicated to W. H. Hendren, whose creative use of intestine in urologic reconstruction, I have been honored to observe.

Neuropathicity, bladder outlet obstruction, or embryologic abnormalities may result in a bladder too small or too hypertonic to provide normal storage and evacuation of urine. The goal of augmentation cystoplasty in the pediatric patient is to provide a sufficiently capacious reservoir that stores urine at low pressure and as a result improves urinary continence and prevents upper urinary tract deterioration. A variety of complications are possible following enterocystoplasty including, but not limited to, metabolic derangements, calculus formation, gastrointestinal disturbances, and spontaneous perforation. In this chapter, we will discuss the options for using stomach, bowel, and ureter in augmentation cystoplasty.

DIAGNOSIS

Radiographic evidences of a high-pressure neuropathic bladder (NB), such as trabeculation, elongation, or high-grade vesicoureteral reflux, are relative indications used by some but not sufficient to make the diagnosis. Instead, the decision to proceed with augmentation cystoplasty is predicated on identifying a small-capacity, noncompliant, or hypertonic bladders as a result of neuropathicity from myelodysplasia or traumatic spinal cord injury, or myogenic failure from posterior urethral valves. Occasionally, augmentation cystoplasty is also required in order to provide adequate bladder volume in cases of classic exstrophy, cloacal exstrophy, and cloacal malformations.

INDICATIONS FOR SURGERY

When urodynamic evidence exists that nonoperative measures have failed, augmentation cystoplasty is indicated. Intravesical storage pressure that has been demonstrated to be greater than 40 cm H_2O is the most robust indication for augmenting the bladder. Incontinence and urinary tract infections, with or without vesicoureteral reflux, are associated symptoms that may benefit from enterocystoplasty. However, a thorough evaluation is warranted in order to ascertain what type of augmentation to perform and whether a secondary procedure is indicated in addition to enterocystoplasty to provide continence and/or prevent upper tract deterioration.

Evaluation of Anatomic and Functional Characteristics

Vesicoureteral Reflux

Vesicoureteral reflux, found in 3% to 5% of newborns with neuropathic bladder dysfunction (detrusor hypertonicity and detrusor-sphincter dyssynergia), increases in prevalence when clean intermittent catheterization (CIC) and anticholinergic medications have not been initiated at birth: 30% at age 5 years and up to 60% in older children (1,2). Conversely, vesicoureteral reflux (VUR) resolves in 30% to 55% of patients with neuropathic bladders when CIC and anticholinergics are instituted (3–5). Since the combination of urinary infection, detrusor hyperreflexia, and VUR poses a significant risk for renal scarring, antireflux surgery should be considered at the time of augmentation cystoplasty when reflux is high-grade or recurrent symptomatic urinary infection has occurred. However, reimplanting ureters into a thick-walled bladder is challenging technically and has been associated with postoperative ureteral obstruction, leading some to consider augmentation without ureteral reimplantation. When children with neuropathic bladders and VUR have undergone augmentation cystoplasty alone, VUR has frequently resolved or been significantly downgraded without the need for reimplantation, even in cases of high-grade VUR (6).

Sphincteric Incontinence

Sphincteric incontinence may coincide with detrusor hyperreflexia in which case a procedure to increase bladder outlet resistance is indicated at the time of augmentation. If bladder outlet surgery is entertained in conjunction with enterocystoplasty, the incontinence procedure should be performed prior to opening the peritoneal cavity in order to minimize insensible fluid loss. In addition, it is of critical importance that the surgeon ascertains that the bladder neck procedure does not make catheterization difficult because ineffective emptying can lead to any one of a number of complications, thus mitigating the benefits of enterocystoplasty.

Evaluation of the Bowel

In the child with no prior history of bowel resection or gastrointestinal comorbidity, it is generally not necessary to evaluate the intestinal tract. However, radiologic imaging is essential in patients with intestinal atresia, intestinal malrotation, and imperforate anus because it is likely that anatomic abnormalities or prior surgical intervention would obviate the use of specific bowel segments. In the most severe circumstances, urogenital and anorectal anomalies coexist (cloacal exstrophy and cloacal malformation) and require an individualized and often creative use of intestinal segments in order to provide urinary storage and emptying, evacuation of feces, and sexual function, whereas alimentary function is preserved. These cases will not be discussed because they are beyond the scope of this chapter. However, helpful references are available to assist the urologic surgeon in the proper management of these patients (7).

ALTERNATIVE THERAPY

Bladder dysfunction should initially be treated with anticholinergic medications and CIC in an effort to diminish uninhibited bladder contractions, improve compliance, and provide regular and effective bladder emptying. Also, injection of botulinum toxin into the detrusor wall has been shown to improve bladder dynamics and postpones the need for augmentation cystoplasty.

SURGICAL TECHNIQUE

Preoperative Counseling

Preoperative preparation must include a thorough review of the anticipated goals of the surgery with the parent and patient, when he or she is an older child or adolescent. During this meeting, the family's ability to comply with the postoperative care of a bladder augmented with bowel must be assessed. When CIC has been performed preoperatively, the postoperative catheterization and irrigations are more readily adhered to. Urinary infection, bladder calculi, or perforation may result when routine emptying and augment cleansing is not performed regularly. Table 107.1 outlines the most common complications of augmentation cystoplasty in the early and late postoperative periods. Some complications are specific to the method of augmentation cystoplasty performed, but the most serious, perforation, occurs whenever CIC is not rigorously performed and is not restricted to any one type of enterocystoplasty.

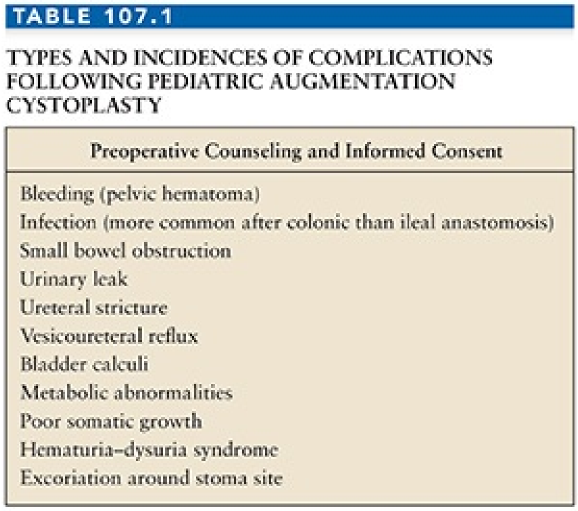

TABLE 107.1

TYPES AND INCIDENCES OF COMPLICATIONS FOLLOWING PEDIATRIC AUGMENTATION CYSTOPLASTY

Preoperative Counseling and Informed Consent
Bleeding (pelvic hematoma)
Infection (more common after colonic than ileal anastomosis)
Small bowel obstruction
Urinary leak
Ureteral stricture
Vesicoureteral reflux
Bladder calculi
Metabolic abnormalities
Poor somatic growth
Hematuria–dysuria syndrome
Excoriation around stoma site

Preoperative Bowel Preparation

The patient with neurogenic bladder dysfunction is likely to have coexistent constipation, thus necessitating that the bowel preparation be started well in advance. The patient should be contacted with explicit instructions to begin clear liquids at home 2 days prior to surgery and to arrive early for a preoperative admission 1 day prior to surgery. Intravenous fluids should be started at the same time that the patient begins ingestion (orally or by nasogastric tube) of GoLYTELY solution (Table 107.2). Enemas and oral antibiotics are administered as well following completion of the GoLYTELY prep, depending on the severity of the patient's fecal load and estimated efficacy of the oral bowel prep. For patients with marginal renal function, the use of phosphate containing laxatives is contraindicated. Instead, twice-daily oral administration of polyethylene glycol 3350 beginning 3 days preoperatively as an adjunct to a clear liquid diet is sufficient to clear most children.

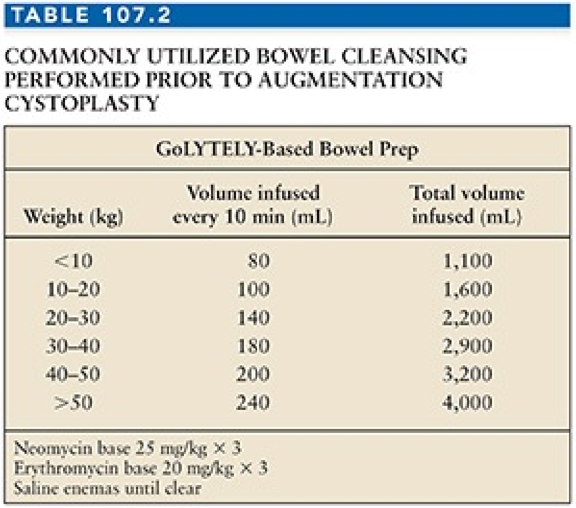

TABLE 107.2

COMMONLY UTILIZED BOWEL CLEANSING PERFORMED PRIOR TO AUGMENTATION CYSTOPLASTY

GoLYTELY-Based Bowel Prep		
Weight (kg)	Volume infused every 10 min (mL)	Total volume infused (mL)
<10	80	1,100
10–20	100	1,600
20–30	140	2,200
30–40	180	2,900
40–50	200	3,200
>50	240	4,000

Neomycin base 25 mg/kg × 3
Erythromycin base 20 mg/kg × 3
Saline enemas until clear

Selection of Bowel Segment to Use

There is no ideal segment of bowel for augmentation cystoplasty; each has a set of characteristics that are advantages or liabilities depending on the clinical scenario (Table 107.3). The following section will review the aspects of each intestinal segment that sets it apart from the remainder in the context of the results and complications following enterocystoplasty. It should be noted that none of these complications are seen following ureterocystoplasty, making it the ideal tissue for bladder augmentation (8,9). However, it is a procedure ideally performed in a patient with a severely dilated ureter that subtends a nonfunctioning kidney. Ironically, most patients with neuropathic bladder dysfunction rarely present with such anatomy as a result of close follow-up and the early institution of anticholinergic medications and CIC. Currently, boys with posterior urethral valves are most likely to present with severely hydronephrotic kidneys and massively dilated ureters that can be used to augment the bladder. In those circumstances, ureterocystoplasty has achieved comparable capacity and compliance as with enterocystoplasty (8).

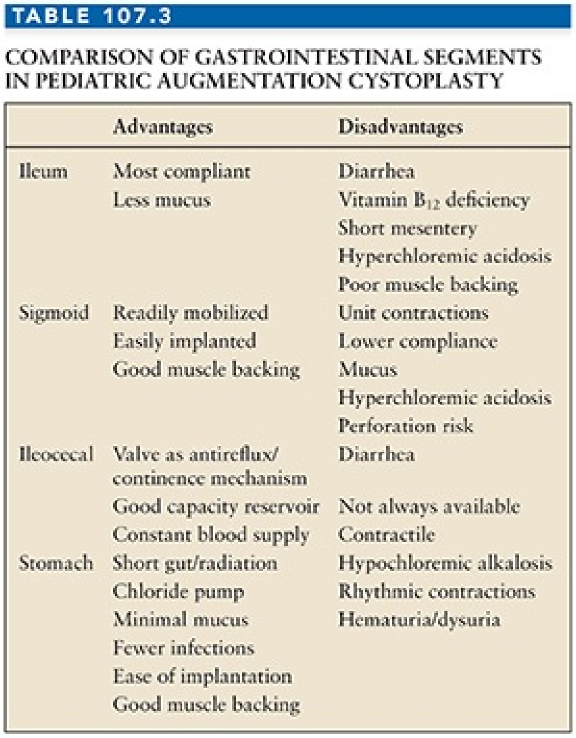

TABLE 107.3

COMPARISON OF GASTROINTESTINAL SEGMENTS IN PEDIATRIC AUGMENTATION CYSTOPLASTY

	Advantages	Disadvantages
Ileum	Most compliant	Diarrhea
	Less mucus	Vitamin B_{12} deficiency
		Short mesentery
		Hyperchloremic acidosis
		Poor muscle backing
Sigmoid	Readily mobilized	Unit contractions
	Easily implanted	Lower compliance
	Good muscle backing	Mucus
		Hyperchloremic acidosis
		Perforation risk
Ileocecal	Valve as antireflux/ continence mechanism	Diarrhea
	Good capacity reservoir	Not always available
	Constant blood supply	Contractile
Stomach	Short gut/radiation	Hypochloremic alkalosis
	Chloride pump	Rhythmic contractions
	Minimal mucus	Hematuria/dysuria
	Fewer infections	
	Ease of implantation	
	Good muscle backing	

Intraoperative Preparation of the Patient

The patient is positioned supine on the operating table. General anesthesia with endotracheal intubation is mandatory; however, if no spinal abnormality exists that contraindicates the use of an epidural catheter, consideration should be given to regional anesthesia as well. The surgical field is prepared and draped from the xiphoid process inferiorly, including the genitalia. A Foley catheter is inserted urethrally. A midline incision is created beginning at the symphysis pubis an extending superiorly toward the umbilicus. In order to avoid the insensible loss of heat and water from peritoneal surfaces, it is recommended that any concomitant procedures on the bladder or bladder neck be performed through a limited incision that does not enter the peritoneal space. Retraction can be provided by either a Denis Browne or Bookwalter retractor at this point.

Preparation of the Bladder for Cystoplasty

When a continent diversion is not planned, a midline cystotomy suffices to prepare the bladder for augmentation (Fig. 107.1). Ureteral reimplants can be easily performed at this point. However, when a continent catheterizable stoma is planned, either a paramedian or transverse cystotomy should be considered since these incisions create bladder flaps that facilitate the creation of a long submucosal tunnel for the appendix or ileal tube. Regardless of the bladder incision created, it must be sufficiently long to open the bladder widely. If the cystotomy is too short, the augmented segment may behave as a diverticulum, thus facilitating urinary stasis and stone formation. Once the bladder has been prepared, the midline incision is carried above the umbilicus and the peritoneum is entered. Retraction at this point is provided by a Bookwalter retractor.

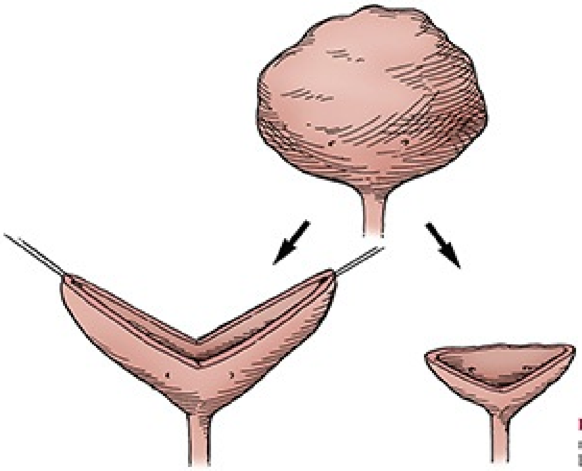

FIGURE 107.1 **A:** Preparation of the bladder for clam augmentation cystoplasty. **B:** Sagittal incision is made to create two bladder flaps.

Should one encounter an augmented bladder in which the intestinal segment has formed a pseudodiverticulum the following technique has been helpful. Create a cystotomy incision that transects the anterior lip of the opening into the intestinal segment. Through this cystotomy, incise the posterior lip of the opening with electrocautery until it is seen to spring open. This incision is not full-thickness. This defect should be closed transversely with continuous 3-0 polyglycolic acid (PGA), thus completing a Heineke-Mikulicz–like repair. The anterior cystotomy should then be closed transversely as well. (Author's personal observation of W. H. Hendren)

Ileocystoplasty

Ileum is by far the most popular segment used for bladder augmentation. The segment, 20 to 25 cm long, is based on a pedicle that is supplied by branches of the superior mesenteric artery and that is sufficiently mobile to be brought into the pelvis (Fig. 107.2). On occasion, an abnormally thick, fatty, or short mesentery can limit mobility of the vascular pedicle, thus necessitating extensive division of the mesentery posteriorly. The terminal 15 to 20 cm of ileum, as measured from the ileocecal valve proximally, is spared in order to retain bile salt absorption, thus preventing steatorrhea and vitamin B_{12} deficiency (Fig. 107.3). The portion of ileum to be used is measured, and 5-0 silk sutures used to mark the proximal and distal limits of resection. Prior to dividing the mesentery, the vascular supply to the isolated segment should be observed by transillumination and the proposed incisions in the mesentery marked. Beginning at the mesenteric border of the bowel, the mesentery is divided between pairs of fine hemostats, and the vascular arcades are ligated with 5-0 silk suture ties. The bowel is then divided between atraumatic bowel clamps that have been applied at the proximal and distal limits of resection. Once the ileal segment reaches into the pelvis without tension on the vascular pedicle, no further mesenteric division is needed. An ileoileal anastomosis is performed cephalad to the isolated ileal segment and the mesenteric trap is closed. The bowel clamps are removed and a thorough lavage of the ileal segment is performed with sterile saline. It is the preference of the authors to configure the ileal segment into a U configuration (Fig. 107.4). The antimesenteric border of the ileal segment can then be opened using scissors or the cutting current with little concern for bleeding that usually ceases spontaneously. The segment is folded 180-degrees and the adjoining edges are sutured as full-thickness using continuous locking 4-0 PGA. Once the ileal cap has been formed, it is anastomosed to the opened bladder beginning at the most posterior portion of the bladder incision (Fig. 107.5). Hemostatic clamps may be left on the short ends of the tied sutures in order to identify the most posterior limit of the anastomotic line, thus facilitating placement of the second, reinforcing suture layer between the serosal surfaces of the bladder and ileum. A suprapubic catheter is placed through the bladder wall prior to completion of the first anastomotic closure (Fig. 107.6).

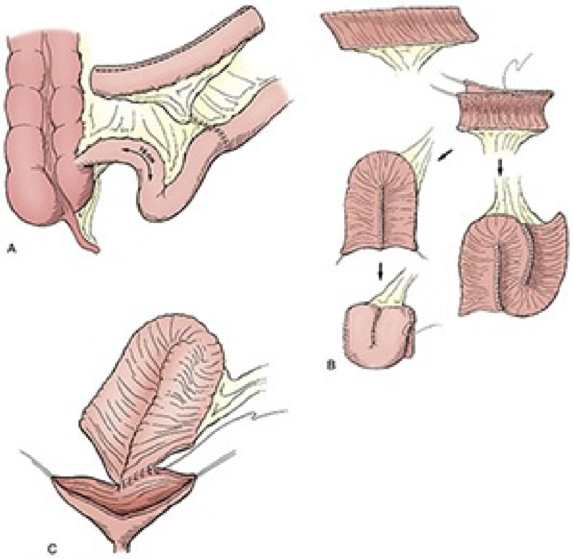

FIGURE 107.3 Ileocystoplasty. **A:** 20- to 40-cm segment of ileum at least 15 cm from the ileocecal valve is removed and opened on its antimesenteric border. Ileoileostomy reconstitutes the bowel. **B:** The opened ileal segment is reconfigured. This can be done in a U, S, or W configuration. It can be further folded as a cup patch. **C:** The reconfigured ileal segment is anastomosed widely to the native bladder. (Reprinted with permission from Adams MC, Joseph DB. Urinary reconstruction in children. In: Wein AJ, Kavoussi LR, Novick AC, et al, eds. *Campbell's Urology*, 9th ed. Philadelphia: WB Saunders, 2007.)

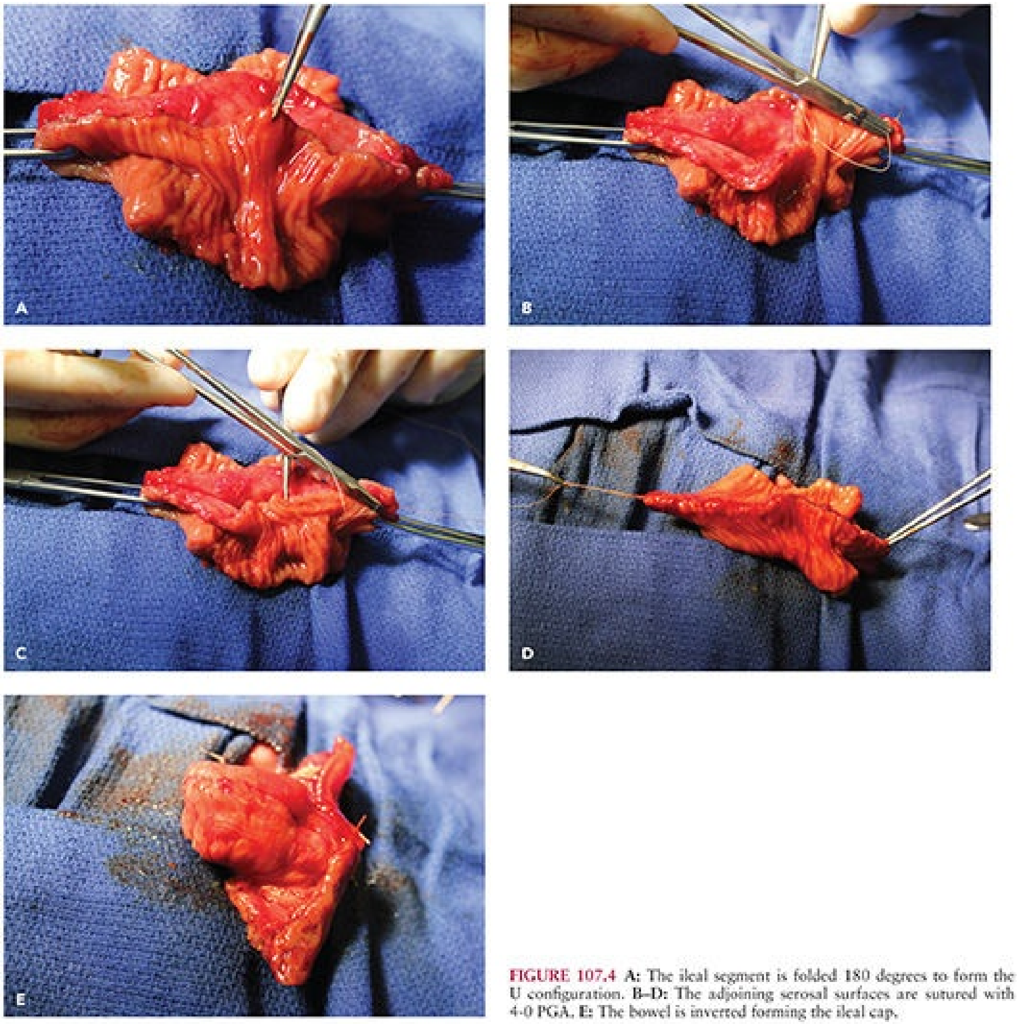

FIGURE 107.4 **A:** The ileal segment is folded 180 degrees to form the U configuration. **B–D:** The adjoining serosal surfaces are sutured with 4-0 PGA. **E:** The bowel is inverted forming the ileal cap.

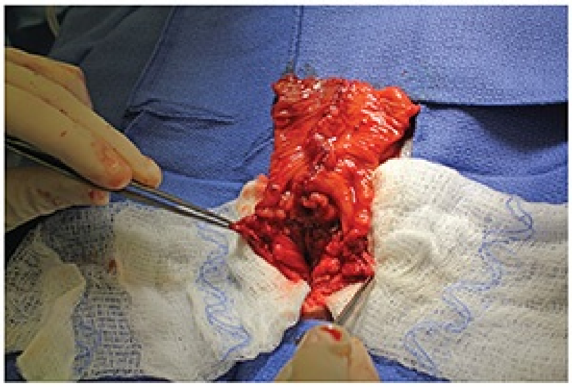

FIGURE 107.5 The ileal cap is anastomosed to the opened bladder starting posteriorly.

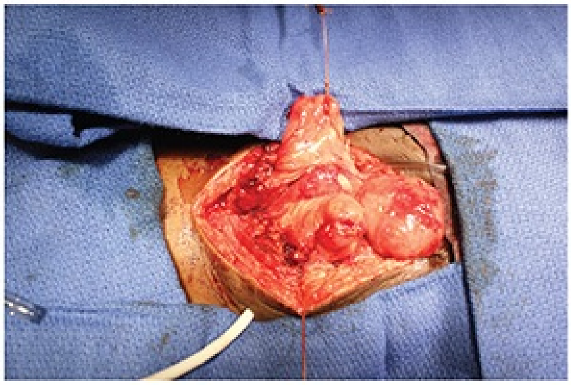

FIGURE 107.6 The completed augmentation cystoplasty anastomosis. The suture tags are on the lateral aspects of the anastomosis. The white suprapubic tube is placed laterally.

Right Colocystoplasty and Mainz Enterocystoplasty

Enterocystoplasty with a segment of ascending colon is based on vascular supply from the ileocolic artery (see Fig. 107.2). Dissection begins at the inferior edge of the cecum and progresses cephalad along the line of Toldt, the peritoneal reflection lateral to the right colon. At the hepatic flexure, the hepatocolic ligament must be divided. Next, the omental attachments to the colon are divided and the omentum is packed into the left upper quadrant with moist lap sponges. The ascending colon is divided at the watershed between the ileocolic and right colic arteries, approximately midway between the cecum and hepatic flexure. The ileum is divided close to the ileocecal valve. An ileocolonic anastomosis is performed and the mesenteric trap is closed. If the appendix will not be used to create a continent catheterizable stoma, an appendectomy is performed at this point. The bowel is folded 180 degrees and the serosal surfaces sutured with 4-0 PGA. The bowel is incised along its antimesenteric border and the edges are sutured full thickness with 4-0 PGA placed in a continuous fashion. The resulting colonic plate is folded once again. This time the full-thickness suture line is placed first and reinforced with a second continuous line of 4-0 PGA. The resulting cup is inverted and anastomosed to the bladder opening as described for the ileocystoplasty. An alternative approach that has gained wide popularity is the Mainz augmentation in which 15 to 30 cm of terminal ileum are isolated in continuity with the right colon and detubularized, anastomosed to each other, and sutured to the cystotomy (Fig. 107.7).

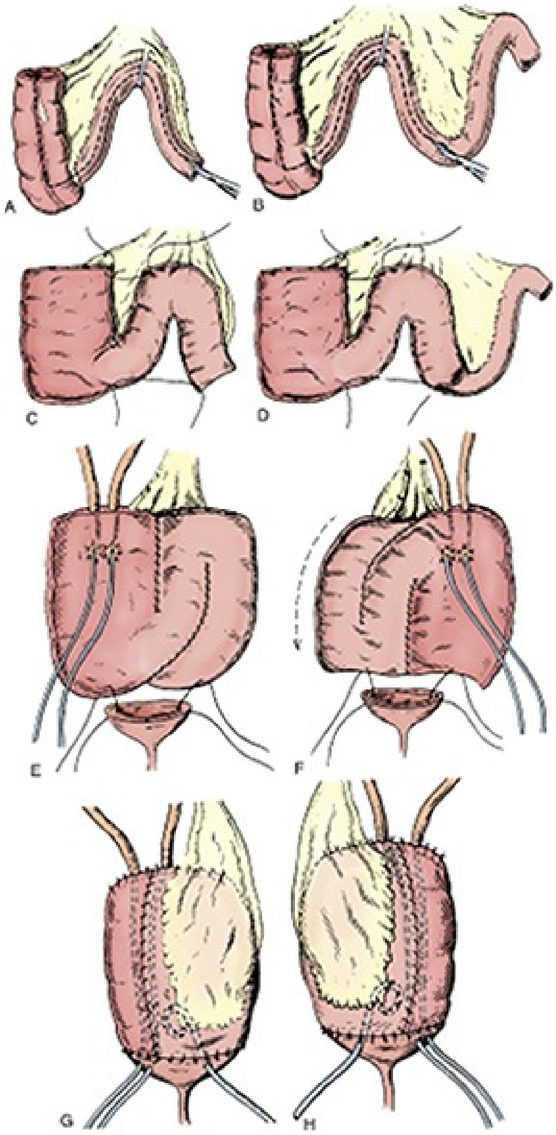

FIGURE 107.7 Mainz ileocecocystoplasty. A and B: The ileal segment is twice the length as the cecal segment. C and D: It is opened on the antimesenteric border. E and F: The ureters can be opened into the opened cecal segment if necessary. G and H: The ileocecal segment is anastomosed to the native bladder. (Reprinted with permission from Thuroff JW, Alken P, Riedmiller H, et al. The Mainz pouch. In: King LR, Stone AR, Websterm GD, et al, eds. *Bladder Reconstruction and Continent Urinary Diversion*. Chicago, IL: Year Book, 1987.)

Sigmoidocystoplasty

Since the diameter of the sigmoid is much greater than that of the ileum, a shorter segment is necessary in order to perform a successful augmentation cystoplasty. The isolated segment derives its blood supply from the sigmoid branches of the inferior mesenteric artery (Fig. 107.8). A mesenteric incision is created proximally and distally and bowel clamps applied to minimize fecal soiling. The sigmoid is divided, and a sigmoidosigmoidostomy performed lateral to the mesentery of the isolated segment (Fig. 107.9). (It is advisable for each surgeon to standardize the side where they perform the sigmoidosigmoidostomy in the event that reoperation is necessary in the future.) Two methods are available for anastomosing the bowel segment to the bladder. In the first, the proximal and distal ends of the segment are closed, and the bowel is opened along its antimesenteric border and sutured to the bladder opening. In the second, the bowel is opened along its antimesenteric border first and then folded 180 degrees into a U shape prior to suturing it to the bladder. The latter method likely disrupts the high unit contractions of the sigmoid more than the first; however, it requires that a greater length of sigmoid be isolated.

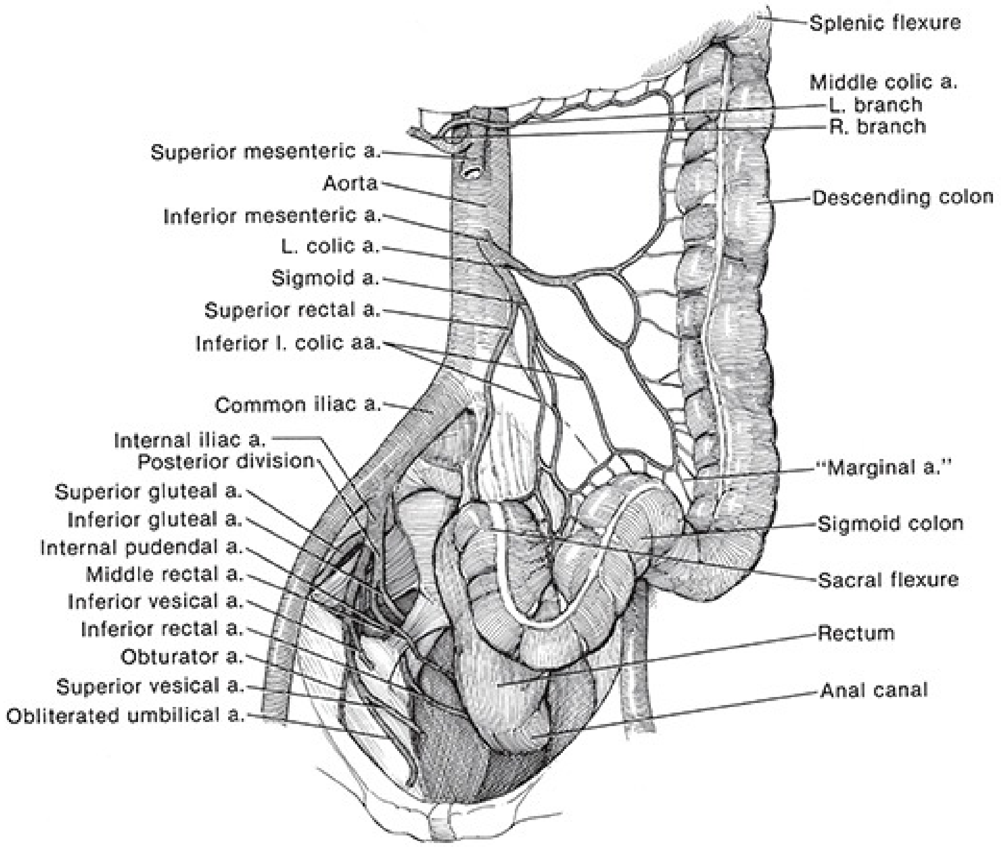

FIGURE 107.8 Blood supply to the descending and sigmoid colon and rectum. (Reprinted with permission from Hinman F Jr, ed. Gastrointestinal tract. In: *Hinman's Atlas of Urosurgical Anatomy*. Philadelphia: WB Saunders, 1993.)

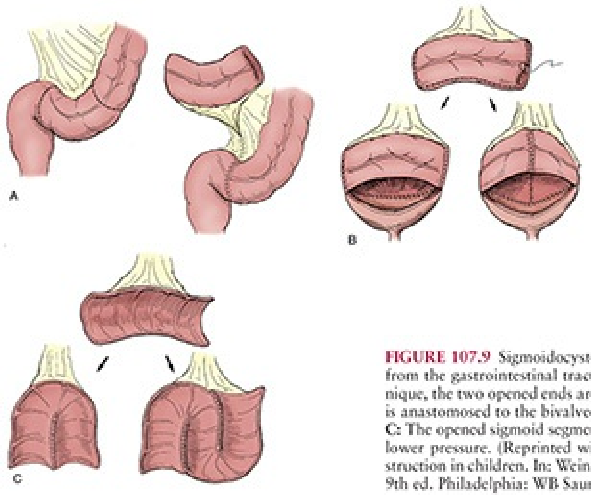

FIGURE 107.9 Sigmoidocystoplasty. **A:** A sigmoid segment of adequate length is removed from the gastrointestinal tract and a colocolostomy is performed. **B:** In the Mitchell technique, the two opened ends are closed. The antimesenteric border is incised and the segment is anastomosed to the bivalved bladder. It may be rotated 180 degrees to allow an easy fit. **C:** The opened sigmoid segment can be reconfigured into a U or S configuration, which may lower pressure. (Reprinted with permission from Adams MC, Joseph DB. Urinary reconstruction in children. In: Wein AJ, Kavoussi LR, Novick AC, et al, eds. *Campbell's Urology*, 9th ed. Philadelphia: WB Saunders, 2007.)

Gastrocystoplasty

The bladder may be augmented with a gastric segment derived from either the antrum or the body of the stomach. When antral gastrocystoplasty is performed, the enteric stream is reconstructed using a Billroth I anastomosis (gastroduodenostomy). This procedure is now rarely performed in children since resection of the antrum has been associated with delayed gastric emptying, gastric dumping syndrome, and feeding difficulties. Currently, most surgeons prefer the use of the stomach body instead. A segment between 10 and 20 cm is marked along the greater curvature of the stomach and drawn as a rhomboid that extends toward the lesser curvature, ending 1 cm from the edge so as not to interrupt branches of the vagus nerve. Two arterial supplies exist to the greater curvature of the stomach: (a) the right gastroepiploic artery, derived from the right gastric artery, and (b) the left gastroepiploic artery, from the splenic artery (Fig. 107.10). If the right gastroepiploic artery is chosen, the gastric segment should be obtained from higher on the greater curvature, lower if based on the left (Fig. 107.11). The gastroepiploic arteries supply the stomach with anterior and posterior branches that must be divided before the segment can be excised from the stomach. Atraumatic intestinal clamps are applied in parallel at the proposed incision sites on the stomach. Alternatively, an intestinal stapling device can be used to divide the stomach; however, the staples must be removed later. The vascular pedicle must be retroperitonealized in order to prevent internal hernia formation. A window is created in the transverse mesocolon that accepts the gastric augment and its vascular pedicle. The segment is passed posterior to the mesocolon and exits a second window that has been created in the small bowel mesentery inferiorly. If the vascular pedicle is too short, additional branches between the gastroepiploic artery and the stomach must be divided. The stomach is sutured to the bladder beginning along the posterior aspect of the cystotomy.

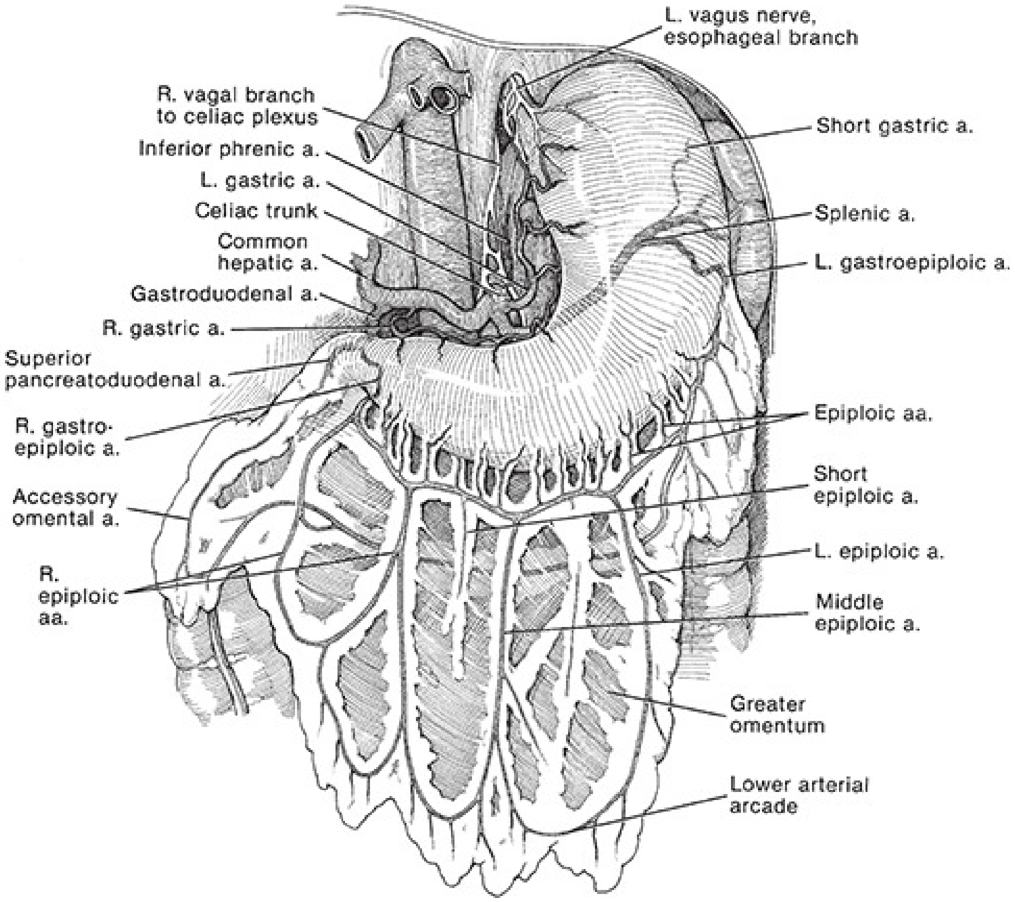

FIGURE 107.10 Blood supply to the anterior aspect of the stomach and greater omentum. (Reprinted with permission from Hinman F Jr, ed. Gastrointestinal tract. In: *Hinman's Atlas of Urosurgical Anatomy*. Philadelphia: WB Saunders, 1993.)

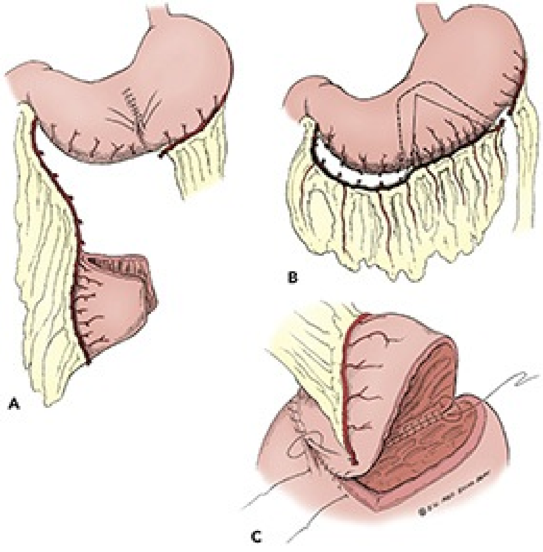

FIGURE 107.11 Gastrocystoplasty using the body of the stomach. **A:** A gastric segment of the body is mobilized on the right gastroepiploic artery. The left vessel may also be used; neither vessel as a pedicle should be free floating through the peritoneum. **B:** A longer gastric segment along the greater curvature with a wider apex provides more surface area for augmentation. **C:** The gastric segment is anastomosed to the bivalved bladder with the mucosa inverted. (Reprinted with permission from Adams MC, Joseph DB. Urinary reconstruction in children. In: Wein AJ, Kavoussi LR, Novick AC, et al, eds. *Campbell's Urology*, 9th ed. Philadelphia: WB Saunders, 2007.)

Ureterocystoplasty

Unlike enterocystoplasty, ureterocystoplasty does not require a midline transperitoneal incision. The entire procedure can be performed retroperitoneally through a flank incision, to perform the nephrectomy and harvest the proximal portion of the ureter, and a Pfannenstiel incision, through which the augmentation is performed. Only a midline incision should be considered when two functioning kidneys exist, since a transureteroureterostomy will be required in order to reestablish continuity of the upper urinary tract after distal ureter has been harvested (Fig. 107.12). Following the nephrectomy, careful mobilization of the ureter from its retroperitoneal location includes dissection of all surrounding adventitia away from the peritoneal lining toward the ureter itself. The ureter is then passed into the pelvis. A midline cystotomy is created such that the posterior portion of the incision includes the ureterovesical junction. The ureter, too, is incised along its anterior aspect. A spherical reservoir can be created by folding the proximal end of the ureter toward the cystotomy in an inverted U and suturing the adjoining edges of the ureter to itself. The remainder of the anastomosis between the ureter and the bladder is performed as in enterocystoplasty, beginning at the posterior aspect of the cystotomy and proceeding in an anterior fashion. Drainage tubes are placed through the native bladder muscle tissue.

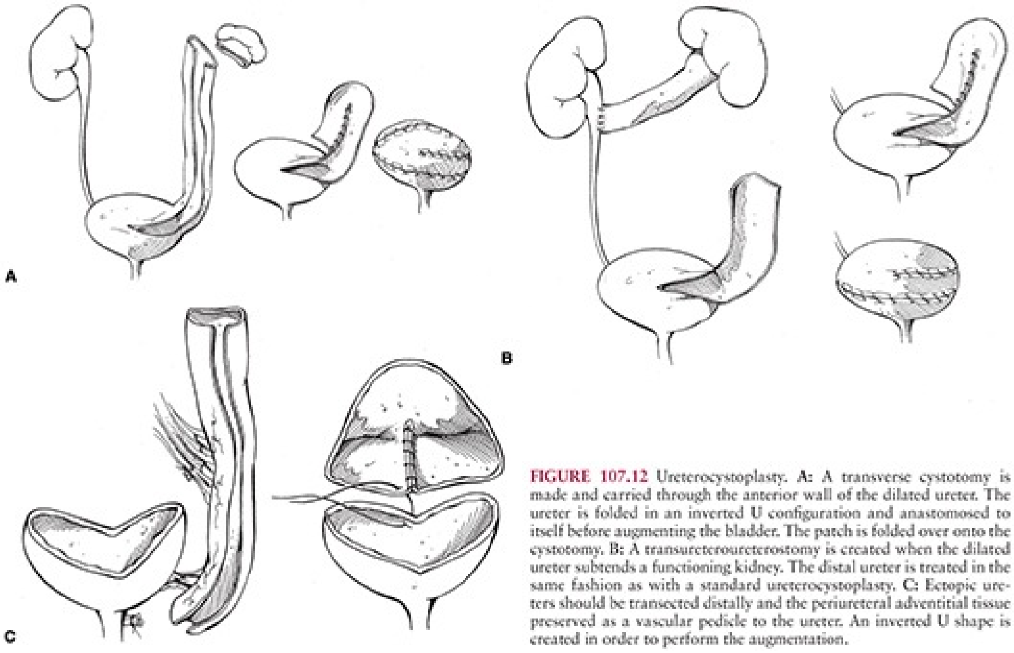

FIGURE 107.12 Ureterocystoplasty. **A:** A transverse cystotomy is made and carried through the anterior wall of the dilated ureter. The ureter is folded in an inverted U configuration and anastomosed to itself before augmenting the bladder. The patch is folded over onto the cystotomy. **B:** A transureteroureterostomy is created when the dilated ureter subtends a functioning kidney. The distal ureter is treated in the same fashion as with a standard ureterocystoplasty. **C:** Ectopic ureters should be transected distally and the periureteral adventitial tissue preserved as a vascular pedicle to the ureter. An inverted U shape is created in order to perform the augmentation.

Urinary and Abdominal Drainage Following Augmentation Cystoplasty

If an incontinence procedure has not been performed, an appropriately sized urethral Foley catheter is used. However, since the retention balloon can cause pressure necrosis of the bladder neck following incontinence procedures, some surgeons would instead use a Rob-Nel catheter or Silastic feeding tube that may be secured with 3-0 silk sutures passed through the bladder and abdominal wall and tied over a cotton bolster. Additionally, a suprapubic Malecot catheter should be placed through a separate incision in the native bladder and brought out through the anterior abdominal wall. It is advised that this tube in particular be secured with 3-0 nylon sutures. Irrigation with sterile saline should be instituted on postoperative day 3 in an effort to cleanse the newly augmented bladder free of the copious amounts of mucus that the enteric segments produce. Jackson-Pratt closed-system vacuum drains may be employed briefly following surgery and removed when minimal peritoneal drainage exists. In patients with ventriculoperitoneal shunts, cerebrospinal fluid can be confused for persistent peritoneal drainage. Particularly in these patients, the surgeon should resist temptation to maintain these drains for an extended period of time.

Postoperative Follow-up

Three weeks postoperatively, the urethral catheter or catheter within the catheterizable stoma should be removed leaving the suprapubic tube in place for safety. A cystogram may be performed to demonstrate a healed anastomosis prior to catheter removal. In cases of continent catheterizable stoma placement, patients should learn to CIC at this time and cap the suprapubic tube. Once the patient adequately demonstrates he or she can catheterize without problems, the suprapubic tube may be used.

COMPLICATIONS

Gastrointestinal Effects

The two most likely gastrointestinal complications following augmentation cystoplasty in children are diarrhea and vitamin B_{12} deficiency (each in up to 23%). Small bowel obstruction may occur in approximately 3% of patients and is no more likely with any one particular segment of bowel. Gastrocystoplasty is associated with a greater risk for small bowel obstruction as a function of the difficulty in retroperitonealizing the vascular pedicle to the gastric patch. The potentially free-floating pedicle can permit internal herniation of bowel loops that in later stages compromises vascularity to the gastric patch itself.

Diarrhea, a complication most often found following the use of the ileocecal valve (up to 23%), may also be seen after standard ileocystoplasty, although less frequently (11%). For this reason, use of the ileocecal valve is not advocated when other segments will serve just as well. The sigmoid, for instance, dilates and lengthens as a consequence of constipation, thus affording the surgeon a more redundant segment with which to augment. An additional advantage of sigmoid is its proximity to the bladder.

Vitamin B_{12} deficiency can be avoided by limiting the length of small bowel harvested and in particular by preserving the terminal 20 cm of ileum, the major site of B_{12} absorption. Ileocecal augmentation cystoplasty carries a greater risk for vitamin B_{12} deficiency (23%) as compared with standard ileocystoplasty (11%), yet one is unlikely to encounter this deficiency at all since in the majority of circumstances a limited portion of nonterminal ileum is employed. However, when vitamin B_{12} absorption is hampered, the deficiency may not manifest for at least 3 years since body stores are sufficiently ample to maintain serum levels. Vitamin B_{12} may be administered prophylactically as an intramuscular injection beginning 3 years after enterocystoplasty. Alternatively, serum levels may be assessed periodically and replacement vitamin B_{12} administered as appropriate.

Metabolic Effects

Ileocystoplasty and Colocystoplasty

Despite the incorporation of intestine into the urinary tract, its absorptive and secretory capacity is retained: Chloride, ammonium, hydrogen ions, and organic acids are readily absorbed and bicarbonate ions are secreted into the urine. The resultant hyperchloremic metabolic acidosis is driven by the absorption of ammonium ions that are followed by chloride in an attempt to maintain electroneutrality. The amount of bowel used, length of time that bowel mucosa is in contact with urine, and the degree of underlying renal impairment contribute to the severity of the metabolic disturbance. Conversely, acidosis is rarely seen in patients with normal renal function, and any measurable increase in serum chloride and decrease in serum bicarbonate is subtle. Mild cases of metabolic acidosis can be managed with oral sodium bicarbonate (1 to 3 mEq/kg/day) with the goal being an increase in serum bicarbonate to a value greater than 20 mEq/L. Severe acidosis requires intravenous administration of bicarbonate, usually as dextrose 5% with 1/4 normal saline and 50 mEq/L of sodium bicarbonate. Hyperchloremic metabolic acidosis may occur following augmentation either with ileum, cecum, colon, or sigmoid but is most common following sigmoidocystoplasty.

Use of jejunum is associated with a pattern of metabolic derangement distinct from any other segment of bowel: a hypochloremic, hyponatremic, hyperkalemic metabolic acidosis. For this reason, it is recommended that jejunum not be used in pediatric augmentation cystoplasty, especially when renal function is poor.

As a consequence of the net secretion of chloride and hydrogen ions across the gastric mucosa, augmentation with stomach results in a hypochloremic metabolic alkalosis in 3% to 24% of the patients (10–14). This effect can be used to advantage in patients with renal dysfunction and acidemia, who will demonstrate decreased serum chloride and increased serum bicarbonate following gastrocystoplasty (12,15,16). In those patients whose renal dysfunction is characterized by a concentrating defect, gastrointestinal illness with vomiting can precipitate significant alkalosis that must be treated with intravenous fluid containing sodium chloride. Milder cases can be treated with oral salt supplementation, or inhibitors of histamine-2 (i.e., cimetidine) or the gastric acid H^+/K^+ ATPase pump (i.e., omeprazole) (17,18). It has also been reported that alkalosis occurs in the absence of gastrointestinal illness and may still be severe enough to require resection of a portion of the gastric segment. Alternatively, addition of ileum may balance the metabolic abnormality.

Bladder Perforation

Perforation is the most serious complication of augmentation enterocystoplasty, and patients may present critically ill despite few localizing signs and symptoms. The condition should immediately be suspected when an augmented patient presents with fever and abdominal pain no matter how mild the symptoms. Shoulder pain secondary to diaphragmatic irritation from urine in the peritoneal cavity has also been reported (19). Which gastrointestinal segment carries the greatest risk of perforation is debatable. The Indiana group reported perforations in 16.5% of sigmoid cystoplasties, 8% of gastrocystoplasties, and 4.5% of ileocystoplasties (9). Conversely, the Boston Children's Hospital experience found a greater incidence of perforations among children who had received augmentation with ileum rather than with stomach or sigmoid, 9%, 3%, and 3%, respectively (19). Therefore, any child is potentially at risk irrespective of the segment used. The underlying etiology for all perforations is believed to be ischemia within the bowel wall as a consequence of either overdistension from infrequent emptying or high-pressure contractions or even reconfiguration by detubularization (19). In addition to late perforations, intestinal anastomotic leakage occurring early following sigmoidosigmoidostomy is a liability that must be considered when using this segment, particularly in a patient with a ventriculoperitoneal shunt in whom spillage of fecal material within the peritoneum can be lethal.

Patients suspected of having bladder perforation should undergo fluid resuscitation and receive intravenous broad-spectrum antibiotics and Foley catheter drainage while the evaluation is underway. A standard cystogram may miss up to 33% of bladder perforations; therefore, computerized tomography cystograms are advocated (20). While some have successfully employed nonoperative management, surgical exploration with resection of necrotic tissue and primary closure of the defect should be performed in a gravely ill patient, or when the patient fails to improve during nonoperative management (21).

Hematuria–Dysuria Syndrome

This disadvantage, occurring in 9% to 70% of patients who have undergone a gastrocystoplasty, presents with perineal pain, dysuria, hematuria, and skin excoriation around either the urethral meatus or the stoma of a catheterizable channel (10,11,22). Sensate patients are more frequently symptomatic than those with diminished sensation, 68% as compared with 25%; however, any patient with incontinence is at risk from clinically significant hematuria–dysuria syndrome (14). A recent study of 10 children with hematuria–dysuria identified a positive correlation between the presence of infecting *Helicobacter pylori*, reduced urine pH, and the presence of symptoms following gastrocystoplasty. The authors recommend evaluating all patients who are under consideration for a gastric augment for the presence of *H. pylori* and treating the infection before performing surgery (23,24). Oral therapy with histamine-2 or H^+/K^+ ATPase blockers should be helpful in symptomatic patients. If prolonged catheterization is anticipated, then bladder irrigations should be performed with a sodium bicarbonate containing solution.

OUTCOMES

Improved Bladder Dynamics

The immediate goal of augmentation cystoplasty should be that intravesical storage pressure decreases well below the threshold of 40 cm H_2O, thus averting progressive upper tract deterioration. Although any gastrointestinal segment can provide a sufficiently compliant augment if it is very long and fully detubularized, most authors agree that, for a given length of bowel, ileum provides the greatest compliance of any segment (25–30). Of 323 patients who had undergone enterocystoplasty in one large review, 6% required an additional augmentation because of persistently elevated intravesical pressure. Colocystoplasty and gastrocystoplasty patients were 10 times more likely to need a repeat procedure as compared with those having undergone an ileocystoplasty (31). The thicker muscular wall of the cecal, ascending, and sigmoid colon segments is most likely responsible for the strong mass contractions that occur, some up to 110 cm H_2O (32). Others have noted that gastric segments in particular display rhythmic sinusoidal contractions that persist following cystoplasty in as many as 80% of patients, irrespective of the portion used (antrum versus body) (16,18,31). These findings should not entirely discourage use of gastrointestinal segments other than ileum because advantages for their application in bladder reconstruction do exist. However, consideration should be given to their use in composite grafts, such as in gastroileocystoplasty. Ureterocystoplasty, by comparison, offers an alternative to ileocystoplasty that can reliably provide similar increases in bladder capacity and compliance without the gastrointestinal, metabolic, infectious, and lithogenic complications of enterocystoplasty (8).

Urinary Tract Infection

Regardless of the segment chosen, persistent bacteriuria is common following augmentation cystoplasty occurring up to 95% (33,34). The Indiana group reported symptomatic urinary tract infection in 23% of ileocystoplasties, 17% of colocystoplasties, 13% of cecocystoplasties, and only 8% of gastrocystoplasties which suggests that bacterial colonization may be impeded by the reduced urine pH in bladders augmented with stomach. Overall, 13% of patients had febrile urinary infections, and although gastrocystoplasties were less likely to be associated with febrile UTI, statistical significance was not met. A more recent study identified a positive urine culture in 95% of colocystoplasty patients, and only 13% of patients receiving a gastric patch augment furthering the notion that gastric augments are protective against colonization (33). Despite these data, others have reported a greater incidence of asymptomatic bacteriuria (66%) and symptomatic UTI (25%) in patients who had undergone a gastrocystoplasty than had previously been demonstrated, thus dispelling conventional wisdom (15). Symptomatic cystitis, defined as incontinence, suprapubic pain, foul-smelling urine and perhaps increased mucus production, may be more likely when CIC is performed sporadically and incompletely or when mucus and stones serve as a nidus for colonizing bacteria. Any patient with symptomatic UTI should be considered for antimicrobial therapy irrespective of the form of augmentation performed.

Calculi Formation and Mucus Production

The reported incidence of bladder calculi has ranged between 8% and 52% of patients following augmentation cystoplasty, yet the occurrence of bladder calculi may not be a specific complication of augmentation cystoplasty (34–38). Instead, poor patient compliance with CIC, colonization with urea-splitting bacteria, and the presence of mucus to serve as a nidus for the aggregation of salts may be the trifecta that results in calculus formation. Barroso et al. (39) found a similar incidence of bladder calculi in patients performing CIC with (10%) and without (7%) augmented bladders: overall, 64% were asymptomatic and 88% had chronic bacteriuria. Fifty percent of the patients demonstrated difficulty in catheterization whether performed via urethra or Mitrofanoff channel, thus implicating residual urine in the genesis of calculi (39). Commonly composed of magnesium ammonium phosphate (struvite), bladder calculi are most likely the result of persistent bacteriuria with urease-producing organisms. However, an inherent predisposition for struvite stone formation has been found in some individuals whose mucus contains increased amounts of calcium, magnesium, and phosphate (40). Additionally, some stone formers who had been identified as hypocitraturic have been treated with oral potassium citrate, thus averting recurrent stone formation (38). By virtue of lesser mucus production and bacteriuria than either ileum or colon, stomach is least likely to be associated with bladder calculi. Mucus production from ileal segments does decrease over time as a result of villous atrophy, a feature not characteristic of colonic epithelium.

CHAPTER 108 THE MITROFANOFF AND MALONE ANTEGRADE CONTINENCE ENEMA PROCEDURES IN PEDIATRIC URINARY TRACT RECONSTRUCTION

MARK P. CAIN

MITROFANOFF PROCEDURE

The Mitrofanoff principle has now been used for over 30 years but still stands as one of the major advancements to continent urinary reconstruction for children and adults. Earlier innovations—including clean intermittent catheterization (CIC), bladder augmentation, and a variety of bladder neck tightening procedures—created the foundation that made continent bladder reconstruction possible. The technically difficult problem was creating a bladder outlet that was tight enough to ensure continence but wide enough to allow reliable catheterization over a lifetime. In addition, many of these patients have physical disabilities that prevent easy access to the urethra, making independent urethral catheterization challenging. The concept of a continent catheterizable abdominal channel was introduced by Paul Mitrofanoff in 1980 (1) and has since been widely adopted as an integral part of urinary tract reconstruction for continence in most pediatric centers worldwide. This principle involves creation of a flap-valve continence mechanism for a conduit that is tunneled into a low-pressure urinary reservoir that can then be catheterized and emptied via an abdominal stoma (Fig. 108.1).

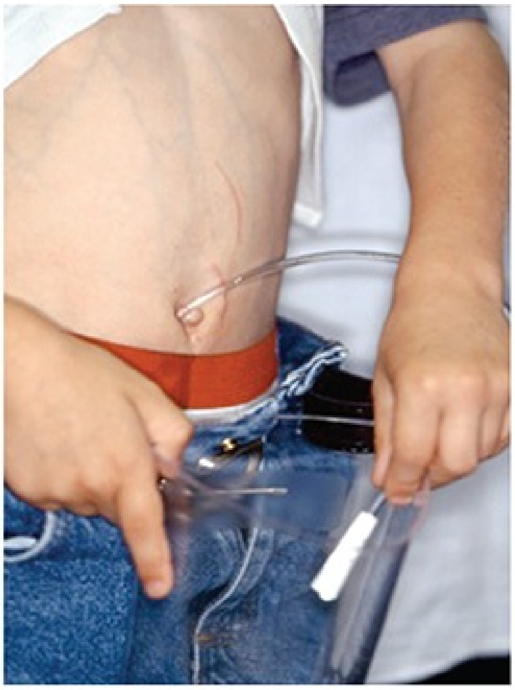

FIGURE 108.1 Umbilical Mitrofanoff stoma allowing catheterization in the sitting or standing position.

There are multiple surgical options for creating the Mitrofanoff channel. Appendicovesicostomy has by tradition been used because of availability, the reliable blood supply, adequate lumen for catheterization, and supple muscular wall. Long-term follow-up has shown that appendicovesicostomy provides a durable channel with minimal late complications (2,3). In the absence of a suitable appendix, or in conditions where the appendix is used for an alternate procedure (such as for a Malone antegrade continence enema [MACE channel]), there are several other options that have been described. The most reliable alternatives have been the Monti–Yang ileovesicostomy, ureterovesicostomy, and continent bladder tube.

Diagnosis

The Mitrofanoff procedure can be performed with essentially any underlying bladder pathology. The most frequent diagnosis for children undergoing the procedure is neuropathic bladder, usually due to myelomeningocele. This procedure has also been described for reconstruction in patients with exstrophy–epispadias, cloacal anomalies, prune belly syndrome, posterior urethral valves, and other conditions. Although many of these children will require a bladder outlet procedure to provide urinary continence, some will have an intact and continent bladder outlet and the Mitrofanoff channel will provide an alternative to urethral catheterization. This is especially useful in wheelchair-bound patients who cannot access their perineum independently and also in patients with normal urethral sensation, in whom catheterization can be traumatic both physically and psychologically.

Indications for Surgery

In the past, the primary indication for bladder reconstruction was for upper urinary tract preservation. In the era of aggressive use of anticholinergics and intermittent catheterization in young patients, the more common indication for a Mitrofanoff channel is for urinary continence and convenient, independent bladder management for the patient. All patients should undergo a trial of CIC to demonstrate that they are reliable and able to comply with a daily routine prior to bladder reconstruction.

Alternative Therapy

The most common alternative to continent bladder reconstruction with a Mitrofanoff stoma is anticholinergic therapy with clean intermittent urethral catheterization. With careful attention to catheterization schedules and fluid intake, social dryness can be achieved in many patients with neuropathic bladder and other underlying bladder pathology without the need for surgical intervention.

Less frequently used alternatives are long-term incontinent cutaneous vesicostomy, incontinent ileovesicostomy channel, and conduit urinary diversion. Although these are considered suboptimal in the era of continent urinary reconstruction, there will be a subset of patients who are unable to care for themselves because of physical, mental, or psychosocial problems, and the incontinent diversion provides a safer long-term option for these patients.

In the rare patient with a completely nonusable bladder, a continent urinary reservoir with a continent catheterizable channel is another alternative.

Surgical Technique

Many centers today have adopted outpatient oral mechanical bowel preparation with admission to the hospital the day of surgery. A urine culture should be obtained preoperatively and urinary tract infection treated. Perioperative intravenous antibiotics should be given for 24 hours. Potential sites for stomal location should be determined preoperatively, with the patient in the sitting and supine position.

Surgical exposure is usually obtained through a small lower midline transabdominal incision that, if needed, may be carried around the umbilicus to leave enough fascia to close the abdomen without compromising an umbilical stoma. A lower transverse Pfannenstiel incision will also allow adequate exposure for both bladder augmentation and the Mitrofanoff stoma in thin patients. Laparoscopy and robotic-assisted laparoscopic surgery has been used in some centers to either to assist in mobilization of the appendix and colon (allowing a smaller abdominal incision to complete the reconstruction without compromising exposure), or to complete the entire procedure, avoiding the larger abdominal incision. The robotic approach has the clear advantage over a pure laparoscopic approach of technically easier intracorporal sewing.

Appendicovesicostomy

The right colon is mobilized beyond the hepatic flexure to allow maximal freedom of the appendiceal mesentery. If the appendix is retrocecal in location, it is mobilized carefully from the cecal attachments with extra caution to avoid injuring the appendiceal artery, which is a branch of the ileocolic artery (Fig. 108.2). In some cases, there is significant peritoneal inflammation due to the presence of a ventriculoperitoneal shunt, and the peritoneal incision must be carried medial to the ileocecal valve to adequately mobilize the appendix. When the length of appendix is inadequate, it can be extended by incorporating a segment of distal cecum as described by Cromie et al. (4). Prior to detaching the appendix, the bladder is mobilized to ensure that the bladder and appendix can easily reach the chosen site for the abdominal stoma without tension. At our center, we now preferentially implant the Mitrofanoff channel in the anterior bladder wall, usually in an extravesical fashion, especially when performing the procedure without simultaneous bladder augmentation. This avoids a large cystotomy, decreasing bladder irritability postoperatively, and also allows improved fixation of the entire channel/bladder to the posterior abdominal wall. In cases where the bladder needs to be opened, the cystotomy is made to the left of the midline for a right lower quadrant appendicovesicostomy or in a wide inverted U-shaped anterior bladder incision for an umbilical stoma. The appendix is detached from the cecum either sharply or with a stapling device, and the cecum is closed with absorbable and permanent sutures. The mesentery to the appendiceal artery can be freed from the cecal mesentery to allow complete mobilization of the appendix if needed (Fig. 108.3). The terminal end of the appendix is then opened, and the channel is irrigated with antibiotic solution. A 12Fr to 14Fr catheter is passed to ensure that the appendix has an adequate lumen. If necessary, the appendix can be gently dilated with serial sounds. If bladder augmentation is to be performed, the segment of bowel is isolated, harvested, and reconfigured appropriately. If an additional segment of intestine is required for the Mitrofanoff (e.g., Monti–Yang) channel, it can be harvested simultaneously. The site of the bladder hiatus is then selected, again ensuring that it can easily reach the posterior abdominal wall fascia without tension. The site of the hiatus is opened wide enough to allow the appendix to pass without any tension, and a vessel loop is passed through the hiatus for traction. A submucosal bladder tunnel is then created using sharp dissection. Placing several traction sutures on the bladder to flatten out the posterior bladder wall facilitates this dissection. The orientation of the tunnel should be directed away from the bladder outlet and trigone to prevent painful catheterization postoperatively. The tunnel length should be at least 2.5 cm in length. It is occasionally helpful to inject 1:200,000 epinephrine along the path of the submucosal tunnel to facilitate the dissection and minimize bleeding. The terminal end of the appendix is then passed through the bladder hiatus and submucosal tunnel. The appendix is spatulated and secured distally with two 4-0 absorbable sutures incorporating full-thickness bites of the appendix and detrusor muscle and mucosa. The remainder of the anastomosis is completed using 4-0 or 5-0 absorbable sutures, securing the bladder mucosa to the appendix. The appendix is also secured at the level of the bladder hiatus using several 4-0 absorbable sutures. The channel is catheterized with a 12Fr or 14Fr catheter to ensure that it passes easily across the hiatus and submucosal tunnel. With an extravesical technique, the detrusor muscle is incised the entire length of the proposed tunnel (3 to 4 cm) using fine needle point cautery, and lateral detrusor flaps are raised using sharp dissection. A small incision is made in the mucosa at the distal end of the tunnel, and the appendix is secured with two 4-0 sutures to the mucosa and bladder muscle. The remainder of the anastomosis is carried out in a mucosa to mucosa fashion with either 4-0 or 5-0 suture. It is helpful to place a catheter across the anastomosis during the mucosal anastomosis. The detrusor flaps are then secured over the appendix with 3-0 interrupted absorbable sutures, with occasional bites that include both detrusor and serosa of the appendix. A right-angle clamp is placed periodically within the tunnel to ensure that the closure is not too tight. The appendix is secured at two sites at the detrusor hiatus. The stomal site is then selected, again taking care to ensure that the bladder hiatus can reach the posterior fascia without tension. A U-shaped (umbilical) or V-shaped skin incision is made at the stomal site, and the flap is freed sharply to the level of the fascia. A cruciate incision is made in the fascia and widened to allow passage of an index finger. The appendix is then brought through the fascial opening and the appendiceal/bladder hiatus is secured to the posterior fascial wall using 3-0 nonabsorbable sutures, taking care not to angulate or compress the appendiceal mesentery (Fig. 108.4). This maneuver ensures a short, straight extravesical appendix channel, which will minimize the potential for traumatic catheterization and creation of a false passage. With an extravesical implant technique on the anterior bladder wall, the detrusor closure sutures can also be used to fix the bladder to the posterior abdominal wall, further securing the closure and continence mechanism. The stomal end of the appendix is then spatulated on the antimesenteric side, and if there is redundant appendix, it is amputated. The stomal anastomosis is secured using interrupted 4-0 absorbable sutures (Fig. 108.5). The stoma is then catheterized multiple times with the bladder both distended and empty to ensure that there is no angulation in the channel. A 12Fr catheter is left indwelling for 3 to 4 weeks before initiating intermittent catheterization.

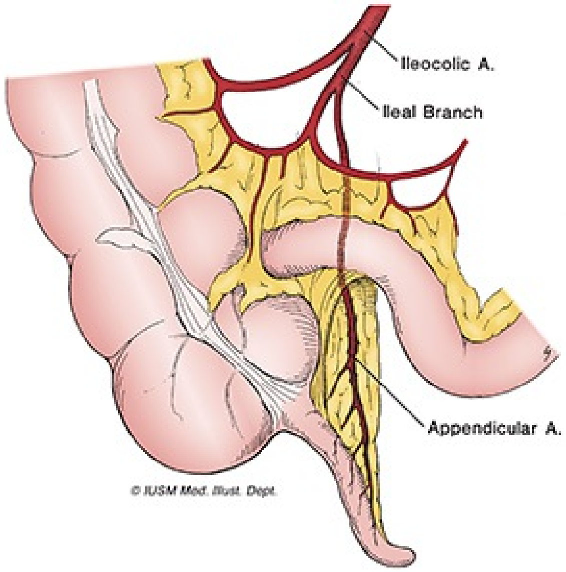

FIGURE 108.2 Vascular anatomy of appendicular artery.

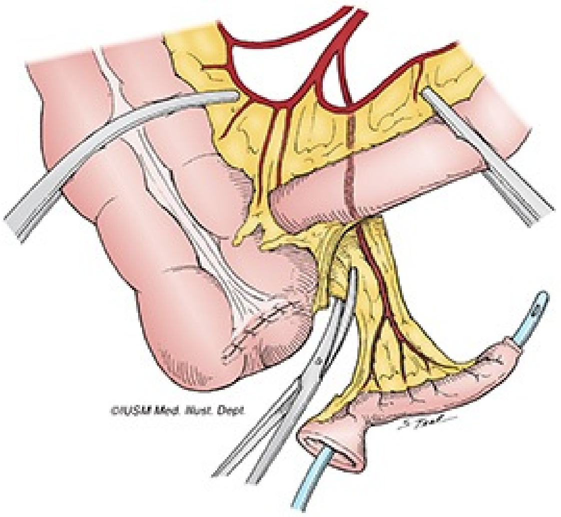

FIGURE 108.3 The mesentery to the appendix can be mobilized carefully, taking care not to injure the appendicular artery.

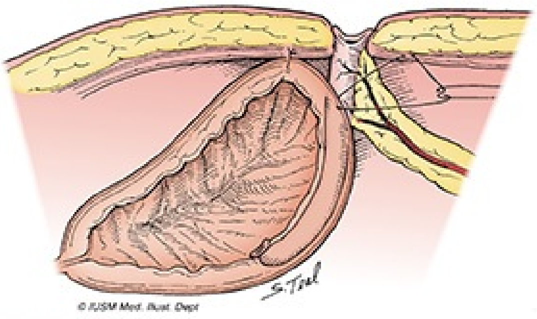

FIGURE 108.4 The bladder is secured to the posterior abdominal fascia to avoid redundancy in the extravesical channel, which can be a source of late catheterization problems.

FIGURE 108.5 The skin stoma is completed by securing the wide-based V flap of skin into the spatulated channel.

When both Mitrofanoff and MACE channels are indicated, and the appendix is of adequate length to create both channels, it can be split, with the majority of the mesoappendix left intact with the Mitrofanoff segment, basing the blood supply to the appendiceal stump off the cecal artery. In some cases, the appendix is too short to use for both channels, but in this circumstance, the appendix can still be used for both channels, utilizing one of the described stapling techniques to extend the proximal portion of the appendix into the cecum for the MACE channel (5,6).

Monti–Yang Ileovesicostomy

The concept of retubularized ileum as a replacement for the appendicovesicostomy was introduced in 1997 (7,8), and it has quickly become the ideal alternate to appendix as a choice for the Mitrofanoff channel. Several large series with intermediate follow-up have confirmed the equivalent outcomes for the Monti–Yang channel and appendicovesicostomy (9). The growing indications for and use of the MACE channel have led to preservation of the appendix for the appendicocecostomy stoma and the need for alternatives for a bladder channel. Because some of the children will also undergo bladder augmentation at the time of reconstruction, the Monti–Yang channel can be easily constructed from a segment of the bowel harvested for augmentation.

A 2.5- to 3-cm segment of intestine is harvested with a well-vascularized segment of mesentery (Fig. 108.6). If ileal augmentation is planned, the Monti–Yang segment can be easily harvested from the distal end of the segment with a shared mesentery. The ileal segment is opened on the antimesenteric side (Fig. 108.7). It can be opened slightly off the midline to provide a longer segment for implanting into the bladder. The opened segment is then retubularized transversely in two layers over a 14Fr catheter. The bowel mucosa is approximated with running 5-0 or 6-0 absorbable sutures and the muscular layer is closed with running or interrupted 4-0 absorbable sutures (Fig. 108.8A and B). The stomal end is not closed initially, providing wide spatulation of the antimesenteric side of the tube for later stomal anastomosis. The technique of implanting the tube into the bladder and creating a stoma is identical to that for appendicovesicostomy (Fig. 108.9). The Monti–Yang tube can be created out of any segment of intestine with good results. If there is inadequate bladder volume for creation of a submucosal tunnel, the tube can be implanted into a segment of bowel using an extravesical technique. Care must be taken to adequately secure the channel in the serosal tunnel. We have found that it is helpful to secure the entire tunnel length to the posterior fascial wall to prevent breakdown of the thin intestinal muscular backing during repetitive bladder filling due to effacement/breakdown of the serosal tunnel, which may be a potential cause for late incontinence. A 12Fr catheter is left across the channel for 3 to 4 weeks before initiating intermittent catheterization. The Monti channel can also be used for the MACE channel, with two channels created side by side (Fig. 108.10).

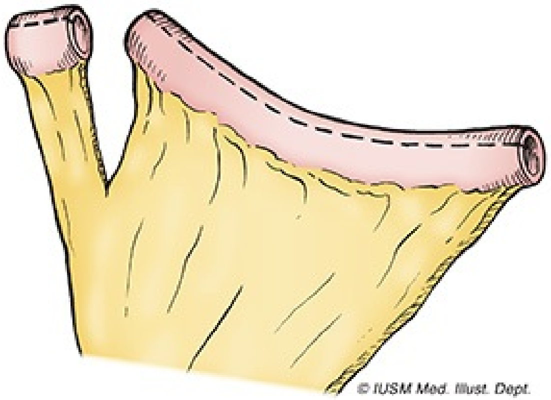

FIGURE 108.6 A 2.5- to 3-cm segment of ileum is harvested, distal to the segment of intestine to be used for augmentation (if indicated).

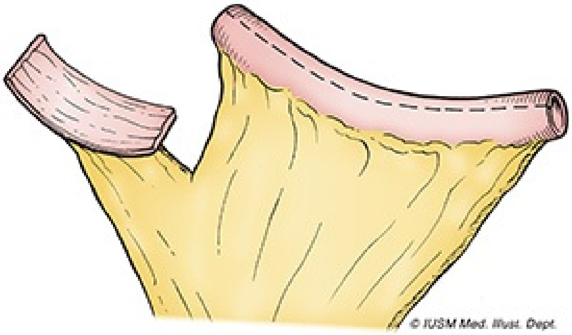

FIGURE 108.7 The Monti segment is detubularized on the antimesenteric side. This incision can be between the 9 and 12 o'clock positions depending on the desired length of intravesical tunnel.

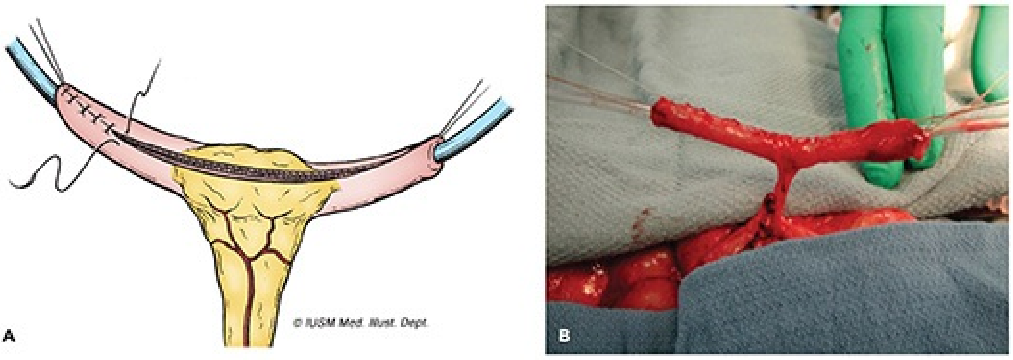

FIGURE 108.8 **A:** The channel is closed with two layers of absorbable sutures. The stomal end is either closed with interrupted sutures or not closed to allow adequate spatulation at the skin stoma. **B:** Operative photo of completed Monti channel.

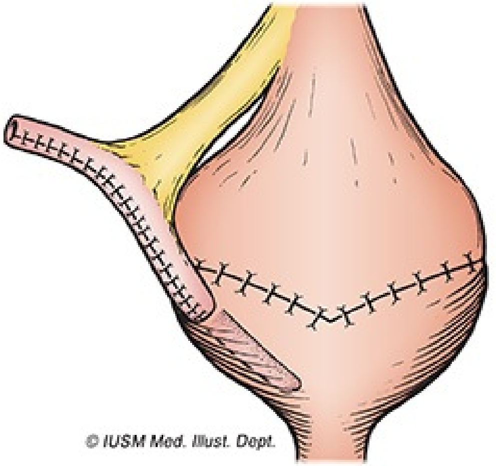

FIGURE 108.9 The Monti channel can be brought out either to a lower abdominal stoma or to the umbilicus. The mesentery is mobilized from the pedicle of the bladder augmentation to provide a tension-free skin anastomosis.

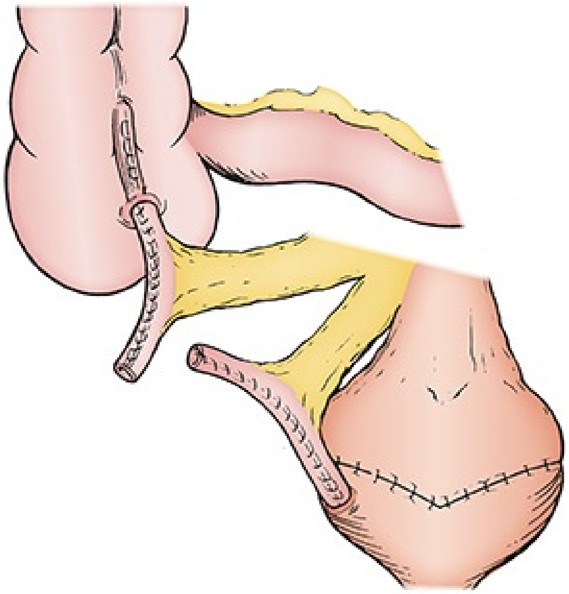

FIGURE 108.10 The “dual Monti,” utilizing a Monti channel for both the Malone antegrade continence enema and Mitrofanoff channels.

When the Monti channel does not provide adequate length for the extravesical section to reach the abdominal stomal site without tension, then two Monti tubes can be reconfigured and connected (the “double Monti”). This can provide a longer limb to reach the skin stoma but also introduces increased risk of postoperative complications of diverticulum, angulation, and perforation at the anastomosis of the two channels (10). To avoid this complication, Casale (11) described a long ileovesicostomy technique using a single piece of bowel to create a channel 10 to 14 cm in length. This technique uses a 3.5- to 4-cm segment of bowel that is isolated on its mesentery and divided into two equal segments for approximately 80% of the bowel circumference, leaving the two segments attached at the mesenteric side. The two loops of intestine are opened close to the mesentery on opposite sides, allowing the bowel to unfold in opposite directions, creating a long flat plate of intestine that can be retubularized after trimming the redundant lateral edges. Late follow-up has demonstrated good results for the Monti and Casale-Monti, with the exception of statistically significant higher open revision rates for the longer spiral Monti (Fig. 108.11) placed in the umbilicus, presumably due to extravesical channel elongation and tortuosity over time and development of a perihiatal diverticulum (Fig. 108.12) (12).

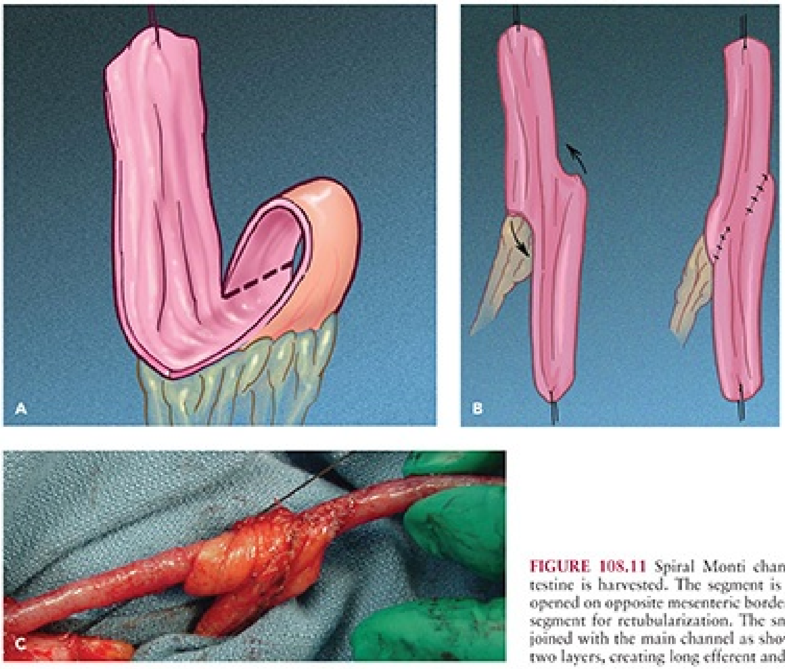

FIGURE 108.11 Spiral Monti channel. A: A 4-cm segment of intestine is harvested. The segment is divided in the middle and then opened on opposite mesenteric borders. B: This creates a 10- to 12-cm segment for retubularization. The small dog ears can be trimmed or joined with the main channel as shown. C: Channel retubularized in two layers, creating long efferent and afferent limb.

FIGURE 108.12 Diverticula in channel directly outside the bladder hiatus. This complication occurs from repetitive difficult catheterization due to a long and tortuous extravesical portion of the Mitrofanoff channel.

Continent Vesicostomy

Small subsets of patients require creation of only a catheterizable bladder channel without bladder augmentation or other intra-abdominal procedures. These patients are good candidates for extraperitoneal continent vesicostomy. The largest reported experience is using the procedure described by Cain and Rink et al. (13) utilizing an intravesical submucosal-mucosal– lined tunnel to create the continence mechanism. This procedure has been successfully used with a variety of underlying bladder pathologies.

The bladder is opened to allow creation of either a midline or lateral full-thickness bladder flap (Fig. 108.13A). Mucosal incisions are extended intravesically, leaving a 2.5-cm plate of mucosa. The mucosa is sharply dissected off the underlying detrusor muscle laterally and medially to allow tension-free mucosal closure (Fig. 108.13B). The intra- and extravesical mucosal tube is created over a 14Fr catheter with running 6-0 absorbable suture (Fig. 108.13C). The detrusor muscle of the extravesical portion of the tube is then closed with 4-0 absorbable sutures (Fig. 108.13D). The continence mechanism is then created by closing the lateral edges of the bladder mucosa over the mucosal tube using running 5-0 absorbable suture (Fig. 108.13E). The stoma can be created in either the lower abdomen or umbilicus. An indwelling 12Fr catheter is left in place for 3 to 4 weeks.

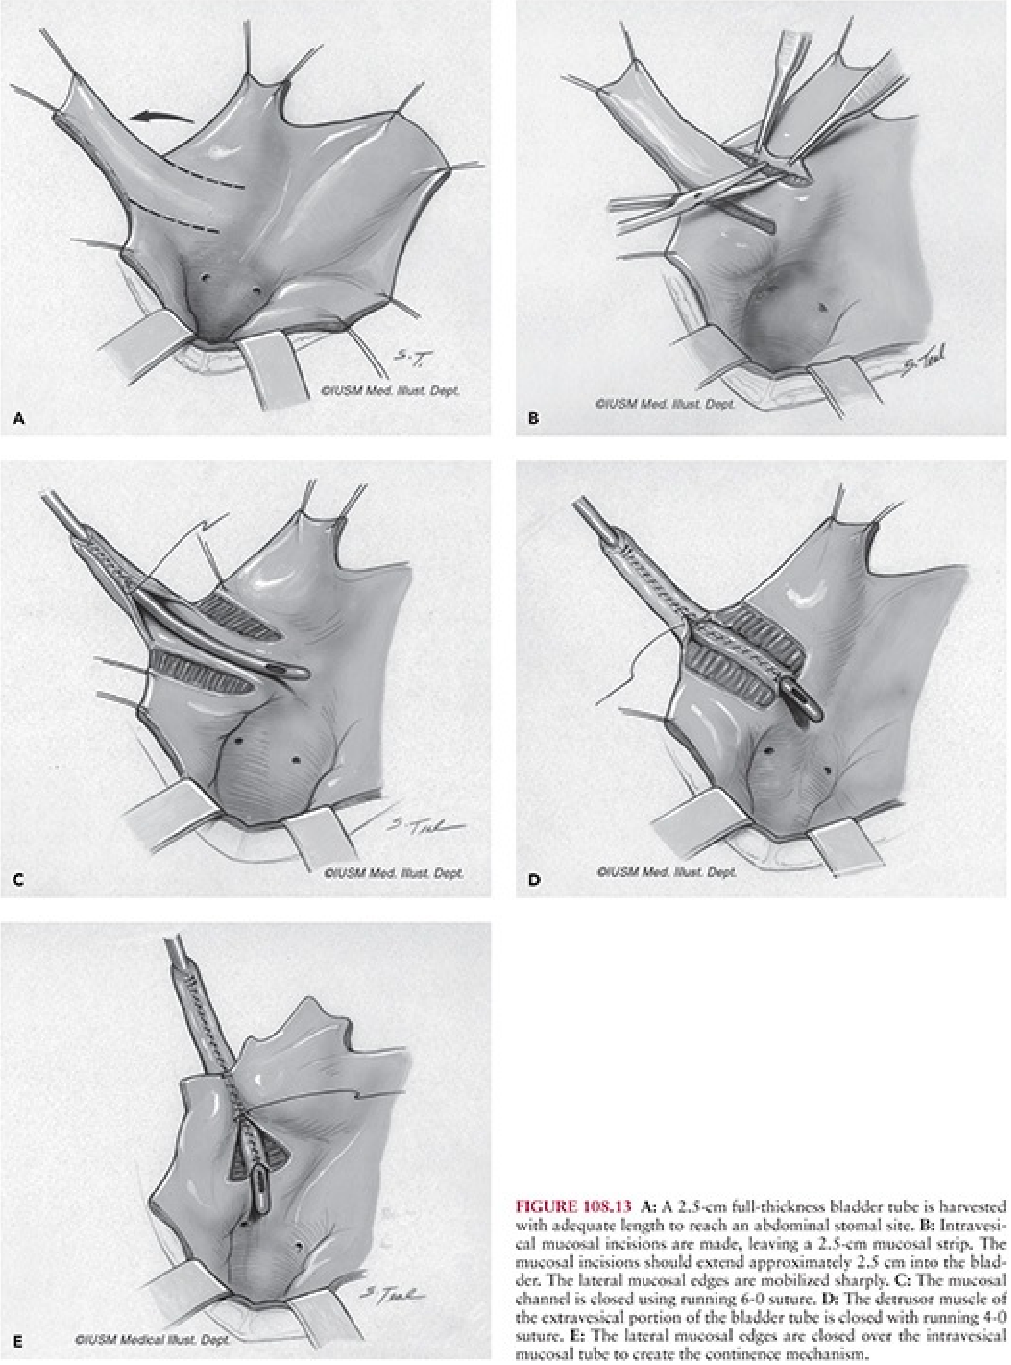

FIGURE 108.13 **A:** A 2.5-cm full-thickness bladder tube is harvested with adequate length to reach an abdominal stomal site. **B:** Intravesical mucosal incisions are made, leaving a 2.5-cm mucosal strip. The mucosal incisions should extend approximately 2.5 cm into the bladder. The lateral mucosal edges are mobilized sharply. **C:** The mucosal channel is closed using running 6-0 suture. **D:** The detrusor muscle of the extravesical portion of the bladder tube is closed with running 4-0 suture. **E:** The lateral mucosal edges are closed over the intravesical mucosal tube to create the continence mechanism.

Ureterovesicostomy

The ureter can be used as a catheterizable channel but has been less popular than bowel channels due to the additional upper urinary tract reconstruction required and the higher risk of skin stenosis and stomal leakage (14,15). When there is a unilateral nonfunctioning kidney with a nonrefluxing distal ureter, a ureteral channel should be considered, but this unfortunate situation should be avoidable in the present era of careful management of these patients from early in life. Several reports have also documented successful distal ureteral reimplantation at the time of the ureterovesicostomy. Obviously, careful mobilization of the ureter to prevent proximal and distal stenosis is an important technical factor.

Outcomes

Complications

Potential complications of the Mitrofanoff channel occur in approximately 20% to 25% of patients.

The common complications are listed in Table 108.1. The most frequent problem is stomal stenosis, occurring in 10% to 20% of channels in most series. The continent vesicostomy has a much higher rate of skin stenosis than either appendix or Monti–Yang channels, with as many as 50% requiring skin level revision. A short period of passive catheter dilation for 7 to 10 days will avoid the need for surgical intervention in some patients. If necessary, revision of the stoma with a well-vascularized flap of skin is usually successful to manage significant stenosis.

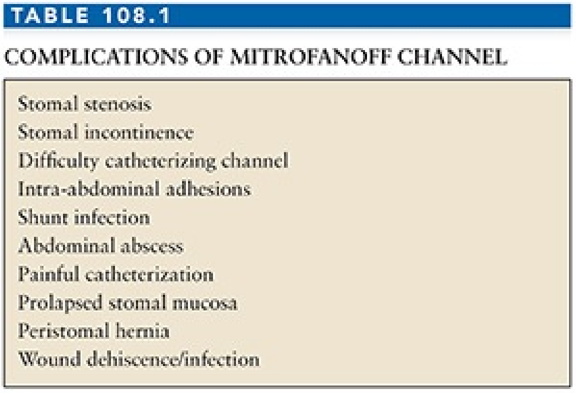

TABLE 108.1

COMPLICATIONS OF MITROFANOFF CHANNEL

Stomal stenosis
Stomal incontinence
Difficulty catheterizing channel
Intra-abdominal adhesions
Shunt infection
Abdominal abscess
Painful catheterization
Prolapsed stomal mucosa
Peristomal hernia
Wound dehiscence/infection

Difficulty catheterizing the channel can occur secondary to angulation, perforation/false passage, or stenosis of the channel. Initially, this should be treated conservatively with endoscopic placement of an indwelling catheter for 1 to 2 weeks. On occasion, reoperation will be necessary, and the patient and surgeon should be prepared to replace the entire tube if required. On a recent unpublished review of over 500 Mitrofanoff channels, our institution has identified a significantly higher risk of subfascial complications requiring major revision in the Monti and spiral Monti procedures compared to the appendicovesicostomy. This difference becomes evident with longer term follow-up and is felt to occur from chronic diverticular outpouching of the channel and chronic minor trauma during catheterization. Many of these channels can be salvaged with excision of the diverticulum, shortening of the extravesical portion of the channel, and resecuring the bladder hiatus to the posterior fascia.

Complications will usually occur within the first year but may occur many years after construction of a Mitrofanoff channel, and long-term follow-up with these patients is mandatory, especially when the Mitrofanoff channel is the sole means to empty the bladder (2,16).

Results

Most large series have reported long-term success in up to 96% to 98% of Mitrofanoff channels (2,17). Because appendicovesicostomy has been used since the initial description of the procedure, there are better long-term data for this specific procedure, which has been shown to be durable over long periods of intermittent catheterization. We recently reported our results using the Monti–Yang channel in 199 consecutive patients, achieving 97% success with an average of 3 years of follow-up, which was identical to our experience with appendicovesicostomy (9). Because of the short continence zone required with the mucosal flap-valve technique for continent vesicostomy, there has been nearly 100% success with this procedure with respect to stomal continence.

Failure to obtain continence can be due to an inadequate submucosal tunnel, a fistula into the Mitrofanoff tube, breakdown of the muscular backing to the submucosal tunnel (especially when implanted into a bowel segment), or poor bladder compliance/high intravesical pressure. In many instances, the underlying problem will be the bladder, and any patient with a failed Mitrofanoff should undergo repeat urodynamic studies of the bladder and a trial of anticholinergics. We have had good success with reimplanting a previously constructed channel at the time of secondary bladder augmentation when the initial Mitrofanoff channel has failed because of changing bladder dynamics.

MALONE ANTEGRADE CONTINENCE ENEMA PROCEDURE

The MACE procedure was introduced by Padraig Malone in 1990 (18), creating the final step for potentially achieving complete urinary and fecal continence. The majority of patients in a pediatric urology practice who would potentially benefit from this procedure are those with spina bifida with neuropathic bladder and bowel, or in patients with functional severe constipation related to their urinary tract disease. The greatest advantage for the MACE technique is providing the patient with poor physical mobility with independent access to the colon to allow antegrade colonic enema washouts either via the right or left colon, avoiding the need for oral laxatives/stool softeners or rectal enemas.

Indications for Surgery

The first step in patient selection is to essentially exhaust medical management for fecal incontinence and constipation. The greatest challenge for medical management in patients with neuropathic bowel is the underlying combination of slow colonic transit, reduced anal sphincter tone, reduced sensation, limited physical mobility/obesity, underlying chronic colon distention, and the added problem of constipating medications (e.g., oxybutynin) to control the associated neuropathic bladder disease. The result is often extremes ranging from controlled constipation to liquid stool accidents. Appropriate medical management should include a trial of aggressive bowel cleanout and daily management as outlined in Table 108.2. Success of medical management relies on maintaining an aggressive program with a multidisciplinary team with reported success of 69% in experienced centers (19). Before progressing to a MACE option, patients must also demonstrate the ability to sit on the toilet for an adequate duration of time to evacuate the colon, usually 30 to 45 minutes.

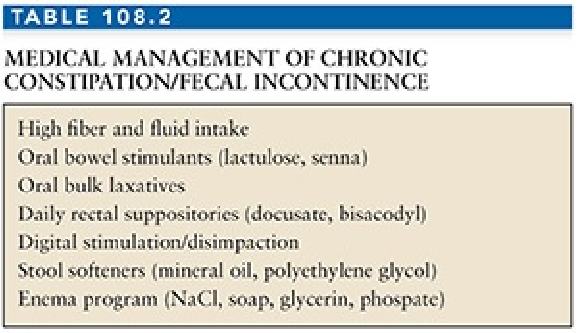

TABLE 108.2

MEDICAL MANAGEMENT OF CHRONIC CONSTIPATION/FECAL INCONTINENCE

High fiber and fluid intake
Oral bowel stimulants (lactulose, senna)
Oral bulk laxatives
Daily rectal suppositories (docusate, bisacodyl)
Digital stimulation/disimpaction
Stool softeners (mineral oil, polyethylene glycol)
Enema program (NaCl, soap, glycerin, phospate)

Alternative Therapy

The alternatives to surgically creating an antegrade enema channel all evolve around successful medical management, frequently involving a retrograde enema program which often requires either a cone enema device or the more recently used Peristeen irrigation system that creates occlusion of the incompetent rectal sphincter to allow high-volume enema infusion. These systems have equivalent outcomes for fecal continence obtained with the MACE technique but frequently require assistance in the less mobile patient. For patients who are poor candidates or wish to avoid major abdominal surgery, another option for the antegrade enema program is percutaneous placement of a cecostomy tube, such as the Chait tube. Results are identical to the MACE irrigation outcomes, but the obvious difference for the patient is an external appliance device. The final option for refractory fecal incontinence/constipation is colostomy, which is rarely needed with all the current available options.

Surgical Technique

Appendicocecostomy

The in situ appendicocecostomy is the most commonly used channel for the MACE procedure. Patients should all undergo preoperative mechanical bowel preparation, which can be accomplished with an outpatient regimen in the majority of patients. Intravenous broad-spectrum antibiotics are given perioperatively for 24 hours to avoid infection. When the MACE is done as an isolated procedure, it can be performed with either a pure open, laparoscopic assisted, or pure laparoscopic/robotic technique. For an open procedure, the abdomen is opened through a small infraumbilical incision. The appendix is identified, and adequate mobility and blood supply are determined by mobilizing the right colon to the hepatic flexure and freeing up the mesoappendix. The tip of the appendix is then amputated, and a 12Fr or 14Fr catheter is passed to insure patency of the appendix. The catheter is secured to the tip of the appendix, and catheter plug is placed to avoid contamination. Small windows are then made in the mesoappendix to allow cecoplication. The appendix is then intussuscepted into the cecum, securing the base of the appendix with several 4-0 nonabsorbable sutures. The appendix is positioned against one of the tenia, and cecoplication is accomplished by bringing the mobile portion of the cecum through the mesoappendix windows, securing it to the colon on the contralateral side of the appendix. Two 4-0 nonabsorbable sutures are placed at each mesenteric window, one of these catching small bites of the serosa of the appendix to fix the appendix in the tunnel. If possible, three to four total plications windows are created, and the cecum is secured to the distal end of the appendix at the terminal hiatus. The stomal site is then selected, and a U- or V-shaped flap is created at the skin level. The fascia is opened with a cruciate incision, and the appendix is brought through the fascia. The cecum is fixed to the posterior fascia at the level of the appendix hiatus with three nonabsorbable sutures to prevent angulation. Once the abdominal and skin incision is closed, the channel catheter is removed, and the appendix spatulated and anastomosed to the skin flaps with 4-0 absorbable suture. For an umbilical stoma, the author prefers a simple U-shaped incision that provides concealment of the stoma (Fig. 108.14). A 12Fr or 14Fr catheter is left indwelling for 3 to 4 weeks before catheterization is initiated. The MACE irrigations are usually started as soon as the patient begins oral feeds after surgery. At our institution, we will usually begin with low-volume (50 mL) flushes and increase the irrigation volume by 50 mL every 2 to 3 days until good results are obtained, which will usually require several weeks.

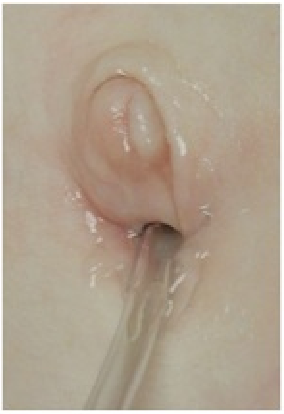

FIGURE 108.14 Umbilical MACE stoma.

Occasionally, the appendix will be of adequate length to be used for both a Mitrofanoff and MACE channel. In these patients, the distal 4 to 5 cm of appendix is separated, taking care to leave both segments with adequate mesenteric blood supply. If the proximal portion is too short for adequate plication, the appendix can be “extended” into the distal cecum using a stapling device as described by Sheldon et al. (6). The tubularized cecal segment can then be imbricated to create the continence mechanism.

In obese patients who would require a larger abdominal incision to mobilize the cecum, or for patients undergoing an isolated MACE procedure, a laparoscopic or laparoscopic-assisted procedure is very useful for intra-abdominal mobilization. For a pure laparoscopic procedure, the appendix can either be plicated or brought directly through the abdominal wall without any plication. Alternatively, the cecum and appendix can be mobilized laparoscopically, the inferior port site can be converted to a small 2- to 3-cm abdominal incision, and the cecum can be brought through the incision for extracorporal appendicocecoplication, and then brought back out through the umbilical port as a stomal site.

Monti–Malone Antegrade Continence Enema and Cecal Flap Malone Antegrade Continence Enema

When the appendix is either absent or not useable, there are still several surgical options for creating a catheterizable MACE channel. These techniques are especially useful when contemplating a left-sided MACE procedure, which in some reports has demonstrated equivalent results with faster washout times. The Monti-MACE tube is constructed as described previously for the bladder channel, using a 3-cm segment of bowel to create a neoappendix (Fig. 108.15A–D). This is then tunneled into a split-tenia channel on either the right or left colon. The serosa flaps on both sides of the tenia in0cision are mobilized and then secured over the Monti channel with nonabsorbable sutures, which can also be used to secure the entire tunnel to the posterior fascial wall to reinforce the continence mechanism and secure the channel.

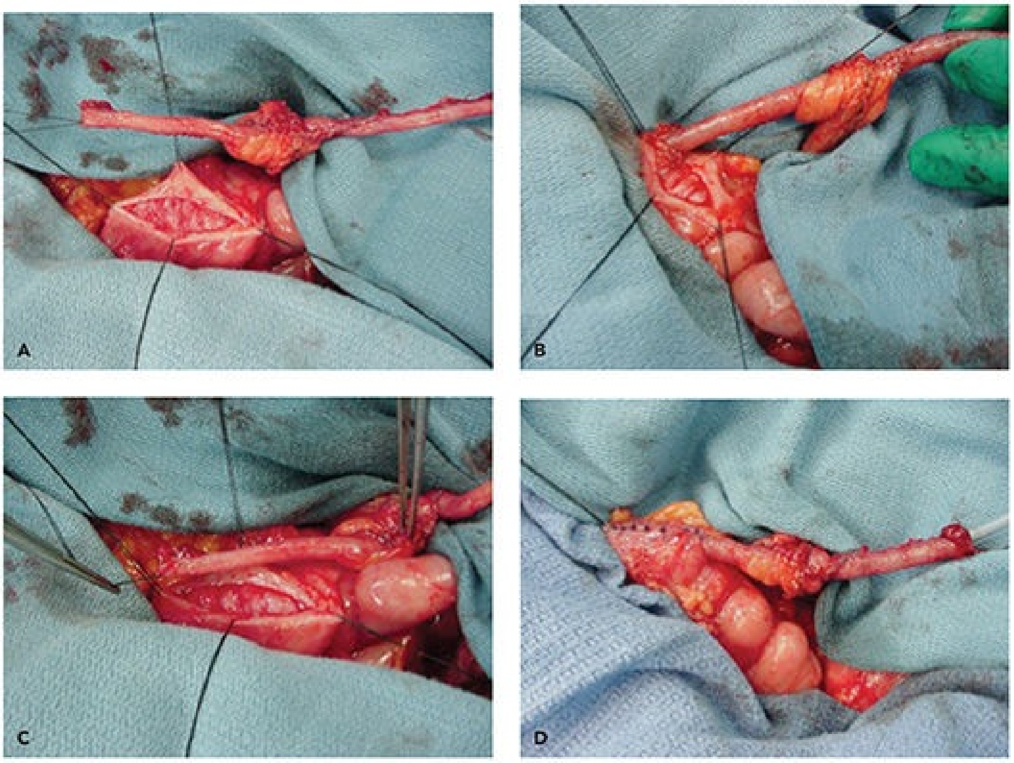

FIGURE 108.15 Monti-MACE. **A:** The Monti is constructed from a 3- to 4-cm segment of intestine. **B:** The serosa of the tenia of the colon segment is incised, and the channel is anastomosed to the bowel mucosa. **C:** Lateral tenia flaps are raised sharply to allow tension-free closure anterior to the MACE channel. **D:** The serosal flaps are closed over the channel up to the border of the mesentery. The channel is then secured to the bowel serosa.

The colon flap MACE relies on a medial based rectangular full-thickness cecal flap that is retubularized and buried in a seromuscular tunnel (20).

Outcomes

Complications

The MACE procedure has similar types of complications as seen with Mitrofanoff channels, including stomal stenosis, channel angulation/obliteration, traumatic false passage, and stomal incontinence. Stomal stenosis is the most frequently cited complication and is reported in 5% to 30% of patients (21,22). This is usually a fairly simple complication to manage, with just a simple skin revision or channel dilation. Several reports have demonstrated success at decreasing skin complications by leaving a small stent or ACE stopper across the stomal anastomosis for the first 6 months after surgery (23). In a sequential review of 280 MACE channels at our institution (22,24), we found that the in situ appendix was associated with the lowest overall complications, with a reoperation rate of 16%, compared to the Monti-MACE (18%), split appendix (21%), cecal flap (30%), and stapled cecal extension (33%). The majority of patients requiring surgical revision can be managed with a single procedure, although 30% require multiple interventions. The incidence of stomal incontinence is 3% to 4% but has been higher in nonplicated appendicocecostomy in multiple series.

Results

Patient satisfaction with the MACE procedure has overall been very positive, with several quality-of-life surveys demonstrating significant improvement in fecal incontinence and quality-of-life scores (25,26). The patients should be counseled preoperatively that the MACE irrigation requires significant time commitment, with flush times averaging from 30 to 45 minutes. The type of MACE irrigation recommended is quite variable, including normal saline or tap water to a variety of additives to either reduce transit time or reduce fecal soiling between irrigation. The average irrigation volume to reach success is also variable and is somewhat dependent on additives but will generally range from 200 to 1,000 mL. At our institution, we start flushes with tap water and add either mineral oil or polyethylene glycol to the irrigation for initial failures. Persistent incontinence is managed with the addition of oral polyethylene glycol and/or glycerine to the MACE flush. With this program, we have achieved a 94% success rate of less than one accident per month in patients who continue with the MACE program.

Argus male sling, 408
Arteriogenic erectile dysfunction
    diagnosis of, 621–622, 621f
    vascular surgery for, 622–626
        outcomes and complications of, 624–626, 625f, 625t, 626f
        patient selection for, 622
        techniques in, 622–624, 623f–624f
Artificial erection, in hypospadias surgery, 828
Artificial urinary sphincter (AUS), 329, 393–403
    alternatives to, 394, 395t
    for children, 811
    contraindications to, 394
    control pump of, 393, 394f
    cuffs of, 393, 393f–394f
    indications for, 394
    male sling *vs.*, 394, 395t, 404–405, 409–410
    in men, 395–398
        bladder neck cuff placement for, 398
        inflatable penile prosthesis implantation with, 400
        male sling *vs.*, 409–410
        perineal cuff placement for, 395–397, 396f
        postprostatectomy, 404–405

        after prior failed sling, 402, 409
        after radiotherapy for prostate cancer, 402–403
        transcorporeal cuff placement for, 397, 397f, 398f
        transverse scrotal incision for placement of, 397–398, 398f–400f
    modifications and advances in, 393
    outcomes and complications of, 401–402, 401t–402t
    in pediatric population, bladder augmentation with, 400–401
    preoperative preparation for, 394–395
    pressure-regulating balloon of, 393
    surgical technique for, 394–395
    tandem cuff placement for, 401
    in women, 398–400, 400f
Asopa technique, in staged urethroplasty, 348, 348f
Atrial thrombus, intracaval tumor and, 33–34
Augmentation colocystoplasty, 178, 914–915, 916f, 920
Augmentation cystoplasty, 177–185
    alternatives to, 178
    bowel segment options in, 178
    complications of, 183–184
    history of, 177
    indications for, 177, 177t
    for interstitial cystitis/bladder pain syndrome, 219, 222, 223f
    outcomes of, 182–183
    patient assessment for, 177–178
    patient positioning for, 179, 179f
    pediatric, 910–922
        alternatives to, 911
        artificial urinary sphincter with, 400–401
        bowel segment for, 912, 913t
        complications of, 911, 912t, 920–921
        evaluation of anatomic and functional characteristics for, 911
        gastrocystoplasty in, 916–919, 918f
        gastrointestinal effects of, 920
        goal of, 910
        ileocystoplasty in, 913–914, 914f–916f
        indications for, 911
        intraoperative preparation of patient in, 912
        metabolic effects of, 920
        outcomes of, 921–922
        postoperative follow-up in, 920
        preoperative bowel preparation for, 911–912, 912t
        preoperative counseling on, 911
        preparation of bladder in, 912–913, 913f
        right colocystoplasty and Mainz enterocystoplasty in, 914–915, 916f
        sigmoidocystoplasty in, 915–916, 917f
        sphincteric incontinence surgery with, 911
        surgical techniques in, 911–919

        - ureterocystoplasty in, 919, 919f
        - urinary and abdominal drainage following, 919
        - vesicoureteral reflux surgery with, 911
    - postoperative care in, 183t
    - pre- and postoperative investigation regimen in, 182, 183t
    - pregnancy and, 184
    - principles of, 178
    - special circumstances in, 184
    - surgical technique in, 178–182, 179f–182f
- Augmentation gastrocystoplasty, 178, 916–919, 918f
- Augmentation ileocystoplasty, 178–184, 913–914, 914f–916f, 920
- Augmentation ureterocystoplasty, 919, 919f
- AUS. *See* Artificial urinary sphincter

  - sensory innervation of, 142
  - storage reflex and, 143–144

Bladder augmentation. *See* Augmentation cystoplasty

Bladder autoaugmentation, 178

Bladder cancer. *See also specific types*
  - kidney-sparing therapy for, 187
  - laparoscopic radical cystectomy for, 230
  - lymphadenectomy in
    - extended and superextended, 155, 156f, 235, 235f, 236f
    - in men, 152–153, 152f–153f, 155, 156f

        - with nephroureterectomy, 186, 186f
        - outcomes of, 239–240
    - nephroureterectomy for, 185–193
    - partial cystectomy for, 148–150
    - radical cystectomy in men for, 151–161, 233–234
    - radical cystectomy in women for, 161–171, 234–235
    - robot-assisted radical cystectomy for, 169–170, 230–242
    - urinary diversion for, 236–238, 236f–238f
- Bladder cuff technique
    - for artificial urinary sphincter, in men, 398
    - for laparoscopic nephroureterectomy, 64–66, 65f, 188–189, 189f
    - for open nephroureterectomy, 187–188
- Bladder denervation, 227, 228
- Bladder diverticula
    - definition of, 171, 242
    - diagnosis of, 172, 173f
    - location of, 171–172, 172f
    - surgical management of, 172–176, 242–243 (*See also* Bladder diverticulectomy)
- Bladder diverticulectomy, 171–176
    - alternatives to, 173
    - combined intravesical and extravesical, 174–175, 176f
    - complications of, 175–176
    - extravesical, 174, 242
    - indications for, 172–173
    - intravesical or transvesical, 174, 175f
    - open, 173, 174–175
    - outcomes of, 175–176
    - preoperative assessment for, 173
    - robotic, 242–243
    - transurethral resection in, 173–174
- Bladder entrapment, in pelvic fracture, 212, 213f
- Bladder exstrophy. *See* Exstrophy, *See* bladder
- Bladder hemorrhage, 214–216. *See also* Hemorrhagic cystitis
- Bladder hydrodistention, 221, 221f–222f, 227–228, 228t
- Bladder neck closure (BNC), 329–335
    - in female patients, 329–334
        - abdominal approach in, 331–334, 333f
        - vaginal approach in, 330–334, 331f–333f
    - indications for, 329–330
    - in male patients, 330, 334
        - abdominal closure in, 334, 334f
        - perineal approach in, 334
    - outcomes and complications of, 335
    - postoperative care in, 334–335

    outcomes and complications in, 904
    scrotal anomalies with, 905
    surgical repair of, 902–903, 903f–904f
Congenital adrenal hyperplasia (CAH), 878, 886. *See also* Disorders of sexual development
Congenital bilateral absence of vas deferens (CBAVD), 443
Congenital curvature of penis, 650–655
    classification of, 650, 650f
    diagnosis of, 651, 651f
    incision and plication for, 651–654, 652f–654f
    multiple parallel plication for, 654–655
    outcomes and complications of, 655
    penile disassembly for, 655
    surgical indications in, 651
    surgical technique for, 651–655
    Yachia longitudinal plication for, 654, 654f
Constipation
    Malone antegrade continence enema for, 178, 181, 930–933
    medical management of, 930–931, 930t
Contigen (GAX-collagen), 373, 374–375
Continent catheterizable reservoir
    appendix as stoma in, 700, 700f, 703–705, 705f
    colonic, 702–715
        alternatives to, 702
        alternative techniques in, 705, 706f–708f
        colon pouch (Mainz pouch III), 710, 711f, 712f
        continence mechanism in, 713–714, 714f–715f
        full-thickness tube for, 705, 706f
        ileocecal pouch (Mainz pouch I) for, 703–705, 703f–705f, 708f
        Indiana pouch for, 706–708, 710f
        indications for, 702

    - intussuscepted ileal nipple in, 703, 703f, 713–714, 714f–715f
    - outcomes and complications of, 710–715
    - seromuscular tube for, 705, 706f
    - surgical technique for, 702–714
    - Tiflis pouch for, 706, 708f
    - troubleshooting for, 713–714, 713f–715f
    - ureterointestinal strictures with, 713, 713f–714f
    - Yang–Monti technique in, 706f
  - ileal, 697–701
    - alternatives to, 698
    - indications for, 698
    - outcomes and complications of, 701
    - patient selection and evaluation for, 698
    - postoperative care of, 701
    - preoperative preparation for, 698
    - surgical technique for, 698–700, 699f–700f
  - Mitrofanoff principle/procedure for, 702, 923–930
- Continuous bladder irrigation, for hemorrhagic cystitis, 215
- Corpora cavernosa
  - anatomy of, 567–569, 567f, 568f
  - decompression, in priapism, 606–607
- Corporal cannulation, for priapism, 608
- Corporo-deep dorsal vein shunt, 609
- Corporoglanular shunts, 607–608, 608f
- Corporoplasty, for Peyronie disease, 598
- Corporoplication, for Peyronie disease, 598
- Corporo-saphenous vein shunt, 609
- Corporospongiosal shunts, 608–609
- Corpus spongiosum, 567–570, 567f, 568f
- Costovertebral ligaments, 3, 4f
- Cowper glands, 444f, 447–448, 447f
- Cremasteric reflex, 521
- Crossed renal ectopic, 738, 739f–740f
- Cross-trigonal repair, of VUR, 788–789, 789f
- Cryotherapy
  - for adrenal lesions, 88–89
  - laparoscopic, for small renal masses, 76–81
    - outcomes and complications of, 79–80, 80t
    - postoperative care in, 79
    - surgical technique in, 79, 79f
  - for penile cancer, 579
  - for prostate cancer, 306
  - for renal tumors, 7
- Cryptorchidism, 854–864
  - blind-ending testicular vessels in, 857, 857f
  - cord structures entering inguinal ring in, 857–858, 857f
  - definition of, 854

    diagnosis of, 855–856
    diagnostic laparoscopy for, 856–858, 857f
    hormonal therapy for, 856
    inguinal orchiopexy for, 855f, 861–863, 862f–863f
    intra-abdominal, 854–855, 858–861, 858f
    in prune belly (triad) syndrome, 763–770, 765, 768–769
    scrotal orchiopexy for, 863–864
    single-stage laparoscopic orchiopexy for, 858–861, 859f–861f
    surgical management of
        alternatives to, 856
        anatomic considerations in, 854, 855f
        indications for, 856
        outcomes and complications of, 864, 864f
        techniques of, 856–864
    testis location in, 854–855
    two-stage Fowler–Stephens procedure for, 861, 861f
Culdoplasty
    Halban, 432, 432f
    McCall, 429, 430f
Curvature of penis. *See* Penile curvature
Cut-back vaginoplasty, 880
Cyanoacrylic glue, for vesicovaginal fistula, 195
Cyclophosphamide, and hemorrhagic cystitis, 214
Cystectomy
    for hemorrhagic cystitis, 216
    partial, 148–150
        alternatives to, 149
        extraperitoneal, 149–150, 149f–150f
        indications for, 148–149
        for interstitial cystitis/bladder pain syndrome, 222–224, 224f
        intraperitoneal, 150
        outcomes and complications of, 150
        for rhabdomyosarcoma, 775
        surgical technique in, 149–150, 149f–150f
        urachal excision with, 242
    radical, in men, 151–161
        alternatives to, 151
        anesthesia and instrumentation for, 152
        cystoprostatectomy in, 153–159, 153f–159f
        indications for, 151
        initial exposure in, 152
        lymphadenectomy in, 152–153, 152f–153f, 155, 156f
        outcomes and complications of, 160
        patient positioning for, 152
        patient preparation for, 151–152
        postoperative care in, 159–160
        prostate-sparing, 159

    radical cystoprostatectomy with nerve sparing in, 159
    radical cystoprostatectomy with orthotopic bladder substitution in, 158, 159f
    surgical technique in, 151–160
    urethral cancer recurrence after, 364
  radical, in rhabdomyosarcoma, 775
  radical, in women, 161–171
    age and medical comorbidities in, 163
    alternatives to, 162
    anatomic considerations in, 163–164
    anterior exenteration in, 161, 164–166, 164f–166f
    challenges and concerns in, 161
    complications of, 170
    “early,” 161
    extent of, paradigm for, 162, 163t
    female continence and, 163–164
    female sexual function and, 164
    functional outcomes and quality of life measures in, 163
    indications for, 161–162
    intractable local symptoms and, 162
    in muscle-invasive disease, 161–162
    in non–muscle-invasive disease, 162
    outcomes of, 170
    postoperative care in, 170
    preoperative care in, 162–163
    preoperative considerations in, 162
    reproductive organ preservation in, 168–169, 169f
    retrograde dissection and urethral-sparing technique in, 169, 169f
    robotic, 169–170
    surgical technique in, 163–170
    urethrectomy in, 167, 167f
    vaginal reconstruction in, 168, 168f
  radical, robot-assisted, 230–242
    alternatives to, 230–231
    anatomic orientation in, 231
    anterior dissection in, 233
    complications of, 240–241
    costs of, 241
    Enhanced Recovery after Surgery protocol in, 231, 231t
    functional outcomes of, 240
    indications for, 230
    lateral dissection of bladder and control of vascular pedicles in, 232–233, 233f
    learning curve in, 241
    lymphadenectomy in, 235, 235f–236f, 239–240
    in men, nerve-sparing modifications in, 233–234
    mobilization and division of ureters in, 231
    oncologic outcomes of, 238–240
    patient positioning and port placement in, 231, 232f

        postoperative care in, 238
        preoperative preparation for, 231
        quality of life after, 241
        retrovesical dissection in, 231–232, 232f
        specimen entrapment in, 233
        surgical margins in, 239
        transection of dorsal vein complex and membranous urethra in, 233
        urinary diversion in, 236–238, 236f–238f, 240
        in women, 234–235, 234f
    renal laparoscopic, 69–73
        decortication in, 70–72, 72f
        prevention of port-site metastases in, 72–73, 73t
        retroperitoneal approach in, 71–72, 72f, 74
        surgical technique in, 74
        transperitoneal approach in, 72, 72f
    simple, 146–148
        alternatives to, 146
        complications of, 148
        in female patients, 147–148
        indications for, 146
        intraperitoneal approach in, 146
        in male patients, 147, 147f–148f
        outcomes of, 148
        patient positioning for, 146–147
        surgical technique in, 146–148, 147f–148f
    total, for interstitial cystitis/bladder pain syndrome, 224
Cystitis. *See also specific types*
    hemorrhagic, 214–216
    interstitial, 217–230
Cystoplasty
    augmentation (*See* Augmentation cystoplasty)
    reduction, in prune belly (triad) syndrome, 765, 767, 767f
    substitution, for interstitial cystitis/bladder pain syndrome, 222–224, 224f
Cystoprostatectomy, 153–159
    one-stage, 155–158, 157f–158f
    radical
        with nerve sparing, 159
        with orthotopic bladder substitution, 158, 159f
    for rhabdomyosarcoma, 775, 776f
    surgical technique in, 153–154, 153f–159f
Cystorrhaphy, 211–213, 212f

D

Dartos fascia, 568–569, 568f
Dartos layer of scrotum, 572
Delayed ejaculation, 503–508
    definition of, 503

    - electroejaculation for, 506–508, 506f–507f, 507t
    - evaluation of, 503–504, 504f
    - medical treatment for, 504–505
    - penile vibratory stimulation for, 505–506, 505f
- Denys–Drash syndrome, 731
- Detrusor external sphincter dyssynergia (DESD), 328–329
- Detrusor muscle, 138, 143
- Detrusor myomectomy, 178
- Dimethyl sulfoxide (DMSO), for interstitial cystitis/bladder pain syndrome, 220
- Direct infusion cavernosometry and cavernosography (DICC), 622
- Direct vision internal urethrotomy (DVIU), 338, 340–341, 340f, 342–343
- Dismembered technique, in pyeloplasty, 742, 743f, 746–748, 747f, 754–756, 754f–756f
- Disorders of sexual development (DSD)
    - categories of, 886
    - clitoroplasty for, 889, 889f–890f
    - diagnosis of, 887, 887f
    - family issues in, 887–888
    - labioplasty for, 890–891, 890f
    - nomenclature for, 886
    - surgical management of, 886–894
        - controversy and concern over, 878, 886
        - external genitalia repair in, 889–891
        - history of, 886
        - outcomes and complications of, 894
        - patient positioning for, 888–889
        - preoperative evaluation for, 888, 888f
        - techniques in, 889–894
        - timing of, 888
    - team approach to, 887
    - total urogenital mobilization for, 891–894, 892f–893f
    - urogenital sinus anomalies in, 877–878, 891–894, 891f–893f
    - vaginoplasty for, 891, 891f–892f, 893–894, 893f
- Distal penile approach, to penile prosthesis implantation, 618
- Distal urethrectomy, in women, 368, 369f
- Diverticulectomy
    - bladder, 171–176, 242–243
    - urethral, female, 322–327
- Diverticulum. *See also specific types*
    - bladder, 171–176, 242–243
    - urachal, 806–807
    - urethral, female, 322–327
- Dondren, urethral injection of, 371
- Donor nephrectomy
    - laparoscopic, 36–43
        - alternatives to, 36
        - contraindications to, 36, 37t
        - donor evaluation for, 36

        - indications for, 36
        - left-sided, 37–41, 38f–41f
        - outcomes and complications of, 42–43, 42t
        - patient positioning for, 37, 38f
        - patient preparation for, 36
        - right-sided, 41
        - surgical techniques in, 36–41, 38f–41f
    - for renal autotransplantation
        - flank, 119–121, 121f
        - midline intraperitoneal approach in, 121–122
- Dorsal flap onlay, for hypospadias, 831–832, 832f
- Double hydrodistention implantation technique, for VUR, 798–799, 798f–799f, 799t
- Double-J stents
    - for megaureter, 758
    - for palliative urinary diversion, 727, 728, 728f
- Dual kidney transplantation, 110, 110f
- Ductus deferens. *See* Vas deferens
- Durasphere, 375–376
- Dynamic sentinel node biopsy, in penile cancer, 585–586, 585f–586f, 591

E

- Eagle–Barrett syndrome. *See* Prune belly (triad) syndrome
- E-aminocaproic acid (Amicar), for hemorrhagic cystitis, 215
- Ebbehoj shunt, 607
- Ectopic adrenal tissue, 2
- Ectopic kidney, 738–748
    - blood supply of, 740–741
    - crossed, 738, 739f–740f
    - diagnosis of, 741
    - embryology of, 738
    - epidemiology of, 738–740
    - location of, 738–740, 741f
    - robotic pyeloplasty for, 744–748, 747f
    - simple, 738
    - surgical management of
        - alternatives to, 742
        - indications for, 741–742
        - outcomes and complications of, 748
        - techniques in, 744–748
    - surgical options for conditions in, 748
- Ectopic scrotum, 905, 905f, 907, 907f
- Eggplant deformity, 630, 630f
- Ejaculation
    - delayed, 503–508
    - disorders of, 503–510
    - retrograde, 508–509
    - retroperitoneal lymph node dissection and, 538, 539f

Ejaculation induction, 503–510
  for delayed ejaculation, 504–508
  for retrograde ejaculation, 508–509
Ejaculatory duct, 445–447
  anatomy of, 446, 456
  assessment of, 445
  histology of, 456
Ejaculatory duct obstruction
  diagnosis of, 456–458, 457f
  medications associated with, 456, 456t
  surgical management of, 456–459
    indications for, 456
    outcomes and complications of, 458–459
    technique in, 458, 458f
Electroejaculation, 506–508, 506f–507f, 507t
Electrosurgery, for benign prostatic obstruction, 253–256
Embolization
  for hemorrhagic cystitis, 216
  for intracaval tumors, 26
  for renal trauma, 97, 97f
En bloc renal transplantation, 109–110, 109f
End cutaneous ureterostomy, for posterior urethral valve, 824, 824f
Endopelvic fascia, 420, 423f
Endopyelotomy, 82
Endoscopic treatment. *See also specific disorders and procedures*
  for benign prostatic obstruction/LUTS, 253–260
  for incontinence in women, 371–379
  for interstitial cystitis/bladder pain syndrome, 222, 227–228, 228t
  for megaureter, 758
  for ureterocele, 802, 803f
  for vesicoureteral reflux, 784, 796–800
Endo Stitch, for pyeloplasty, 84, 86f
Enema, continence
  Malone antegrade, 178, 181, 930–933, 931f–932f
  Monti–Malone, 931–932, 932f
Enhanced Recovery after Surgery (ERAS) protocol, 231, 231t
Enterocele
  McCall culdoplasty for, 429, 430f
  sacrospinous ligament fixation for, 430–431, 431f
  transvaginal repair of, 427–431, 428f–431f
  uterosacral ligament fixation for, 429–430, 430f
Enterocystoplasty, pediatric, 914–915, 916f
Enterovesical fistulas, 202. *See also* Intestinovesical fistulas
Epididymal fluid, 442–443
Epididymal obstruction
  diagnosis of, 481–482
  vasoepididymostomy for, 481–488

Epididymal sperm retrieval, 520–521
  microsurgical, 500, 520–521, 520f
  outcomes of, 520–521
Epididymectomy, 498–503
  anatomic considerations in, 499
  anesthesia for, 499
  closure in, 501
  complete, 500–501
  counseling issues in, 498–499
  handling of vas deferens in, 500
  incision in, 499–500
  indications for, 498, 498t
  for malignancy, 501
  outcomes of, 501–502, 502t
  partial, 500
  postoperative evaluation in, 501
  surgical techniques in, 499–501
Epididymis, 441–443
  anatomy of, 441–443, 442f, 444f, 572–573, 574f
  blood supply of, 443
  development of, 441
  function of, 443
  innervation of, 443
  physical examination of, 441
Epididymoorchitis, simple orchiectomy for, 521
Epispadias
  with bladder exstrophy, 835, 837, 846, 850–851
  surgical repair of, 567, 568f, 850–851, 851f
Erectile disorders. *See also specific types*
  erectile dysfunction, 610–629
  priapism, 569, 603–610
Erectile dysfunction (ED)
  arteriogenic, 620–626
  diagnosis of, 612, 621–622, 621f
  epidemiology of, 620
  etiology of, 620
  medical management of, 622
  penile prosthesis for, 610–619
  priapism and, 603, 609
  vascular surgery for, 620–629
    outcomes and complications of, 624–626, 625f, 625t, 626f, 627–628
    patient selection for, 622
    techniques in, 622–624, 623f–624f, 626–627, 627f–628f
  venogenic (veno-occlusive), 620–622, 626–628
Erection
  artificial, in hypospadias surgery, 828
  physiology of, 620–621

Estrogen, for hemorrhagic cystitis, 216
Ethylene vinyl alcohol copolymer, urethral injection of, 371
Excision and primary anastomosis (EPA), for urethral strictures, 338–339, 341, 343–344, 344f
Exstrophy, bladder, 835–854
  in boys
    complete penile dissection and deep dissection in, 837–840, 840f–841f
    complete primary repair of, 837–842
    lines of dissection in, 837, 837f, 838f
    penile/urethral dissection in, 837, 838f–840f
    primary closure in, 840–842, 841f–842f
  diagnosis of, 835–836, 846
  epispadias with, 835, 837, 846
    surgical repair of, 850–851, 851f
  in girls
    final reconstruction in, 844, 844f
    lines of incision in, 842, 843f
    primary repair technique for, 842–844, 843f–844f
  modern staged repair of, 845–854
  physical manifestations of, 835, 836f
  scrotal anomalies with, 905
  surgical management of, 836–845
    adjunctive hernia repair in, 844
    alternatives to, 847
    bladder, posterior urethral, and abdominal wall closure in, 848–850, 849f
    continence and antireflux procedure in, 852–853, 852f
    goals in, 836
    history of, 846
    indications for, 836, 846–847
    operative considerations in, 837
    osteotomy in, 847–848, 848f
    outcomes and complications of, 845, 853–854
    postoperative care in, 844–845, 845f
    preoperative care in, 836, 847
    techniques in, 836–844, 846–853
    timing and staging of, 847–848
  urinary diversion for, 846, 847
Extra-anatomic pyelovesical prosthetic bypass, 729
Extracorporeal shock wave lithotripsy (ESWL), 130–132, 744
Extraperitoneal bladder repair, 213
Extraperitoneal partial cystectomy, 149–150, 149f–150f
Extraperitoneal repair, of vesicovaginal fistula, 199, 200f
Extravaginal testicular torsion, 547–549, 548f
Extravesical bladder diverticulectomy, 174, 242
Extravesical megaureter surgery, 760–761
Extravesical nephroureterectomy, 187–189, 189f
Extravesical VUR technique, 784–785, 784f–785f

F
Fat, urethral injection of, 371
Fecal incontinence
  Malone antegrade continence enema for, 178, 181, 930–933
  medical management of, 930–931, 930t
Female pseudohermaphrodite, 886. *See also* Disorders of sexual development
Feminizing genitoplasty, 886–894. *See also* Disorders of sexual development
Fengerplasty, 83, 83f
Fibrin glue, for vesicovaginal fistula, 195
Fine needle aspiration (FNA), of small renal mass/cyst, 73–74
Fine needle biopsy, testicular, 517–518, 518f
Fistulas. *See also specific types*
  intestinovesical, 202–209
  ureteral, after renal transplantation, 112–117
  urethral, female, 315–321
  urethral, male, 351, 351f
  vesicovaginal, 193–202
Flap vaginoplasty, 880, 883, 883f, 891, 891f–892f
Flexible robot-assisted ureteroscopy, 307–308, 307f–308f
Foley Y-V technique
  in pyeloplasty, 742, 743f
  in UPJ repair, in horseshoe kidney, 742, 743
Foreskin
  anatomy of, 569
  circumcision of (*See* Circumcision)
  stage T1G1-3 cancer of, 579
Formalin, for hemorrhagic cystitis, 216
46XX disorder of sexual development, 886. *See also* Disorders of sexual development
Fossa navicularis, 313
Fournier gangrene
  circumcision and, 901, 901f
  male genital trauma and, 556, 563–564
Fowler–Stephens procedure
  one-stage, 858–861, 859f–861f
  two-stage, 861, 861f
Fusiform megalourethra, 764, 764f

G
Gastrocystoplasty, augmentation, 178, 916–919, 918f
GAX-collagen, urethral injection of, 373, 374–375
Genesis penile prosthesis, 611, 611f, 611t
Genital trauma, male, 554–566. *See also specific types*
  avulsion, 554–555, 561–562, 561f
  chemical (burns), 563
  classification of, 554
  diagnosis of, 554–557

  - foreign bodies in, 554–555
  - Fournier gangrene in, 556, 563–564
  - penetrating, 554–555, 558–560, 559f–560f
  - radiation-induced, 554, 556, 563, 564f–565f
  - simple orchiectomy for, 522
  - surgical management of, 557–566
    - alternatives to, 557–558
    - indications for, 557
    - outcomes and complications of, 564–566
  - thermal (burns), 554, 555–556, 556f, 562–563, 563f
- Genitoplasty
  - female (*See* Clitoroplasty; *See* Vaginoplasty)
  - feminizing, 886–894
- Germ cell tumors, testicular
  - diagnosis of, 527–528, 532, 532f, 533f
  - organ-preserving surgery for, 532–537
    - alternatives to, 532–533
    - indications for, 532
    - outcomes and complications of, 535–536
    - surgical technique in, 533–534, 533f–536f
  - radical inguinal orchiectomy for, 527–531
  - retroperitoneal lymph node dissection for, 537–547
  - simple orchiectomy for, 521–527
- Gerota fascia, anatomy of, 3–4, 4f
- Glans approximation procedure (GAP), 829, 830f
- Glansectomy, for penile cancer, 580
- Glans penis
  - anatomy of, 567–570, 567f
  - stage T2 cancer of, 580
  - stage T1G1-3 cancer of, 579–580
- Glenn–Anderson repair, of VUR, 788, 788f
- Glutaraldehyde cross-linked bovine collagen (GAX-collagen), urethral injection of, 373, 374–375
- Gomco clamp, for circumcision, 898, 899f
- Gonadotropin-releasing hormone (GnRH), in medical castration, 522
- Goodwin–Hohenfellner technique, for transverse colonic conduit, 663–664, 664f
- Gracilis interposition flap, for rectourethral fistula, 208–209, 208f
- Grayhack shunt, 609

H

- Halban culdoplasty, 432, 432f
- Hammock hypothesis, 379, 388
- Hand-assisted laparoscopic nephroureterectomy, 58, 62–63, 63f
- Heineke–Mikulicz principle, 83
- Hematoma
  - penile, 568–569, 569f
  - scrotal, 557, 557f–558f
- Hematuria–dysuria syndrome, 921

Hemiscrotal agenesis, 905, 907–908
Hemorrhagic cystitis, 214–216
    algorithm for, 216f
    bacterial, 214, 214t
    bladder irrigation for, 214–215
    drug-induced, 214, 214t
    etiology of, 214, 214t
    fungal, 214, 214t
    hypogastric artery embolization for, 216
    intravesical medications for, 215–216
    management of, 214–216, 216f, 216t
    radiation-induced, 214, 214t
    supravesical diversion for, 216
    viral, 214, 214t
Heparin, for interstitial cystitis/bladder pain syndrome, 220
Hermaphrodite, 886. *See also* Disorders of sexual development
Hernia
    inguinal, 864–865
        with bladder exstrophy, 844, 846
        diagnosis of, 865
        outcomes and complications of, 865
        surgical technique for, 865
    umbilical, with bladder exstrophy, 844
High-intensity frequency ultrasound (HIFU), for prostate cancer, 307
HIV infection, circumcision and prevention of, 895
Holmium laser ablation of prostate (HoLAP), 259–260
Holmium laser enucleation of prostate (HoLEP), 256–259, 256t, 257f–258f
Holmium:YAG laser therapy
    for benign prostatic obstruction, 256–260
    for posterior urethral valve, 820
Hormonal therapy, for cryptorchidism, 856
Horseshoe kidney, 738–748
    blood supply of, 738, 739f
    diagnosis of, 741
    embryology of, 738
    epidemiology of, 738
    pyeloplasty for, 742, 743f
    stone surgery in, 744
    surgical management of
        alternatives to, 742
        indications for, 741–742
        outcomes and complications of, 748
        techniques in, 742–744
    tumors in, surgery for, 744, 746f
    ureterocalicostomy for, 744, 745f–746f
“Hostile” bladder, 183
Human chorionic gonadotropin (hCG), for cryptorchidism, 856

Human papilloma virus (HPV), and penile cancer, 576
Hydrocele, 572, 642–647, 864–865
  communicating, 642, 643f
  definition of, 642
  diagnosis of, 642–644, 865
  embryology and etiology of, 642, 643f
  indications for treatment of, 644
  noncommunicating, 643f
  nonsurgical repair of, 644
  surgical repair of, 644–647, 865
    Andrews procedure for, 645–646, 646f
    Jaboulay procedure for, 644–645, 645f, 646f
    Lord procedure for, 646, 647f
    microsurgically assisted hydrocelectomy for, 646–647, 648f
    outcomes and complications of, 647, 865
    patient preparation for, 644
  types of, 643f
  with varicocele, 494
  varicocelectomy and, 495
Hydrocelectomy, microsurgically assisted, 646–647, 648f
Hydrodistention, for VUR, 798–799, 798f–799f, 799t
Hydronephrosis, pyeloplasty for, 753–756
Hydroxyzine, for interstitial cystitis/bladder pain syndrome, 220
Hyperbaric oxygen, for hemorrhagic cystitis, 216
Hypospadias, 826–835
  anterior, treatment of, 828–832
  definition of, 826
  diagnosis of, 826–827
  dorsal flap onlay for, 831–832, 832f
  glans approximation procedure for, 829, 830f
  meatal abnormalities in, 826, 827f
  meatal advancement and glanuloplasty for, 828–829, 830f
  onlay island flap for, 832, 832f
  outpatient repair of, 827–828
  penile curvature in, 826, 827
  posterior, treatment of, 832–834
  skin and scrotal abnormalities in, 826–827
  split prepuce in situ only repair of, 832, 832f
  surgical management of
    age for operation in, 827
    algorithm for, 829f
    artificial erection in, 828
    dressings in, 828
    hemostasis in, 828
    nerve block for, 828
    operative setup for, 828
    outcomes and complications of, 834–835

        postoperative problems in, 834
        preoperative evaluation for, 827
        surgeon's experience in, 827
        techniques in, 826, 827–834
        urethral plate preservation in, 829–830
        urinary diversion in, 828
    Thiersch–Duplay or primary tubularization for, 830, 831f
    tubularized incised plate urethroplasty (Snodgrass modification) for, 830–831, 831f
    two-stage repair of, 833–834, 833f–834f
Hysterectomy
    for rhabdomyosarcoma, 776
    vaginal, with vault suspension, 425–427, 425f–428f

I

Ifosfamide, and hemorrhagic cystitis, 214
Ileal augmentation cystoplasty, 178–184, 913–914, 914f–916f, 920
Ileal conduit urinary diversion, 656–660
    alternatives to, 656
    bowel segment for, 657, 657f

        outcomes and complications of, 552–553
        surgical technique in, 551–552, 551f
Orchitis, simple orchiectomy for, 521–522
Organ-preserving techniques
    in hypospadias surgery, 829–830
    in kidney cancer, 187
    penile, in anterior urethrectomy with perineal urethrostomy, 362–364, 363f–364f
    in radical cystectomy, in men, 159
    in radical cystectomy, in women, 168–169, 169f
    in radical urethrectomy, in women, 368–370, 370f
    in testicular cancer, 532–537
    in ureterocele surgery, 802–803, 802t
Orthotopic bladder substitution, 667–673
    age and, 667
    atraumatic dissection of urethra in, 669
    bowel function and, 668
    bowel segment for, 669–670, 670f
    colonic, 688–697
        alternatives to, 689
        blood supply in, 693, 695f
        construction of reservoir in, 689–693, 690f–694f, 696f
        indications for, 689
        outcomes and complications of, 696–697
        preoperative preparation for, 689
        rationale for, 688
        surgical technique for, 689–695
        ureteral implantation in, 695
    goal of, 667
    ileal, 680–688
        approach to female urethra in, 681–684, 681f–684f
        approach to male urethra in, 680–681, 681f
        construction of reservoir for, 684–685, 684f–686f
        cystectomy in, 680–684, 680f
        ileoureteral anastomosis in, 685–687, 687f
        outcomes and complications of, 687–688
        ureteral mobilization in, 680, 680f
    ileal low-pressure, 674–679
        alternatives to, 674
        construction of reservoir in, 676–678, 676f–678f

        - cystectomy in, 675
        - in obese patients, 678, 678f
        - outcomes and complications of, 679
        - postoperative care in, 678–679
        - preparation of ileum segment for, 675, 675f
        - surgical technique for, 675–678, 675f–678f
        - ureteroileal end-to-side anastomosis in, 675–676, 676f
        - urethral anastomosis in, 676–678, 676f–678f
    - indications for, 674
    - in interstitial cystitis/bladder pain syndrome, 224
    - liver function and, 668
    - long-term follow-up in, 672, 673f
    - metabolic acidosis with, 672
    - outcomes of, 667
    - paracollicular/bladder neck biopsy and, 668
    - patient motivation/mental status and, 667
    - patient selection for, 667, 667t, 674, 689
    - postoperative management of, 671–672, 671t
    - preoperative preparation for, 668
    - preservation of pelvic innervation in, 668, 669f
    - in radical cystectomy, 158, 159f, 236–237, 237f–239f, 240
    - renal function and, 667–668
    - surgical technique for, 668–670
    - ureter management in, 669
    - urinary continence status and, 668
    - voiding and urinary continence with, 671–672
- Orthotopic kidney transplantation, 109, 109f
- Orthotopic neobladder. *See* Orthotopic bladder substitution
- Outside-in transobturator midurethral sling, 385–386, 385f–386f

    pathophysiology of, 423
    perineal body reconstruction for, 437, 437f–438f
    posterior colporrhaphy for, 434–436, 436f–437f
    risk factors for, 423
    sacral colpopexy for
        laparoscopic, 433, 433f
        open, 431–433, 432f–433f
        robot-assisted laparoscopic, 433
    sacrospinous ligament fixation for, 430–431, 431f
    site-specific rectocele repair for, 436–437
    surgical management of, 424–439
        alternatives to, 424
        anterior compartment, 433–434, 439
        apical compartment, 425–433, 438–439
        basic tenets of, 424
        complications of, 437–438
        indications for, 424
        outcomes of, 438–439
        posterior compartment for, 434–437, 439
        postoperative care in, 437
        techniques in, 424–437
    transvaginal enterocele repair for, 427–431, 428f–431f
    uterosacral ligament fixation for, 429–430, 430f
    vaginal hysterectomy with vault suspension for, 425–427, 425f–428f
    vaginal paravaginal repair for, 434
Pelvioureterostomy-en-Y, for posterior urethral valve, 823–824, 823f
Peña posterior sagittal anorectovaginourethroplasty (PSARVUP), 882
Penectomy
    partial
        indications for, 580
        surgical technique in, 581, 581f–582f
    total
        indications for, 580
        technique of, 583–584, 583f–584f
Penile amputation, 636–641
    outcomes of, 641
    postoperative care in, 641
    preservation of severed penis in, 637
    reconstruction of nonsalvageable penis (stump) in, 637–641, 639f–6401f
    replantation of viable penis in, 637, 638f–639f
    self-mutilation and, 637
    surgical complications in, 641

Penile cancer, 576–589
  circumcision for, 578
  circumcision for prevention of, 576
  cryotherapy for, 579
  diagnosis of, 577–579, 577f–579f, 590–591
  epidemiology of, 576, 590
  glansectomy for, 580
  histologic subtypes of, 576
  HPV and, 576
  laser therapy for, 579
  lymph node management in, 578–579, 578f, 585–588
    complications of, 595
    dynamic sentinel node biopsy in, 585–586, 585f–586f, 591
    general considerations in, 585–586
    inguinal dissection technique in, 586–588, 587f, 590–596
    pelvic dissection technique in, 586
    workflow diagram for, 592f
  Mohs micrographic surgery for, 580
  natural history of, 576
  partial penectomy for, 580, 581, 581f–582f
  radiation therapy for, 580–581
  risk factors for, 576
  stage T3-4, 580–581
  stage Ta-Tis, 579
  stage T1G1-3, of foreskin, 579
  stage T1G1-3 of glans, 579–580
  stage T2 of corpora, 580
  stage T2 of glans, 580
  staging of, 577, 578t, 590–591, 590t
  surgical management of, 576–577, 579–585
    complications of, 584–585, 585f
    degree of resection and margins in, 578–579
    follow-up in, 588
    indications for, 579–581
    postoperative care in, 584–585
    technique in, 581–584
  total penectomy for, 583–584, 583f–584f
  wide local excision for, 580
Penile curvature
  acquired, 650
  congenital, 650–655
    classification of, 650, 650f
    diagnosis of, 651, 651f
    incision and plication for, 651–654, 652f–654f
    multiple parallel plication for, 654–655
    outcomes and complications of, 655
    penile disassembly for, 655

        surgical indications in, 651
        surgical technique for, 651–655
        Yachia longitudinal plication for, 654, 654f
    hypospadias and, 826, 827, 833–834, 834f
Penile disassembly, for congenital curvature, 655
Penile hematoma, 568–569, 569f
Penile hyposensitivity, age-related, 504
Penile preservation, in anterior urethrectomy with perineal urethrostomy, 362–364, 363f–364f
Penile prosthesis, 610–619
    alternatives to, 613
    currently available, 611, 611f–612f, 611t
    for erectile dysfunction, 610–619
    for incontinence, 395t, 400
    indications for, 612–613
    infection/infection prevention with, 611, 613, 618–619
    mechanical, 611, 611f
    multiple-component, 611–612, 612f
    outcomes and complications of, 618–619
    for Peyronie disease, 602, 612–613
    for priapism, 609–610
    reliability of, 610, 619
    semirigid, 611, 611f, 619
    surgical implantation of, 613–618
        distal penile (subcoronal) approach in, 618
        infrapubic approach in, 617–618
        “no touch” technique in, 613
        penoscrotal approach in, 613–617, 613f–617f
Penile reconstruction
    anatomy and, 570, 571f
    postoperative care in, 641
    stump, from amputation, 637–641, 639f–640f
Penile replantation, 636–641
    nonsalvageable penis (stump) for, 637–641, 639f–640f
    outcomes and complications of, 641
    postoperative care in, 641
    preservation of severed penis for, 637
    surgical technique for, 637–641
    viable penis for, 637, 638f–639f
Penile rupture (fracture), 629–632
    conservative management of, 630
    diagnosis of, 630, 630f
    etiology of, 629–630
    surgical management of, 630–632
        alternatives to, 630
        indications for, 630
        outcomes and complications of, 632
        technique in, 630–632, 631f

Penile skin loss, 632–634
  diagnosis of, 632, 632f
  surgical management of
    indications for, 632
    outcomes and complications of, 634
    technique in, 632–634, 633f–634f
    vacuum-assisted closure in, 633–634, 634f
Penile trauma, 629–636. *See also specific types*
  blunt, 629–632
  penetrating, 634–636
    alternative therapy for, 635
    diagnosis of, 634
    outcomes and complications of, 636
    surgical indications in, 634–635
    surgical technique for, 635, 635f
Penile urethral trauma, 353–356
Penile vascular surgery, 620–629
  alternative treatments to, 622
  for arteriogenic erectile dysfunction, 622–626
    outcomes and complications of, 624–626, 625f, 625t, 626f
    patient selection for, 622
    techniques in, 622–624, 623f–624f
  for venogenic (veno-occlusive) erectile dysfunction, 626–628
    outcomes and complications of, 627–628
    patient selection for, 626
    technique in, 626–627, 627f–628f
Penile vibratory stimulation, 505–506, 505f
Penis. *See also specific disorders and procedures*

    in robot-assisted laparoscopic radical prostatectomy, 285–286, 288, 288f
  function of, 447
  imaging of, 445, 445f, 449
  innervation of, 447, 449
  physical examination of, 445
  prostate relationship with, 245, 245f
Seminal vesicle chromotubation, 458
Seminal vesicle lesions
  alternative therapy for, 449
  diagnosis of, 449
  endoscopic treatment of, 455
  primary *vs.* secondary, 449
  surgical management of, 449–456
    indications for, 449–450
    laparoscopic techniques in, 454–455, 454f
    outcomes and complications of, 456, 456t
    paravesical approach in, 452–453
    preoperative preparation for, 450
    retrovesical approach in, 452f, 453
    robotic-assisted, 455
    techniques in, 450–456
    transcoccygeal approach in, 453–454, 453f
    transperineal approach in, 450–452, 451f
    transvesical approach in, 450, 451f
Seminiferous tubules, 441
Semirigid rod penile prostheses, 611, 611f, 619
Sentinel node biopsy, in penile cancer, 585–586, 585f–586f, 591
Sexual development, disorders of. *See* Disorders of sexual development
Sexual function, female, radical cystectomy and, 164
Shunts, for priapism, 607–610, 608f
Sigmoid colonic conduit, for palliative urinary diversion, 726
Sigmoidocystoplasty, 915–916, 917f
Sigmoid-rectal pouch, 716–724
Silicone polymers, urethral injection of, 375
Silver nitrate
  for hemorrhagic cystitis, 215
  for interstitial cystitis/bladder pain syndrome, 220
Simple renal cysts, 69–70
Simpson–Golabi–Behmel syndrome, 731
Sinus epididymis, 441

Sleeve technique, in circumcision, 897, 897f
Slings
  bladder neck, 379–388, 812–813, 812f
  fascial, 812–813, 812f
  male, 394, 395t, 402, 403–410
  for neurogenic bladder, 329
  pubovaginal, 320f, 321, 812–813, 812f
  urethral, female, 379–388
Small renal masses (SRMs)
  laparoscopic ablation of, 76–81
    complications of, 79–80
    contraindications to, 77
    indications for, 77
    mechanisms of action, 77–78
    perioperative preparation and considerations in, 78
    positioning, portal placement, and exposure in, 78
    postoperative care in, 79
    surgical technique in, 78–79, 78f–79f
  percutaneous biopsy of, 73–74
Snodgrass modification, for hypospadias, 830–831, 831f
Sober loop ureterostomy, for posterior urethral valve, 823–824, 823f
Sodium oxychlorosene, for interstitial cystitis/bladder pain syndrome, 220
Sodium pentosan polysulfate (SPPS)
  for hemorrhagic cystitis, 215–216
  for interstitial cystitis/bladder pain syndrome, 220
Sotos syndrome, 731
SPARC urethral sling, 382–384, 382f–384f
Spectra penile prosthesis, 611, 611f, 611t
Spermatic cord, 572, 574f
Spermatocele, 648–649
  definition of, 648
  diagnosis of, 648
  indications for treatment of, 648
  outcomes and complications of, 648–649
  surgical technique for, 648, 649f

Spermatocelectomy, 648, 649f
Spermatogenesis, 441
Sperm cryopreservation, 528, 539
Sperm maturation, 441, 443
Sperm retrieval, 516–517
    contraindications to, 516
    epididymal, 500, 520–521
        microsurgical, 500, 520–521, 520f
        outcomes of, 520–521
    intraoperative specimen evaluation in, 516–517
    quality and quantity of sperm retrieved in, 516
    in retrograde ejaculation, 508–509
    testicular, 517–520
        conventional, 518–519
        fine needle aspiration for, 517–518, 518f
        indications for, 517
        microscopic-assisted, 518–519, 519f
        open biopsy for, 517–518, 518f
        outcomes of, 519–520
        percutaneous biopsy for, 517–518, 518f
    timing of, 516
    vasoepididymostomy *vs.*, 482
    vasovasotomy *vs.*, 470
Sphincteric incontinence surgery, with augmentation cystoplasty, 911
Split prepuce in situ onlay hypospadias repair, 832, 832f
Squamous cell carcinoma
    penile, 576–596
    urethral, 360, 367
SRMs. *See* Small renal masses
Starr plication, for megaureter, 760, 760f
Stem cell therapy, for incontinence in women, 377
STING technique, for VUR, 798
Stones. *See* Calculus disease
Storage reflex, 143–144
Straddle injury, 353–356
Stress urinary incontinence (SUI)
    in men, postprostatectomy
        diagnosis of, 404
        male sling for, 403–410
        prevalence of, 403–404
        risk factors for, 404
        surgical indications in, 404
    in women
        abdominal retropubic approaches for, 388–392
        alternative therapies for, 380
        Burch urethropexy, 388–392
        diagnosis of, 379–380, 389

        - injection therapy for, 371–379
        - Marshall-Marchetti-Krantz (MMK) procedure for, 388–389
        - pathophysiology of, 379, 388
        - urethral slings for, 379–388
- Subcapsular orchiectomy, 525, 525f, 526f
- Subcoronal approach, to penile prosthesis implantation, 618
- Subcostal incision, in radical nephrectomy, 17f, 22–23
- Subepididymal orchiectomy, 525–526, 526f
- Substitution cystoplasty, for interstitial cystitis/bladder pain syndrome, 222–224, 224f
- Substitution urethroplasty, 341, 341f, 344–347
    - dorsal onlay graft for, 346, 346f–347f
    - penile skin flap for, 346–347, 347f
    - ventral onlay graft for, 344–346, 345f–346f
- Subureteric Teflon injection, for VUR, 798
- Supradiaphragmatic intracaval tumor, 33–34, 33f–34f
- Suprapubic catheter placement, for urethral trauma, 358–359, 359f
- Suprapubic orchiectomy, 524–525, 524f
- Suprapubic prostatectomy, 260–261, 261f–262f
- Supra-11th rib mini-flank surgical incision, 8–10, 8f–11f
- Supravesical diversion
    - for hemorrhagic cystitis, 216
    - for posterior urethral valve, 822–824, 822f–825f

T

- Tadalafil, for delayed ejaculation, 504
- Teflon
    - for female incontinence, 371
    - for vesicoureteral reflux, 784, 798
- Tegress, urethral injection of, 371
- TESA. *See* Testicular sperm aspiration
- Testicular amputation, 558–560

Thermal ablation, of renal tumors, 7

Thermal injuries (burns), scrotal, 554, 555–556, 556f, 562–563, 563f

Thiersch-Duplay or primary tubularization, 830, 831f

Thiotepa, and hemorrhagic cystitis, 214

Thoracoabdominal incision, in radical nephrectomy, 17f, 20–22, 21f–22f

Thulium laser transurethral vaporesection of the prostate (ThuVARP), 260

Tibial nerve stimulation, 226–227, 227f, 412

Tiflis pouch, 706, 709f

Titan penile prosthesis, 611, 612f, 613

Top-down retropubic midurethral sling, 382–384, 382f–384f

Total penectomy
- complications of, 584–585, 585f
- indications for, 580
- postoperative care in, 584–585
- technique of, 583–584, 583f–584f

Total urogenital mobilization (TUM), 882–884, 882f–885f, 891–894, 892f–893f

Transabdominal bladder repair, 212–213, 213f

Transabdominal incision, in radical nephrectomy, 17f, 22–23, 23f

Transabdominal repair
- of rectourethral fistula, 209
- of vesicovaginal fistula, 197–199, 197f–199f, 200t

Transanal approach, to rectourethral fistula, 206, 206f

Transcoccygeal approach, to seminal vesicle, 453–454, 453f

Transitional cell carcinoma. *See* Urothelial (urothelial cell) carcinoma

Transitional epithelium, of bladder, 139, 140f

Transobturator midurethral sling
- inside-out, 386
- outside-in, 385–386, 385f–386f

Transobturator retrourethral sling, 405–407
- mechanism of action, 406
- outcomes of, 406–407
- surgical technique for, 405–406, 406f

Transperineal approach

  - to rectourethral fistula, 207–208, 208f
  - to seminal vesicle, 450–452, 451f
- Transperineal ultrasound, in delayed ejaculation, 503–504, 504f
- Transperitoneal nephrectomy
  - laparoscopic partial, 48–52, 48f–53f
  - laparoscopic radical or total, 44–47, 45f–47f
  - pediatric laparoscopic, 873–875, 874f–875f
  - robotic partial, 52–53, 53f
- Transperitoneal nephroureterectomy, laparoscopic radical, 61–66
- Transperitoneal pyeloplasty, pediatric laparoscopic, 867f, 869, 869f–870f
- Transperitoneal transureteroureterostomy, 750, 750f–751f
- Transrectal ultrasound (TRUS)
  - for brachytherapy guidance, 291, 293–297, 293f–295f
  - of ejaculatory duct obstruction, 456–457, 457f
- Transureteroureterostomy (TUU), 749–753
  - alternatives to, 749
  - indications for, 749
  - laparoscopic/robot-assisted, 752
  - outcomes and complications of, 752
  - retroperitoneal, 751–752
  - surgical technique in, 749–752
  - transperitoneal, 750, 750f–751f
- Transurethral incision of the prostate (TUIP), 253–255, 255t
- Transurethral injection, for incontinence in women, 372
- Transurethral microwave thermotherapy (TUMT), 252
- Transurethral needle ablation (TUNA), 252–253

    alternative therapy for, 113
    after renal transplantation, 112–117
Ureteral reimplantation. *See also specific procedures*
    for VUR, 782, 783–791
Ureteral strictures
    diagnosis of, 134
    laparoscopic ureterolysis for, 134–136
Ureteral unroofing technique, 190–191, 191f
Ureteral vesical junction, 140–141
Ureteric complications, of renal transplantation, 112–117
    alternative therapy for, 113–114
    categories of, 113t
    diagnosis of, 112–113
    ipsilateral native to allograft ureterostomy or ureteropyelostomy for, 116, 116f–117f
    surgical management of, 113–116
        general considerations in, 114
        indications for, 113
        outcomes and complications of, 116–117

        patient preparation and exposure in, 114–115, 115f
        technique in, 114–116
    ureterovesical reanastomosis (redo) procedure for, 115–116
Ureterocalicostomy, 744, 745f–746f, 748
Ureterocele, 801–804
    diagnosis of, 801–802, 801f
        alternatives to, 802
        indications for, 802
        techniques in, 802–804, 802t
    endoscopic incision of, 802, 803f
    excision, with ureteral reimplantation, 802, 803f
    surgical management of, 802–805
        complete lower urinary tract reconstruction in, 802, 803f
        complete reconstruction in, 802t, 804
        outcomes of, 804
        upper pole ablation in, 802t, 803–804
        upper pole preservation in, 802–803, 802t
    upper pole nephrectomy and partial ureterectomy for, 803–804, 804f
    ureteroureterostomy/ureteropyelostomy for, 803
Ureterocutaneostomic stoma, construction of, 726
Ureterocystoplasty, augmentation, 919, 919f
Ureterolithotomy, open, 130
Ureterolysis, laparoscopic, 134–136
    indications for, 134
    outcomes and complications of, 136
    postoperative care in, 136
    surgical technique in, 134–136
Ureteroneocystostomy
    in renal autotransplantation, 123–124, 124f
    in renal transplantation, 106–108, 107f–108f
Ureteropelvic junction (UPJ) obstruction
    classification of, 753
    diagnosis of, 81, 753, 866–867
    endopyelotomy for, 82
    horseshoe kidney and, 741, 742–744
    laparoscopic pyeloplasty for, 81–87
        alternatives to, 82
        Anderson-Hynes dismembered method of, 83–85, 83f, 85f, 86f
        contraindications to, 81–82
        cystoscopy and retrograde ureterography for, 82
        drain placement and exit in, 85
        Endo Stitch for, 85, 86f
        entry and port placement in, 82, 83f
        exposure of operative field in, 82
        Fengerplasty method of, 83, 83f
        indications for, 81
        instrumentation for, 82

        intraoperative complications of, 86–87
        literature review of, 87
        mini-method of, 85
        natural orifice method of, 85
        patient positioning for, 82
        pediatric, 866–872
        postoperative care in, 86
        postoperative complications in, 87
        preoperative preparation for, 82
        pyelolithotomy in, 83, 85
        robotic-assisted, 85–86, 86f
        selecting type of repair in, 83, 83f–84f
        single-site method of, 85
        surgical alternatives in, 85–86
        surgical technique in, 82–85
        UPJ dissection in, 82–83
        ureteral stent placement for, 82
        Y-V plasty method of, 83, 84f, 85
    pediatric laparoscopic pyeloplasty for, 866–872
        alternatives to, 867
        indications for, 867
        outcomes and complications of, 871–872, 871t
        patient positioning for, 867, 867f
        retroperitoneoscopic approach in, 868–869, 868f–869f
        robot-assisted, 744–748, 747f, 866, 870–871, 870f–871f
        special considerations in, 870
        techniques in, 867–871
        transperitoneal approach in, 867f, 869, 869f–870f
    pediatric open pyeloplasty for, 742, 743f, 753–756
        alternatives to, 754
        indications for, 753–754
        open, 866
        outcomes and complications of, 756
        surgical technique for, 754–756, 754f–756f
    renal autotransplantation for, 118
    ureterocalicostomy for, 744, 745f–746f
Ureteropyelostomy
    for renal transplantation complications, 116, 116f–117f
    for ureterocele, 803
Ureteroscopy, flexible robot-assisted, 307–308, 307f–308f
Ureterosigmoidostomy, 716–724
    alternatives to, 717
    for bladder exstrophy, 847
    classical, 717–718, 717f–718f
    colorectal carcinoma after, 722–723
    continence rates with, 723
    contraindications to, 716

    indications for, 716
    Mainz pouch II technique in, 718–720, 719f–720f
    outcomes and complications of, 722–723
    preoperative preparation for, 717
    quality of life after, 723
    surgical technique in, 717–722
    surgical tricks in, 722
    upper urinary tract safety after, 723
Ureterostomy. *See also* Transureteroureterostomy; *See also* Ureterosigmoidostomy
    allograft, for renal transplantation complications, 116, 116f–117f
    bilateral, with single stoma, 726
    distal cutaneous, in prune belly (triad) syndrome, 766
    partial, for ureterocele, 803–804, 804f
    for posterior urethral valve
        end cutaneous, 824, 824f
        high cutaneous loop, 823, 823f, 824, 825f
        sober loop, 823–824, 823f
    transureteral cutaneous, 726
    transureteropyelocutaneous, 726
Ureteroureterostomy, for ureterocele, 803
Ureterovesical reanastomosis, 115–116
Ureterovesicostomy, in Mitrofanoff procedure, 928
Urethra, 311–314. *See also* Urethra, *See also* female; *See also* Urethra, *See also* male; *See also* *specific disorders and procedures*
Urethra, female, 311–312
    gross anatomy of, 311, 311f–313f, 569–570
    innervation of, 311
    lymphatics of, 312
    microscopic anatomy of, 311, 311f
    reconstruction of, 315–321
    structures contiguous to, 312, 313f
    vascular anatomy of, 311
Urethra, male, 246, 312–314
    gross anatomy of, 312–313, 314f, 447f
    in ileal orthotopic bladder substitution, 680–681, 681f
    innervation of, 313
    lymphatics of, 313–314
    microscopic anatomy of, 313
    structures contiguous to, 314
    vascular anatomy of, 313
Urethral cancer, 360–370
    histologic subtypes of, 360
    lymph node management in, 370
    male-to-female ratio of, 360
    in men, 361–366
        alternative treatments for, 362
        anatomy and, 361–362

        diagnosis of, 361
        epidemiology, risk factors, and presentation of, 361
        histopathology of, 361–362
        partial urethrectomy for, 364–365
        penile-preserving anterior urethrectomy with perineal urethrostomy for, 362–364, 363f–364f
        radical cystoprostatectomy with en bloc urethrectomy for, 365–366, 366f–367f
        recurrence, after radical cystectomy, 364
        staging of, 361, 361t
        surgical complications of, 366–367
        surgical treatment of distal tumors in, 362–365, 363f–364f
        surgical treatment of proximal tumors in, 365–366
    in women, 367–370
        alternative treatments for, 368
        anatomy and, 367
        diagnosis of, 367
        distal urethrectomy for, 368, 369f
        epidemiology, etiology, and risk factors of, 367
        histopathology of, 367
        radical urethrectomy with bladder preservation for, 368–370, 370f
        staging of, 367
        surgical treatment of distal tumors in, 368–370
        surgical treatment of proximal tumors in, 370
Urethral disruption. *See also* Urethral trauma
    complete, 354
    partial, 354
Urethral diverticulum, female
    coexisting conditions with, 322
    diagnosis of, 322–323, 323f
    formation of, 322, 323f
    urethral reconstruction for, 322–327
        alternatives to, 324
        indications for, 323
        outcomes and complications of, 326–327
        principles of, 324, 324t
        surgical technique in, 324–326, 324f–327f
Urethral fistula, female
    diagnosis of, 315–316
    diverticulectomy and, 326–327
    etiology of, 315, 315t
    urethral reconstruction for, 315–321
        advancement anterior vaginal flap for, 316, 317f
        alternatives to, 316
        bladder flap for, 318, 319f
        complications of, 321
        general principles of, 316, 316t
        indications for, 316

        - labia minora pedicle flap for, 318, 319f
        - outcomes of, 321, 322t
        - primary closure for, 316, 317f
        - pubovaginal sling for, 320f, 321
        - surgical technique in, 316–321
        - tube flap for, 318, 318f
        - vascular pedicle graft (Martius flap) for, 320–321, 321f
- Urethral fistula, male, urethroplasty and, 351, 351f
- Urethral injections, for female incontinence, 371–379
- Urethral lacunae, 313
- Urethral lengthening
    - Kropp procedure for, 814–816, 815f
    - Pippi Salle procedure for, 816–817, 816f
- Urethral reconstruction, female
    - for urethral diverticulum, 322–327
        - alternatives to, 324
        - indications for, 323
        - outcomes and complications of, 327
        - principles of, 324, 324t
        - surgical technique in, 324–326, 324f–327f
    - for urethral fistula, 315–321
        - advancement anterior vaginal flap for, 316, 317f
        - alternatives to, 316
        - bladder flap for, 318, 319f
        - general principles of, 316, 316t
        - indications for, 316
        - labia minora pedicle flap for, 318, 319f
        - outcomes and complications of, 321, 322t
        - primary closure for, 316, 317f
        - pubovaginal sling for, 320f, 321
        - surgical technique in, 316–321
        - tube flap for, 318, 318f
        - vascular pedicle graft (Martius flap) for, 320–321, 321f
- Urethral reconstruction, male, 336–352
    - anastomotic techniques for, 338–339, 341, 343–344, 344f
    - anatomic considerations in, 338–339, 339f
    - antibiotic prophylaxis in, 342
    - buccal mucosal harvest for, 342, 342f
    - complications of, 351, 351f
    - flaps for coverage in, 340
    - free grafts for, 339
    - general considerations in, 341–342
    - internal urethrotomy for, 338, 340–341, 340f, 342–343
    - outcomes and follow-up in, 351
    - patient positioning for, 341–342
    - perspectives on, 351
    - postoperative care in, 342, 343t

  preoperative and intraoperative decision making in, 340–341, 340f–341f
  principles of, 338–340
  skin flaps for, 339, 339f
  staged urethroplasty for, 347–351, 348f–351f
  substitution urethroplasty for, 341, 341f, 344–347, 345f–347f
  surgical techniques in, 342–351, 344f–351f
  urethral sonography in, 342
Urethral slings, for men. *See* Male sling
Urethral slings, for women, 379–388
  alternatives to, 380
  indications for, 380
  midurethral, 379–387
    bottom-up retropubic, 384–385
    inside-out transobturator, 386
    outside-in transobturator, 385–386, 385f–386f
    top-down retropubic, 382–384, 382f–384f
  outcomes and complications of, 386–387
  postoperative considerations with, 386
  preoperative considerations for, 380–381
  rectus fascia bladder neck, 379–382, 386–387
    abdominal incision for, 381
    adjusting tension of, 382, 382f
    cystoscopy of, 381
    fascial harvest for, 381, 381f
    suture passer advancement for, 381, 381f
    vaginal dissection for, 381
    wound closure for, 382, 382f
  surgical technique for, 380–386
Urethral-sparing cystectomy, in women, 169, 169f
Urethral strictures, male, 570, 570f
  anterior disease, 336–352
    algorithm for management of, 340f
    anastomotic techniques for, 338–339, 341, 343–344, 344f
    anatomic considerations in, 338–339, 339f
    buccal mucosal graft for, 342, 342f
    endoscopic studies of, 337–338
    epidemiology and pathophysiology of, 336
    evaluation of, 336–338
    flaps for coverage in, 340
    free grafts for, 339
    general surgical considerations in, 341–342
    internal urethrotomy for, 338, 340–341, 340f, 342–343
    outcomes and follow-up in, 351
    perspectives on, 351
    postoperative care in, 342, 343t
    preoperative and intraoperative decision making for, 340–341, 340f–341f
    radiographic studies of, 337, 337f–338f

        reconstructive principles for, 338–340
        skin flaps for, 339, 339f
        staged urethroplasty for, 347–351, 348f–351f
        substitution urethroplasty for, 341, 341f, 344–347, 345f–347f
        surgical complications in, 351, 351f
        surgical techniques for, 342–351, 344f–351f
    clinical presentation of, 336
    historical perspective on, 336
    individualized approach to, 336
    with rectourethral fistula, 205
Urethral trauma, 353–360
    anatomic considerations in, 353, 353f
    anterior, 353–356
        alternative therapy for, 354–355
        anatomy and, 353, 353f
        classification of, 354
        diagnosis of, 354, 354f
        outcomes and complications of, 356
        surgical indications in, 354
        surgical technique for, 355, 355f
    posterior, 356–359
        alternative therapy for, 358
        anatomy and, 353f, 356
        classification of, 357, 357t
        delayed urethroplasty for, 359
        diagnosis of, 356–357, 357f
        open suprapubic catheter placement for, 358–359, 359f
        outcomes and complications of, 359
        surgical indications in, 357–358
        surgical technique for, 358–359, 359f
Urethral valve
    anterior, 825–826
    posterior, 818–825
Urethrectomy
    in men
        anterior, with perineal urethrostomy, 362–364, 363f–364f
        en bloc, with radical prostatectomy, 365–366, 366f–367f
        in one-stage cystoprostatectomy, 155–158, 157f–158f
        partial, 364–365
    in women
        distal, 368, 369f
        radical, with bladder preservation, 368–370, 370f
        in radical cystectomy, 167, 167f
Urethropelvic ligaments, 420–421, 421f
Urethroplasty
    for anterior urethral trauma, 354–355, 355f
    for posterior urethral trauma, 359

    in prune belly (triad) syndrome, 769, 769f–770f
    staged, 347–351
        Asopa technique in, 348, 348f
        first stage of, 347–349, 348f
        second stage of, 349–351, 349f–351f
    substitution, 341, 341f, 344–347
        dorsal onlay graft for, 346, 346f–347f
        penile skin flap for, 346–347, 347f
        ventral onlay graft for, 344–346, 345f–346f
    Thiersch Duplay or primary tubularization, 830, 831f
    tubularized incised plate, 830–831, 831f
Urethrostomy, perineal
    with anterior urethrectomy, 362–364, 363f–364f
    with total penectomy, 583–584, 584f
Urethrotomy, internal, 338, 340–341, 340f, 342–343
Urethrovaginal fistula. *See* Urethral fistula, *See* female
Urethrovaginal sphincter, 311, 312f
Urgency urinary incontinence (UUI)
    alternative therapy for, 412
    diagnosis of, 411–412
    sacral neuromodulation for, 411
    surgical indications in, 412
Urinary bladder. *See* Bladder
Urinary diversion. *See also specific procedures*
    for anterior urethral trauma, 354–355
    for bladder cancer, 236–238, 237f–239f, 240
    for bladder exstrophy, 846, 847
    continent catheterizable reservoirs for
        colonic, 702–715
        ileal, 697–701
        Mitrofanoff principle/procedure for, 702, 923–930
    for hemorrhagic cystitis, 216
    in hypospadias surgery, 828
    ileal conduit, 656–660, 725–726, 725f
    for interstitial cystitis/bladder pain syndrome, 219, 224
    orthotopic bladder substitution for, 667–674
        colonic, 688–697
        ileal, 680–688
        ileal low-pressure, 674–679
    palliative, 724–730
        bilateral ureterostomy with single stoma for, 726
        double-J stents for, 727, 728, 728f
        eliminating function of contralateral kidney in, 727
        extra-anatomic pyelovesical prosthetic bypass for, 729
        ileal conduit for, 725–726, 725f
        indications for, 724–725
        metallic mesh stents for, 728–729

        - percutaneous nephrostomy for, 726–727
        - sigmoid colon conduit for, 726
        - surgical technique for, 725–727
        - transureteral cutaneous ureterostomy for, 726
        - transureteropyelocutaneous ureterostomy for, 726
        - transverse colon conduit for, 726
        - transverse retubularized colon segment for, 729, 729f
        - for ureteral obstruction, 727–729, 728f–729f
        - ureterocutaneostomic stoma for, 726
    - in prune belly (triad) syndrome, 765
    - transverse colonic conduit, 661–666, 726
    - ureterosigmoidostomy for, 716–724, 847
- Urinary retention
    - alternative therapy for, 412
    - diagnosis of, 411–412
    - sacral neuromodulation for, 411–419
    - surgical indications in, 412
- Urinary sphincter, artificial. *See* Artificial urinary sphincter
- Urinary tract infections, augmentation cystoplasty and, 183, 921
- Urinary tract reconstruction, in renal transplantation, 106–108, 107f–108f
- Urogenital mobilization
    - partial, 882f, 883–884
    - total, 882–884, 882f–885f, 891–894, 892f–893f
- Urogenital sinus anomalies, 877–885, 877f. *See also* Disorders of sexual development
    - clitoroplasty for, 879–880, 879f–880f, 883
    - decompression therapy for, 878–879, 882
    - diagnosis of, 878
    - labioplasty for, 881, 881f
    - partial urogenital mobilization for, 882f, 883–884
    - pure, 877, 878
    - surgical management of, 878–885, 891–894
        - outcomes of, 883–885, 894
        - techniques in, 879–883, 891–894
    - total urogenital mobilization for, 882–884, 882f–885f, 891–894, 892f–893f
    - vaginoplasty for, 880–881, 891, 891f–892f, 893–894, 893f
- Urolithiasis. *See* Calculus disease
- Urothelial (urothelial cell) carcinoma
    - bladder
        - diagnosis of, 148, 151
        - partial cystectomy for, 148–150
        - radical cystectomy in men for, 151–161, 233–234
        - radical cystectomy in women for, 161–171, 234–235
        - robotic radical cystectomy for, 230–244
    - prostate, 361t, 362
    - upper tract (*See* Upper tract urothelial carcinoma)
    - urethral, 360, 367
- Urothelium, 139, 140f

Uterine rhabdomyosarcoma, 773, 776, 780
Uterosacral ligament fixation, 429–430, 430f
Uterus, ligament support of, 421, 421f
UTUC. *See* Upper tract urothelial carcinoma

V

Vaginal canal
  anatomy of, 420
  pelvic organ prolapse and, 420–440
Vaginal hysterectomy, with vault suspension, 425–427, 425f–428f
Vaginal paravaginal repair, 434
Vaginal reconstruction, in radical cystectomy, 168, 168f
Vaginal rhabdomyosarcoma, 773, 774f, 776, 777f, 778f, 780
Vaginal trauma, with bladder trauma, 211
Vaginoplasty, 880–881
  cut-back, 880
  flap, 880, 883, 883f, 891, 891f–892f
  for high vaginal confluence, 881, 893–894, 893f
  for low vaginal confluence, 880, 891, 891f–892f
  pull-through, 881, 882
Varicocele, 490–497
  classification of, 490, 490t
  definition of, 490
  diagnosis of, 490
  hydrocele with, 494
  laparoscopic ligation of, 132–134
    alternatives to, 132
    indications for, 132
    outcomes and complications of, 133–134
    surgical technique in, 132, 132f–135f
  recurrence of, 496
  subclinical, 490
  surgical repair of, 490–497 (*See also* Varicocelectomy)
Varicocelectomy, 490–497
  alternatives to, 491
  anesthesia for, 491
  delivery of testis in, 494, 494f–495f
  dissection of cord in, 493–494, 493–494f
  hydrocele after, 495
  indications for, 490–491
  inguinal, 491–493, 491t
  microsurgical, 491–497
  outcomes and complications of, 495–496
  radiographic occlusion techniques in, 495
  subinguinal, 491–493, 491t, 492f–493f
  testicular artery injury in, 495–496
Vas deferens, 443–445

  - anatomy of, 444–445, 444f, 572–573, 574f
  - blood supply of, 445
  - congenital bilateral absence of, 443
  - development of, 444
  - function, 445
  - innervation of, 445
  - physical examination of, 443
- Vasectomy, 460–468
  - access in, 462, 462f–463f
  - alternatives to, 461
  - anesthesia for, 461–462, 461f–462f, 465
  - AUA guidelines on, 460
  - consultation on, 460
  - follow-up semen analysis in, 467
  - indications for, 460
  - minimally invasive, 462
  - no-scalpel technique in, 461, 463f, 465–466, 465f–466f
  - occlusion techniques in, 464–466, 464f, 466f
  - outcomes and complications of, 467–468
  - postoperative care in, 466
  - preferred technique in, 465–466, 465f–466f
  - reversal of
    - vasoepididymostomy for, 481–488
    - vasovasotomy for, 469–481
  - surgical technique in, 461–467
  - three-finger technique in, 462, 462f–463f
- Vasoepididymostomy, 481–488
  - alternatives to, 482
  - closure in, 486
  - completing anastomosis in, 485–486, 485f–486f
  - cost-benefit analyses of, 488
  - identification of appropriate epididymal tubule in, 482–483
  - indications for, 482
  - longitudinal intussusception, 483–485, 484f–485f, 487
  - maneuvers to gain extra length to bridge larger gap in, 487
  - outcomes and complications of, 488
  - postoperative care and follow-up in, 487–488
  - preparation of epididymal tubule and vas approximation in, 483, 483f
  - preparation of vas deferens in, 482
  - surgical caveats on, 487
  - surgical technique in, 482–488
  - technical challenge of, 481
- Vasovasostomy, 469–481
  - alternatives to, 470
  - anastomosis of vas deferens in, 476f, 477
  - anesthesia for, 471
  - closure in, 480, 480f

- complications of, 481
- exposure of vas deferens in, 471–472, 472f–473f
- incision for, 471, 471f
- indications for, 470
- multilayer microsurgical, microdot technique for, 477–480, 477f–480f
- operating room setup for, 470–471, 471f
- postoperative care and follow-up in, 481
- preoperative workup for, 469–470
- preparation of vas deferens in, 473f, 474
- prognostic factors in, 470
- special circumstances in, 480–481
- surgical technique in, 470–481
- vasal fluid evaluation in, 475–476, 475f–476f, 475t

Vena cava, renal tumor extension to. *See* Intracaval tumors
Venogenic (veno-occlusive) erectile dysfunction (VED), 620
- diagnosis of, 621–622, 621f
- vascular surgery for, 626–628
  - outcomes and complications of, 627–628
  - patient selection for, 626
  - technique in, 626–627, 627f–628f

Venovenous bypass, in intracaval tumor surgery, 34
Vesical neck. *See* Bladder neck
Vesicopelvic ligaments, 421
Vesicostomy
- in Mitrofanoff procedure, 927–928, 929f
- for posterior urethral valve, 820–822, 821f
- in prune belly (triad) syndrome, 766

Vesicoureteral reflux (VUR), 782–795
- American Academy of Pediatrics on, 782–783
- classification of, 782, 783f
- cross-trigonal (Cohen) repair of, 788–789, 789f
- diagnosis of, 782–783, 796
- ectopic kidney and, 748
- endoscopic treatment of, 784, 796–800
  - double hydrodistention implantation method of, 798–799, 798f–799f, 799t
  - indications for, 796–797
  - outcomes and complications of, 797, 797t, 799–800
  - patient positioning for, 798
  - STING (subureteric Teflon injection) in, 798
  - surgical technique in, 798–799
- flap-valve mechanism for, 782
- Glenn–Anderson repair of, 788, 788f
- minimally invasive repair of, 789–794, 791f–794f
- Paquin repair of, 789, 790f–791f
- Politano–Leadbetter repair of, 786–788, 787f
- primary, 782
- after renal transplantation, 112–113

  - secondary, 782
  - spontaneous resolution of, 782, 783–784, 796–797
  - surgical management of, 782, 783–791
    - alternatives to, 783–784, 797–798
    - with augmentation cystoplasty, 911
    - extravesical approach in, 784–785, 784f–785f
    - indications for, 783, 796–797
    - intra-extravesical approach in, 789, 790f–791f
    - intravesical approach in, 785–789, 786f–789f
    - outcomes and complications of, 794–795
    - postoperative care in, 794
    - techniques in, 784–794
  - ureteral duplication in, 789, 790f
  - voiding patterns in, 782
- Vesicovaginal fistula, 193–202
  - adhesive materials for, 195
  - definition of, 193
  - diagnosis of, 194
  - etiology of, 193, 193t
  - fulguration of, 194–195
  - historical perspective on, 193
  - locations of, 193–194
  - nonsurgical therapy for, 194–195
  - occlusive therapy for, 194–195
  - surgical repair of, 194–201
    - comparison of techniques, 200t
    - controversies over technique in, 201
    - excision of fistula edges in, 201
    - indications for, 194
    - laparoscopic and robot-assisted, 200–201, 200t
    - outcomes and complications of, 201
    - techniques in, 195–201
    - tissue interposition in, 201
    - transabdominal (intraperitoneal), 197–199, 197f–199f, 200t
    - transvaginal, 195–197, 195f–197f, 200t
    - transvesical (extraperitoneal), 199, 200f
- Virtue quadratic sling, 407–408, 407f–408f
- von Willebrand disease, 731
- VUR. *See* Vesicoureteral reflux

W

- WAGR syndrome, 731
- Waldeyer sheath, 141, 141f
- Wallace technique
  - for ileal conduit, 658–659, 659f
  - for transverse colonic conduit, 662–663, 663f
- Wallstent, for palliative urinary diversion, 728–729

Webbed penis, 895, 895f, 905, 908–909, 908f–909f
Wilms tumors, 731–738
    adjuvant therapy for, 736–737, 736t
    bilateral, 735–736
    diagnosis of, 731–732
    epidemiology of, 731
    in horseshoe kidney, 744
    recurrence of, 737
    staging of, 732, 732t
    surgical management of, 732–737
        indications for, 732
        outcomes of, 737
        preoperative considerations for, 732
        technique in, 732–736, 733f–735f
    syndromes associated with, 731
Winter shunt, 607, 608f

Y

Yachia longitudinal plication, 654, 654f
Yang–Monti technique, 706f, 925–927, 926f–928f
York–Mason approach, to rectourethral fistula, 206–207, 207f
Young–Dees–Leadbetter bladder neck repair, 813–814, 813f–814f, 852–853, 852f
Y-V plasty
    in laparoscopic pyeloplasty, 83, 84f, 85
    in pyeloplasty, 742, 743f
    in UPJ repair, in horseshoe kidney, 742, 743

Remembrances
Preface
Section I Adrenal, Renal, Ureter, Pelvis
  1 Anatomy of the Adrenal Glands, Kidney, Ureter, and Pelvis
  2 Open Partial Nephrectomy
  3 Radical Nephrectomy
  4 Intracaval Tumors
  5 Donor Nephrectomy: Laparoscopic Techniques
  6 Laparoscopic/Robotic Nephrectomy and Partial Nephrectomy
  7 Minimally Invasive Nephroureterectomy
  8 Laparoscopic Renal Procedures: Renal Cystectomy, Biopsy, and Nephropexy
  9 Laparoscopic Ablation of Small Renal Masses
  10 Laparoscopic and Robotically Assisted Pyeloplasty in Adults
  11 Laparoscopic Adrenalectomy
  12 Renal Trauma
  13 Renal Transplantation
  14 Ureteric Complications Following Kidney Transplantation
  15 Renal Autotransplantation
  16 Miscellaneous Laparoscopic Urologic Procedures: Lymphoceles, Calculus, Varicocele, Ureterolysis
Section II Bladder
  17 Anatomy of the Bladder
  18 Simple and Partial Cystectomy
  19 Radical Cystectomy in Men
  20 Radical Cystectomy in Women
  21 Bladder Diverticulectomy
  22 Bladder Augmentation
  23 Management of the Distal Ureter for Nephroureterectomy
  24 Vesicovaginal Fistula
  25 Intestinourinary Fistulas
  26 Vesical Trauma and Hemorrhage
  27 Interstitial Cystitis/Bladder Pain Syndrome
  28 Minimally Invasive Bladder Procedures: Radical Cystectomy, Partial Cystectomy, Urachal Excision, Diverticulectomy
Section III Prostate
  29 Anatomy of the Prostate
  30 Surgery for Benign Prostatic Obstruction
  31 Open Radical Retropubic Prostatectomy
  32 Radical Perineal Prostatectomy
  33 Robotically Assisted Laparoscopic Radical Prostatectomy
  34 Brachytherapy for Localized Prostate Cancer

- 35 Imaging, Innovation, and Novel Therapies

Section IV Urethra

- 36 Anatomy of the Urethra
- 37 Female Urethral Reconstruction for Fistula and Female Urethral Diverticulum
- 38 Surgical Management of the Incompetent Bladder Outlet in the Patient with a Neurogenic Bladder
- 39 Anterior Urethral Stricture Disease
- 40 Surgery for Urethral Trauma Including Urethral Disruption
- 41 Carcinoma of the Urethra (Male and Female)
- 42 Injectable Therapies for Incontinence in Women
- 43 Urethral Slings
- 44 Abdominal Retropubic Approaches for Female Incontinence
- 45 The Artificial Urinary Sphincter
- 46 The Male Sling for Postprostatectomy Incontinence: Current Concepts and Controversies
- 47 Sacral Neuromodulation
- 48 Surgical Treatment of Pelvic Organ Prolapse

Section V Testis, Epididymis, Vas Deferens, And Seminal Vesicles

- 49 Anatomy of the Epididymis, Vas Deferens, and Seminal Vesicle
- 50 Seminal Vesicle and Ejaculatory Duct Surgery
- 51 Vasectomy
- 52 Vasovasostomy and Vasoepididymostomy
- 53 Microsurgical Varicocelectomy
- 54 Epididymectomy
- 55 Ejaculation Induction Procedures
- 56 Anatomy of the Testis
- 57 Sperm Retrieval Techniques
- 58 Simple Orchiectomy
- 59 Radical Inguinal Orchiectomy
- 60 Organ-Preserving Surgery in Testicular Tumors
- 61 Retroperitoneal Lymph Node Dissection
- 62 Torsion of the Testicle
- 63 Scrotal Trauma and Reconstruction

Section VI Penis And Scrotum

- 64 Penile and Scrotal Anatomy
- 65 Partial and Total Penectomy in the Management of Invasive Squamous Cell Carcinoma of the Penis
- 66 Inguinal Lymphadenectomy for Penile Carcinoma
- 67 Surgical Treatment of Peyronie’s Disease
- 68 Priapism
- 69 Penile Prosthesis Implantation
- 70 Penile Vascular Surgery
- 71 Penile Trauma
- 72 Penile Replantation
- 73 Hydrocele and Spermatocele
- 74 Congenital Curvature
- 75 Ileal Conduit Urinary Diversion

Section VII Urinary Diversion

76 Transverse Colonic Conduit
77 Managing the Patient with Orthotopic Bladder Substitution
78 Orthotopic Urinary Diversion Using an Ileal Low-Pressure Reservoir with an Afferent Tubular Segment
79 Ileal Neobladder
80 Colonic Orthotopic Bladder Substitution
81 Continent Catheterizable Reservoir Made from Ileum
82 Continent Catheterizable Reservoir Made from Colon
83 Ureterosigmoidostomy and Mainz Pouch II
84 Palliative Urinary Diversion
Section VIII Pediatrics
85 Wilms Tumor
86 Renal Fusion and Ectopia
87 Transureteroureterostomy
88 Pyeloplasty
89 Megaureter
90 Prune Belly (Triad) Syndrome
91 Childhood Rhabdomyosarcoma
92 Vesicoureteral Reflux
93 Endoscopic Treatment of Vesicoureteral Reflux
94 Ureteroceles
95 Urachal Anomalies and Related Umbilical Disorders
96 Vesical Neck Reconstruction
97 Surgery for Posterior Urethral Valves
98 Hypospadias
99 Complete Primary Repair for Exstrophy
100 Exstrophy and Epispadias—Modern Staged Approach
101 Pediatric Cryptorchidism, Hydroceles, and Hernias
102 Pediatric Laparoscopic and Robotic Pyeloplasty
103 Pediatric Laparoscopic Nephrectomy and Partial Nephrectomy
104 Urogenital Sinus and Cloacal Anomalies
105 Surgery to Correct Ambiguous Genitalia (46XX Disorder of Sexual Development)
106 Circumcision, Concealed Penis, and Scrotal Abnormalities
107 Augmentation Cystoplasty in Children
108 The Mitrofanoff and Malone Antegrade Continence Enema Procedures in Pediatric Urinary Tract Reconstruction
Index
